One man will say that production costs are high because the cost of living is high, whilst another maintains that the cost of living is high because production costs are high. Both are right. It is a vicious circle, from which it is extremely difficult to break away. In my view, the most feasible method of so doing, and thereby reducing the cost of living, is either for one and all to work a little harder, or to improve manufacturing methods. If everyone would agree to work half an hour a day longer, it is my firm belief that all weekly earnings could be increased by at least 5s.; that the cost of living would come down considerably, and that at the end of a few years the unemployment problem would have practically disappeared.

Dr. Fleming recently gave an arresting example of what a quite insignificant increase of output might mean. He showed that if it were possible to increase the output of our coal-fields by only 5 per cent, the extra coal so produced would generate as much electrical energy as all the water-power plants in Switzerland and Sweden put together. The 5 per cent would represent less than half an hour per day extra work on the part of the miners, or it could be got, one would imagine, by the introduction of a little more machinery into the pits.

Of course the nationalization of industry has long been a favourite panacea for all our ills. It is most unfortunate that this question, like that of free trade, should have become a political one, since unbiased discussion of either problem is well-nigh impossible. We are engineers, however, and not politicians, so that we can look at the matter from a practical standpoint. What, then, are the claims made for nationalization? It is usually stated (although the connection with nationalization is not clear) that the distribution of wealth is unequal—which no one will deny—and that the distribution is arbitrary and unfair—whether this is true or not, we need not now stop to consider. One of the professed aims of nationalization is to raise the general standard of living by removing this supposed anomaly, and it is of great interest to inquire what the result of such an attempt would be. One method of equalization that has been suggested is to issue a decree that all money in excess of say **£5** per week per family should revert to the State, and go towards swelling the incomes of those families who are in receipt of less than **£5** per week.

Sir Josiah Stamp, the eminent economist, has recently made a computation of the result of such a policy. He puts the income available for distribution (i.e. the amount taken from those whose incomes exceed **£5** per week) at **£1 000 000 000** per annum, from which sum must obviously be deducted the amounts which are at present paid in rates, taxes, etc., by those having incomes in excess of **£5** per week. This comes to about **£450 000 000**, so that the available surplus drops to **£550 000 000**. The next question to be considered is the provision of capital for the future. It is obviously of vital importance that provision should be made for the building of houses, factories, ships, etc., quite apart from the question of whether they are to be owned by individuals or by the State, and such provision can only be made out of this surplus of **£550 000 000** per annum. If the same rate of capital investment is to be maintained now as was the case before the war (and no one would seriously suggest that the provision of new buildings, etc., could safely be made less than at that

time—in fact, rather the reverse), this would mean the putting aside of about £500 000 000 each year, so that the surplus now available for distribution is reduced to £50 000 000. This distributable surplus would have to be divided amongst the 11 million families who at present receive less than the suggested £5 per week. A simple calculation therefore shows that the increase in income for each family would amount to something under 2s. per week. Sir Josiah Stamp states quite frankly that a large margin of error is inevitable in a calculation of this kind. He gives reasons, however, for believing that, after making all possible allowance for such errors, the ultimate increase per family must lie between nothing and 5s. per week.

The figures which I have quoted seem to me to be well worthy of study. To the man in the street, who has been led to believe that there is, somewhere or other, an almost inexhaustible " widow's cruse " full of money if only it can be tapped, they will come as a severe shock; but to the engineer, who is accustomed to averaging out the peaks of a curve, they will be quite understandable. For, after all, rich men, like mountain peaks, are numerically insignificant. It is easy to pull them down, but by so doing we shall only raise the general level of wages by a few pence, and we shall have gone a long way towards destroying a civilization which it has taken thousands of years to build up.

As a humdrum alternative, I cannot help pointing out that to increase the working week from 47 to 50 hours would be a much more effective way of increasing the earnings of everybody, and would do so to a much greater extent.

The second contention of those who favour nationalization is that the productiveness of the workers would be increased in two ways. Firstly, all would be employed (although how the goods made are to be sold at a non-competitive price is not explained); and secondly, if all were working for the community, instead of for individuals, they would work with a swing and a gusto, at present lacking. Those who advance this argument seem to forget that in the municipal worker we have long had an example of men who are working solely for the community, but I have looked in vain amongst them for signs of that swing or that gusto which we are led to expect.

All will agree that what is really wanted is some *rapprochement* between employers and employed. The employers are quite ready, I am sure, and so are the vast majority of the employed; but, unfortunately, the latter are not free agents. What is the use of continually advocating external good will if we are all the time to be faced with internal ill will, and that between two sections of the community, neither of whom can get on without the other. There are, however, hopeful signs that the absurdity of this position is being more and more widely recognized.

To sum up the points which I have tried to make. (1) Let us reduce unemployment by insisting on the purchase of British-made goods, thus keeping at least 90 per cent of their value in this country. (2) Lower the cost of living, not so much by lowering wages and salaries, as by producing more, either by working harder or by employing more machinery and better methods. (3) Don't expect Governments to perform miracles. The State already " coddles " us far too much; the slacker loses all sense of responsibility, whilst the worker has to " foot the bill." (4) Don't be pessimists; do, please, be optimists! The Old Country is not done yet by a very long way, although her enemies, within and without, would dearly like to think so.

What is wanted, it seems to me, is a little more enthusiasm, a little more pulling together, a little less talk of rights and a little more of duties :—In the words of Daniel Webster, " a little more keenness to develop the resources of our land, call forth its powers, build up its institutions, promote all its great interests, and see whether we also, in our day and generation, may not perform something worthy to be remembered."

PROCEEDINGS OF THE INSTITUTION.

731st ORDINARY MEETING, 22 OCTOBER, 1925.

(Held in the Institution Lecture Theatre.)

Mr. W. B. Woodhouse, Past-President, took the chair at 6 p.m.

The minutes of the Annual General Meeting held on the 7th May, 1925, were taken as read and were confirmed and signed.

A list of candidates for election and transfer approved by the Council for ballot was taken as read and was ordered to be suspended in the Hall.

The Chairman announced the result of the ballot to fill the vacancies on the Council (see vol. 63, page 843), and a vote of thanks was passed to the scrutineers of the ballot.

Lists of donations to the Benevolent Fund (see vol. 63, pages 615, 721, 844, 931 and 1044) were taken as read and the thanks of the meeting were accorded to the donors.

The Premiums and Scholarships (see vol. 63, pages 574, 613 and 721) awarded during the session 1924–25 were presented by the Chairman to such of the recipients as were present.

The chair was then vacated by Mr. Woodhouse and taken by **Mr. R. A. Chattock,** President, amid applause.

Mr. Roger T. Smith: It was said of the life of King Charles I that nothing became that life so well as the manner in which he left it. Of Mr. Woodhouse, our retiring President, it can be said that nothing throughout his professional life became him so well as the manner in which he has conducted, during the last year, the affairs of this great Institution. I can assure the members that presiding over this Institution, although it has many compensations, is no light burden. The burden is very real, and it does not get lighter as years go on, as the arms of the Institution stretch further throughout the country. Fortunately, owing to the wise policy of several of our Hon. Treasurers and of the Council, there is no financial anxiety, but the other burdens are so great that those whose business it is to suggest a President to the members for election each year have, since the war, hesitated to suggest anyone who had not at least his work in London, even if he did not live in London. It is an added distinction to the conduct of the office of the chair which Mr. Woodhouse is now vacating that he, living 185¾ miles by the shortest route from London, has yet been able to discharge the duties with such singular success. The precedent so set has resulted in my old friend, Mr. Chattock, who lives more than 100 miles from London, being elected this year as President. I move with great pleasure: "That the best thanks of the Institution be accorded to Mr. W. B. Woodhouse for the very able manner in which he has filled the office of President during the past year."

Dr. A. Russell: I have great pleasure in seconding the resolution so ably proposed by Mr. Roger Smith. I am sure that the members will agree with me that we have never had a more kindly and dignified President than Mr. Woodhouse. As Chairman of the Council he was ideal. Members of the Council often do not see eye to eye, but after Mr. Woodhouse had summed up the discussion there was always in sight some decision that would please everybody. We are specially indebted to him for the many addresses he gave to the Local Centres. Apart from their literary excellence, they possessed that local flavour which was so appreciated by his audience. I have great pleasure in seconding the resolution.

The resolution was then put to the meeting by the President and carried with acclamation.

Mr. W. B. Woodhouse: I thank the members very much for their vote of thanks, and especially Mr. Roger Smith and Dr. Russell for the very kindly way in which they put it to the meeting. I have had a very pleasant year of office, very largely because I have had the support and help of a very able Council, and also because we felt in the Council that we had the support of the general body of members. I feel that the Institution is progressing in the right way. I believe that it is becoming more and more useful to its members and to the industries in which they are engaged. I was particularly impressed during my year of office with the strength of our Local Centres, with the enthusiasm, and with the time and thought put into the organization of the meetings there. I believe that they are a great source of strength to the Institution, and a growing one. I hope and believe that my successor and friend, Mr. Chattock, will have an equally happy year of office, and I feel confident that under his guidance the Institution will continue to progress as it has done in recent years.

The President then delivered his Inaugural Address (see page 1).

Mr. C. P. Sparks: The electricity supply industry started over 40 years ago, and this is the first occasion on which the Institution has seen fit to select as its President the engineer and manager of a municipal undertaking. Mr. Chattock is an old friend of so many here to-night that it is a matter of historic interest to be able to congratulate him on being the first municipal engineer to become President of this Institution. I think, myself, that the Institution has missed something in waiting so long, when we see that the invested funds of the municipalities in our industry now exceed £120 000 000. I much appreciate the opportunity of being the first to congratulate our President on his interesting Address and have pleasure in moving: "That the best thanks of the Institution be accorded

to Mr. R. A. Chattock for his interesting and instructive Presidential Address and that, with his permission, the Address be printed in the *Journal* of the Institution."

Dr. W. M. Thornton: I have much pleasure in seconding this vote of thanks to the President for his most able and informative Address, so full of practical wisdom. The great undertaking over which Mr. Chattock rules in Birmingham is one of the most progressive in the country. We convey to him our heartiest good wishes for a successful year of office.

The resolution was then put to the meeting by Mr. Woodhouse, Past-President, and was carried with acclamation. After the President had briefly replied, the meeting terminated at 7 p.m.

48TH MEETING OF THE WIRELESS SECTION, 4 NOVEMBER, 1925.

(Held in the Institution Lecture Theatre.)

Mr. E. H. Shaughnessy, O.B.E., Past-Chairman, took the chair at 6 p.m.

The minutes of the meeting of the Wireless Section held on the 3rd June, 1925, were taken as read and were confirmed and signed.

A list of Premiums awarded by the Council for papers before the Wireless Section during the Session 1924–25 (see vol. 63, page 613) was read.

The chair was then vacated by Mr. Shaughnessy and taken by Major Binyon amid applause.

A vote of thanks to Mr. Shaughnessy for his services as Chairman of the Wireless Section during the past two sessions was proposed by Prof. C. L. Fortescue, seconded by Mr. C. F. Phillips, and carried with acclamation.

Major B. Binyon, O.B.E., M.A., Chairman of the Wireless Section, then delivered his Inaugural Address (see page 83).

A vote of thanks to Major Binyon for his Address, proposed by Admiral Sir Henry Jackson, G.C.B., K.C.V.O., F.R.S., and seconded by Mr. E. H. Shaughnessy, O.B.E., was carried with acclamation, and the meeting terminated at 7.45 p.m.

732ND ORDINARY MEETING, 5 NOVEMBER, 1925.

(Held in the Institution Lecture Theatre.)

Mr. R. A. Chattock, President, took the chair at 6 p.m.

The minutes of the Ordinary Meeting of the 22nd October, 1925, were taken as read and were confirmed and signed.

The President announced that the Council had elected Dr. S. Z. de Ferranti to be an Honorary Member of the Institution.

Messrs. O. P. Moller and C. H. D. Lang were appointed scrutineers of the ballot for the election and transfer of members, and, at the end of the meeting, the result of the ballot was declared as follows:

ELECTIONS.

Member.

Gray, James Gordon, D.Sc.

Associate Members.

Badger, William Herbert.
Bartlett, Sydney, B.Sc.
Child, Henry Adair, B.Eng.
Dixon, Joseph Laurence, B.Sc.
Jamieson, Charles Dudson.
Jarrett, Austin Yorke.
Lyons, Henry Montagu.
Vernon, Robert Jackson.

Graduates.

Akister, Frederick.
Barnett, Reginald Hugh.
Bentley, Francis Ecroyde.
Bruges, William Ernest.
Cardew, Reginald William, Captain, R.E.
Cleary, Herbert.
Clyma, Hugh Palmer.
Conway, George Harold.
Cowen, Alan Biddulph.
Dawson, William James.
Eales, Alfred Billington.
Golding, James.
Jacobi, Erhard.
Kingston, Alfred Thomas.
Knowlson, John McKerrow, B.A.
Leary, John Francis.

Graduates—continued.

Lobo, Alfred.
Manyam, Venkataram Subrah.
O'Brien-Malone, Patrick Joseph.
Ramaswami, Kuppuswami.
Ranganatham, Mayavaram Krishnasami, M.E.
Rees, Cyril Mostyn.
Rogans, Thomas Harold.
Schulitz, Walter Hans, B.Sc.
Staygle, Edmund George.
Stredwick, Stephen Bertie.
Teather, Reginald Herbert, B.Sc.
Toplis, Leslie George.

Students.

Bacon, Anthony Walter, B.A.
Ballantine, James Rogers.
Barrell, Frank.
Beer, Jack.
Bell, George Barrett.
Benn, Leslie Robert.
Bishop, William Russell.
Boardman, Archibald Richard.
Boyne, Samuel Noel.
Briggs, Arthur.
Carter, Robert Owen.
Clarke, George Green.
Collins, Wilfred John.
Crawshaw, William Henry.
Currey, John Heylyn.
Davies, Harold Charles.
Deglon, Cedric Russell.
De Larue, Serge.
Desai, Shantilal Ranchhodbhai.
Dixon, Douglas Leslie.
Ely, Raymond Edward V.
Erskine, Alexander.
Easterbrook, Charles Bertram.
Fearnley, Gilbert Leslie.
Gill, Thomas, B.Sc.
Gilroy, Gordon Leslie.
Goffer, Norman Frank.
Gordon, David Alexander, B.Sc.
Greasley, George.
Griffiths, Cecil.
Gubbins, John Bryan M.
Hall, Edmund Burbidge.
Harbour, Joseph Richard.
Harris, Frederick Henry.
Harries, Merfyn Aeiron.
Heale, John Ernest A.
Hinchliffe, Donald.
Ingamells, George Harry.
Jaffe, Charles Cecil.

Students—continued.

James, Gwynne Frederick.
Jordan, Edwin Horace.
Kerr, Douglas Ramsdale.
Leith, Allan Ramsay.
Lyne, Edward Aubrey.
Macmaster, Malcolm Morrison.
McNicholl, John Gerard.
Milmore, Andrew Skillen.
Mitchell, Harold Edward.
Mozumdar, Dhirendra Nath, B.Sc.
Newstead, Dudley Francis.
Noel, Roger Joseph M. L., B.Sc.(Eng.).
O'Reilly, Christopher B. E.
Purkins, Leslie.
Rhys-Jones, John Emyr.
Ritchie, Roderick MacIntosh.
Russell, James.
Shafi, Sheikh Mohd.
Shields, Douglas.
Spence, Herbert William.
Starkey, Albert Ernest.
Stewart, Ian.
Stewart, James Charles.
Sutton, Percy William.
Talling, Frank Charles.
Taylor, Cecil William.
Thomas, Noel, B.Sc.
Topliss, Maurice Joseph.
Tyson, Lubbock Temple I.
Uden, Frank Arthur.
Ullah, Nimat.
Vincent, Stephen Clement.
Watson, Richard.
Weller, Bertram Frederick.
White, Howard Sydney.
White, Joseph John.
Whitehead, Stanley, B.A.
Williams, Hugh Laity.
Winwood, William.
Woods, John.

TRANSFERS.

Associate Member to Member.

Brydon, Sydney, D.Sc.
Carey-Thomas, Hubert Carey, Captain, R.C.S., B.A.
Lunn, Alfred Lawrence.
Pinkney, William Ferrier T.
Schuster, Leonard Walter, M.A.
Scott, George Smith.
Thomas, John Henry.

Associate to Member.

Morshead, Leslie Robert.

Graduate to Associate Member.

Brown, Vance Auberon, B.Sc.Tech.
Chapman, Sydney Ronald, M.Sc.
Lloyd, William Francis, B.A.
Messent, Keith Santo, B.E.
Steele, William Herbert.

Student to Associate Member.

Ashmore, Joseph.
Burt, Brian Morton, B.Sc. Tech.
Reyner, John Hereward, B.Sc.
Walker, Charles Ian B.

Student to Graduate.

Barton, Thomas, B.Sc. Tech.
Beard, James Reginald, B.Sc.
Collyns, Charles Henry A.
Johnson, Arthur.
Lane, Gerald Nassau S.
Mather, Gilbert, B.Sc. Tech.
Yates, Joseph Henry.

A list of donations to the Benevolent Fund (see vol. 63, page 1147) was taken as read and the thanks of the meeting were accorded to the donors.

A paper by Mr. P. Dunsheath, Member, entitled "Dielectric Problems in High-Voltage Cables" (see page 97) was read and discussed. On the motion of the President a vote of thanks to the author was carried with acclamation, and the meeting terminated at 7.50 p.m.

733RD ORDINARY MEETING, 19 NOVEMBER, 1925.

(Held in the Institution Lecture Theatre.)

Sir James Devonshire, K.B.E., Vice-President, took the chair at 6 p.m. in the absence of Mr. R. A. Chattock, President.

The minutes of the Ordinary Meeting held on the 5th November, 1925, were taken as read and were confirmed and signed.

A list of candidates for election and transfer approved by the Council for ballot was taken as read and was ordered to be suspended in the Hall.

A lecture by Mr. T. Carter, Member, entitled "The Engineer: His Due and His Duty in Life" (see page 193), was read and discussed. On the motion of the Chairman a vote of thanks to the lecturer was carried with acclamation, and the meeting terminated at 8.15 p.m.

49TH MEETING OF THE WIRELESS SECTION, 2 DECEMBER, 1925.

(Held in the Institution Lecture Theatre.)

Major B. Binyon, O.B.E., M.A., Chairman of the Section, took the chair at 6 p.m.

The minutes of the meeting of the Wireless Section held on the 4th November, 1925, were taken as read and were confirmed and signed.

A paper by Mr. H. A. Thomas, M.Sc., entitled "The Performance of Amplifiers" (see page 253), was read and discussed. On the motion of the Chairman a vote of thanks to the author was carried with acclamation, and the meeting terminated at 8 p.m.

734TH ORDINARY MEETING, 3 DECEMBER, 1925.

(Held in the Institution Lecture Theatre.)

Mr. R. A. Chattock, President, took the chair at 6 p.m.

A vote of condolence with His Majesty the King and the Royal Family on the death of Queen Alexandra was passed, the members standing in silence.

The minutes of the Ordinary Meeting held on the 19th November, 1925, were taken as read and were confirmed and signed.

A list of candidates for election and transfer approved by the Council for ballot was taken as read and was ordered to be suspended in the Hall.

A list of donations to the Benevolent Fund (see page 92) was taken as read and the thanks of the meeting were accorded to the donors.

A paper by Professor S. Parker Smith, D.Sc., Member, entitled "An All-Electric House" (see page 289), was read and discussed. On the motion of the President a vote of thanks to the author was carried with acclamation, and the meeting terminated at 8.5 p.m.

735TH ORDINARY MEETING, 17 DECEMBER, 1925.

(Held in the Institution Lecture Theatre.)

Mr. R. A. Chattock, President, took the chair at 6 p.m.

The minutes of the Ordinary Meeting held on the 3rd December, 1925, were taken as read and were confirmed and signed.

A paper by Mr. C. E. Webb, B.Sc.(Eng.), Associate Member, entitled "The Power Losses in Magnetic Sheet Material at High Flux Densities" (see page 409), was read and discussed. On the motion of the President a vote of thanks to the author was carried with acclamation, and the meeting terminated at 7.25 p.m.

50TH MEETING OF THE WIRELESS SECTION, 6 JANUARY, 1926.

(Held in the Institution Lecture Theatre.)

Major B. Binyon, O.B.E., M.A., Chairman of the Section, took the chair at 6 p.m.

The minutes of the meeting of the Wireless Section held on the 2nd December, 1925, were taken as read and were confirmed and signed.

A paper by Lieut.-Col. K. E. Edgeworth, D.S.O., M.C., Royal Signals, Associate Member, entitled "Frequency Variations in Thermionic Generators" (see page 349), was read and discussed.

On the motion of the Chairman a vote of thanks to the author was carried with acclamation, and the meeting terminated at 7.40 p.m.

736TH ORDINARY MEETING, 7 JANUARY, 1926.

(Held in the Institution Lecture Theatre.)

Mr. R. A. Chattock, President, took the chair at 6 p.m.

The minutes of the Ordinary Meeting held on the 17th December, 1925, were taken as read and were confirmed and signed.

A list of candidates for election and transfer, approved by the Council for ballot, was taken as read and was ordered to be suspended in the Hall.

The following lists of donations were taken as read and the thanks of the meeting were accorded to the donors.

Library: Air Ministry; American Railway Association; I. Aprihăneanu; Association of Municipal Electrical Engineers (Union of South Africa); Astronomer Royal; "Australasian Electrical Times"; Prof. F. Bacon, M.A.; Messrs. J. B. Baillière et Fils; Messrs. H. C. Baird & Co., Inc.; Messrs. E. Benn, Ltd.; Messrs. Blackie & Son, Ltd.; J. G. Blanco; Board of Education; British Aluminium Co., Ltd.; British Engine, Boiler & Electrical Insurance Co., Ltd.; British Engineering Standards Association; British Science Guild; T. M. Carey; C. Cater; Messrs. Chapman & Hall, Ltd.; Chief Inspector of Factories; Messrs. E. Chiron; Comité International des Tables Annuelles de Chimie, de Physique et de Technologie; Messrs. Constable & Co., Ltd.; Messrs. Craven Brothers (Manchester), Ltd.; Department of Scientific & Industrial Research; Electricity Commissioners; M. A. El-Sayed; Empire Mining and Metallurgical Congress; Prof. J. A. Fleming, M.A., D.Sc., F.R.S.; E. Garcke; G. Giorgi; P. Good; W. Greenwood; M. D. Hart; Dr. W. H. Hatfield; C. C. Hawkins, M.A.; Institution of Engineers, Australia; Institution of Railway Signal Engineers; J. T. Irwin; Japanese Electrotechnical Committee; Prof. A. E. Kennelly, D.Sc.; J. W. Lieb; Sir Oliver Lodge, D.Sc., F.R.S.; Marconi's Wireless Telegraph Co., Ltd.; C. W. Marshall; R. L. Morrison; D. Murray; New Zealand Public Works Department (Chief Electrical Engineer); P. O. Pedersen; Royal Albert Observatory, Mauritius; A. Russell, M.A., D.Sc., LL.D., F.R.S.; Schweizerischer Elektrotechnischer Verein; Signals Experimental Establishment, Wool-

wich (Chief Experimental Officer); Prof. S. P. Smith, D.Sc.; W. W. Smith; Spolku Československých Inženýrů; Messrs. E. & F. N. Spon, Ltd.; Messrs. J. Springer; A. L. Stanton; T. Stevens; Surveyor-General of India; Messrs. Tata, Ltd.; W. T. Taylor; W. J. Thorrowgood; Union des Syndicats de l'Electricité; Verlag des Vereines Deutscher Ingenieure; C. H. Yeaman.

Benevolent Fund: (See list of Donations on page 192.)

Captain P. P. Eckersley, Member, then delivered a lecture entitled "The Past, Present and Future Development of Wireless Telephony, and the lecture was followed by a discussion.

On the motion of the Chairman a vote of thanks to the lecturer was carried with acclamation, and the meeting terminated at 8 p.m.

INSTITUTION NOTES.

Discussions at Meetings.

The Council are especially desirous that the remarks of speakers at the meetings of the Institution should not be read from manuscript, the view being held that the presentation of remarks in this manner is contrary to the true spirit of a "Discussion" and that contributions in manuscript should more appropriately be sent to the Secretary for publication in the *Journal* as communicated remarks. It is therefore hoped that those taking part in discussions will confine themselves as far as possible to the use of notes only.

Model Form of General Conditions of Contract (Home).

Clause 37 (Regulations of Local Authorities) of the September, 1921, edition of the Model Conditions "A" for Home Contracts, with erection, has been amended by the Council to make it clear that the Regulations and Bye-Laws with which the Contractor shall conform are those which the Local or other Authorities are authorized by Statute to make. In Clause 37 of the new edition (revised January, 1926), the words "which they are authorized by Statute to make and" have been inserted after the word "Authorities." The new edition in all other respects is similar to the old edition.

National Certificates and Diplomas in Electrical Engineering.

The following colleges, etc., have been approved under the scheme drawn up by the Board of Education and the Institution:—

Approved for Ordinary Grade Certificates (Senior Part-time Course):

Sunderland Technical College.

Approved for Higher Grade Certificates (Advanced Part-time Course):

Coventry Municipal Technical Institute.
Sheffield University (Department of Applied Science).

Approved for Ordinary Grade Diplomas (Senior Full-time Course):

Swansea Municipal Technical College.

The Benevolent Fund.

The following is a list of the Donations and Annual Subscriptions received during the period 26 January–25 February, 1926:—

THE POWER LOSSES IN MAGNETIC SHEET MATERIAL AT HIGH FLUX DENSITIES.

By C. E. Webb, B.Sc.(Eng.), Associate Member.

[From the National Physical Laboratory.]

(*Paper first received 7th August, and in final form 15th October,* 1925; *read before* The Institution *17th December,* 1925, *and before the* South Midland Centre *27th January,* 1926.)

Summary.

From an examination of the results of a number of investigators it is shown that while there is general agreement as to the validity of Steinmetz's expression ηB^x, where x is a constant index, for the hysteresis loss at flux densities up to about 10 000 C.G.S. units, there are considerable divergences between the results of different experimenters at flux densities above that value, particularly in tests on sheet material. Some find Steinmetz's law to apply closely up to the highest flux densities at which tests could be carried out, whilst others record more rapid variations of hysteresis loss with B in the region of $B = 10\,000$–$16\,000$. The extent of the departure from Steinmetz's law also varies considerably, some observers finding a maximum exponent of approximately 2·0 and others obtaining values as high as 3·2.

In the paper a series of tests, both by a.c. and ballistic methods, on a wide range of sheet materials is described. The results of this appear to confirm the increase in the exponent of B in the expression for the hysteresis loss at values of B between 10 000 and 15 000. They also show comparatively little difference between the various specimens of sheet material tested.

The construction of a new Lloyd square for tests at still higher flux densities, and a further, more detailed, series of tests, both a.c. and ballistic, on a representative specimen of each type of material, making use of this square, are then described. These tests were carried up to $B = 17\,000$ or 18 000 and, while confirming and extending the previous results of increased exponents of B for values up to 16 000, they indicate a rapid decrease in the exponent at the highest values of B employed.

(1) Introduction.

At the present time there is a marked tendency amongst designers of electrical machinery to employ higher flux densities in electrical sheet steel than have been customary in the past, and, in consequence, to demand guaranteed figures for the total power losses due to hysteresis and eddy currents at correspondingly higher densities. It is therefore a matter of increasing importance to obtain reliable and accurate knowledge of the way in which the power losses vary with the flux density at high densities, particularly in the special brands of sheet material which are now so extensively employed.

Of the two components—hysteresis and eddy currents—of which the total loss consists, the hysteresis loss is usually the more important, and is also the one concerning the law of variation of which there is more uncertainty. There is general agreement as to the validity of Steinmetz's empirical law that

$$\text{Hysteresis loss in ergs per cm}^3\text{ per period} = \eta B^x$$

where x is a constant index for any given material, having a value of approximately 1·6, for flux densities between about 4 000 and 10 000 C.G.S. units; but at higher densities surprising differences between the results of different investigators appear to exist, as will be seen from the following brief survey of some of the principal papers bearing on the subject.

(2) Summary and Discussion of Results of Other Investigators.

Before proceeding to examine these results, reference should be made to a matter of terminology, in order to avoid an ambiguity which frequently arises in the discussion of laws of variation of the form to be considered when dealing with magnetic hysteresis. P. G. Agnew,* pointed out that if in an expression of the form $W = \eta B^x$ the index, x, is not a constant, but is itself a function of B, then the methods usually employed to evaluate x, for any given range of B do not give a correct result. These methods are the determination of the slope of the logarithmic curve connecting W and B, and the solution for x of the equations obtained by substituting two pairs of corresponding values of W and B, and Agnew pointed out that when x is variable the quantity found in each case is not the true exponent, x, but the value of the function $[x + B \log B(dx/dB)]$. To this quantity he gave the name "ratio of variation," and he showed that it may be very different from the true exponent and may give very little indication as to the value of the latter. He also pointed out that the ratio of variation is in practice a much more convenient and useful quantity to employ than the true exponent, and that it has generally been used under the name of "exponent" by other investigators.

In view of this and of the fact that Agnew's term is not generally familiar, it is proposed to adopt the term "exponent" throughout this paper when referring to the quantity described by Agnew as the "ratio of variation." This use of the word is also justified by analogy with the case of a constant index, and at least for small ranges this quantity is the true exponent for a curve of constant index approximating to the actual variable-index curve.

Proceeding now to the consideration of published results bearing on the law of variation of hysteresis loss at high flux densities, the most direct treatment of the subject is that of F. Stroude, in "An Accurate Examination of the Steinmetz Index for Transformer Iron, Stalloy and Cast Iron." † From tests on rings

* See Appendix IV, (1). † *Ibid.*, (2).

of each of these materials by the method of uniformly varying flux (slow cyclic) checked by ballistic tests he concludes that the Steinmetz index is practically constant for values of B above 4 000, the values found being 1·7 for transformer iron (tested up to $B = 17\,000$), 1·66 for stalloy (up to $B = 12\,000$), and 1·82 for cast iron (up to $B = 6\,000$). It is to be noted, however, that the determination of the exponent is made from the slope of the logarithmic curve, and that owing to the compression of the curve above $B = 10\,000$ when plotted in this way the determination is not very accurate at these densities. In fact, on re-plotting the logarithmic curve on a large scale, there appears to be a distinct tendency for the exponent to increase for transformer iron to a value of about 1·9 or 2·0 between $B = 10\,000$ and $B = 17\,000$. This is confirmed if the exponent is found by solving for two points on the mean curve through the points obtained by plotting the hysteresis loss (W_H) and B. For stalloy the values found do not lie well on any smooth curve, and in any case do not extend much beyond the range for which Steinmetz's law is known to apply fairly closely.

Stroude refers to the work of a number of earlier investigators whose conclusions may be summarized as follows: Steinmetz in his original paper,* working from Ewing's results and from his own experiments using a.c. wattmeter and magnetometer methods, found a practically constant index of approximately 1·6 from $B = 2\,000$ to $B = 20\,000$. Ewing and Klaassen † from ballistic tests found that the exponent (deduced from the slope of the logarithmic curve) had a different value in each stage of the process of magnetization, changing quite suddenly from one value to another. The value was approximately 2 for very low flux densities, fell to about 1·5 in the region of high permeability, and increased again to about 1·7 at high densities.

Both these experimenters used commercial soft iron such as was used in dynamo armatures—not at that time, of course, containing silicon or other special alloying constituents. Gumlich and Rose ‡ tested rings containing various percentages of silicon by the ballistic method and also by alternating current using a Franke curve-tracer. They assumed a constant index of 1·6 and calculated the corresponding value of the Steinmetz coefficient, η, for various densities. In every case η was found to increase from $B = 10\,000$ to $B = 16\,000$, in one case by as much as 25 per cent, corresponding to an increase in the index from 1·6 to 2·4. They also found that, assuming the eddy-current loss to vary as the square of the flux density, the coefficient of the eddy-current term decreased as the flux density increased, and that the eddy-current loss appeared actually to vary as the 1·8th or 1·9th power of the flux density. Prof. E. Wilson, V. H. Winson and G. F. O'Dell § carried out ballistic tests on lohys and stalloy sheets chiefly at low inductions, but recorded a few results between $B = 6\,000$ and $B = 13\,500$. These showed a marked tendency for the exponent to rise with increase of B, particularly in the case of stalloy. With both materials, however, the exponent exceeded 2 for the range of $B = 11\,500$ to $B = 13\,500$.

* See Appendix IV, (3). † *Ibid.*, (4). ‡ *Ibid.*, (5). § *Ibid.*, (6).

Lloyd and Fisher * using the a.c. wattmeter method measured the total losses in both transformer steel and silicon steel specimens at two frequencies—30 and 60 periods per second. They separated the total losses into hysteresis and eddy-current components by assuming these to be proportional to the first and second power of the frequency respectively, and found that for both types of material the exponent tended to increase at high flux densities, obtaining values ranging from 1·8 to 2·2 between $B = 10\,000$ and $B = 12\,500$. These measurements were made with great care and covered a large variety of specimens, and the results are probably the most reliable and accurate of those quoted by Stroude.

It will be seen that the investigators to whom Stroude refers obtained very divergent results, some in agreement with those recorded in his paper but others definitely in conflict with them. Before attempting to summarize the evidence for and against the constancy of the Steinmetz index, the author proposes to refer briefly to some other investigations of interest in this connection.

Prof. F. G. Baily † using a calorimetric method deduced the hysteresis loss in a laminated sample subjected to various alternating inductions up to $B = 22\,000$. His figures indicate a gradual increase in the exponent to a maximum of about 2·4 in the region between $B = 14\,000$ and $B = 18\,000$, followed by a rapid and continuous decrease to a value slightly less than unity when B approaches 22 000. That this latter effect was not due to the H lines, which might be expected not to affect the hysteresis, becoming relatively a large proportion of B, is shown by the fact that when the curve of hysteresis loss was re-plotted to a base of intensity of magnetization $J = (B - H)/4\pi$ a similar tendency to bend over above about $J = 1\,400$ was observed. This result, which does not seem to have been noticed by other investigators, is of considerable interest in view of the similar results recorded later in this paper.

Barrett, Brown and Hadfield ‡ in their comprehensive paper on the electrical conductivity and magnetic properties of a great variety of iron alloys record ballistic tests on samples of annealed silicon iron (2·5 per cent Si), and annealed Swedish charcoal iron in which, assuming a constant index of 1·6, they found a considerable increase in the value of the coefficient η when B was raised to about 17 000. This increase amounted to nearly 20 per cent for the silicon iron, corresponding to an exponent between $B = 12\,000$ and $B = 17\,000$ of approximately 2·1.

Czepek § in the course of a comparison between the losses under rotating and alternating magnetization at various frequencies and inductions made a number of measurements of hysteresis loss by ballistic and a.c. wattmeter methods. Some of his ballistic results indicate a fairly constant index of about 1·9 for flux densities between 9 000 and 17 000, but he also records alternating-current results from which, assuming a constant hysteresis exponent of 1·6, he calculates the value of η and finds, in agreement with other investigators already quoted, that η increases considerably at high densities—in one case from 1·62 at $B = 8\,000$

* See Appendix IV, (7). † *Ibid.*, (8). ‡ *Ibid.*, (9). § *Ibid.*, (10).

to 2·22 at $B = 16\,000$. He also records in the same tests that, assuming the eddy-current losses to be proportional to the square of the frequency and the square of the density, the coefficient of the eddy-current term decreases very rapidly with increasing flux density—from 4·5 at $B = 8\,000$ to 1·84 at $B = 16\,000$.

Richter * from ballistic and a.c. wattmeter results on a series of 7 rings of soft iron sheet endeavoured to establish the law $W_H = aB + bB^2$, where a and b are constants, as giving a more accurate representation of the observed results than the Steinmetz formula. This, it will be seen, implies a continuous increase with increasing B of the exponent, which, however, can never exceed 2. His results indicate a considerably smaller deviation from a law of this form than from a law involving a constant index, but it is noticeable on some of his curves that the experimental results at high densities, say $B = 17\,000$, show an even more rapid increase of hysteresis loss than is given by Richter's law.

L. W. Wild † made a large number of measurements of total losses on lohys and stalloy sheets of various thicknesses by the a.c. wattmeter method, using several different ways of building up the test-square. The tests were made at a number of values of B ranging from 2 500 to 15 000, and at 25 and 50 periods per second. He did not separate the losses, but from his total-loss figures for any given B at two frequencies the hysteresis loss may be readily calculated, assuming the proportionality of the hysteresis and eddy-current components to the first and second power of the frequency respectively, as was done by Lloyd and Fisher in their paper referred to above. The hysteresis values thus obtained show a slightly increasing exponent above $B = 10\,000$, but the maximum value found does not exceed 2. Too much reliance must not be placed on the accuracy of these results, as the tests were made with the object of comparing the various methods of building up the square, and hence the attainment of identical conditions in each test, rather than high absolute accuracy, was aimed at.

A short note by W. J. Wooldridge ‡ on "Hysteresis and Eddy-Current Exponents for Silicon Steel" bears directly on the question at issue and gives very interesting curves showing an increase of the hysteresis exponent from approximately 1·6 at flux densities below 7 000 to 3·2 at $B = 16\,000$, and a decrease of the eddy-current exponent from 2·0 to 1·6 over the same range of B. Unfortunately, the value of the paper is much reduced as no details of the method of testing (which was a wattmeter method) or actual results from which the curves were deduced are given, but in the course of the discussion L. T. Robinson claimed to have obtained closely similar results by ballistic tests.

M. MacLaren,§ in an investigation primarily directed to finding the effect of temperature on the hysteresis loss in sheet steel, determined the hysteresis loss in samples of commercial armature steel and high silicon transformer steel at various flux densities between 6 000 and 14 000, from a.c. wattmeter measurements at 25 and 60 periods per second, employing for the separation of the losses a method based on the usual assumption as to the variation of the two components with frequency, but involving the determination first of the coefficient of the eddy-current term. He determined the true exponent at each flux density, adopting as the coefficient of the hysteresis term the value found by assuming the exponent to be 1·6 at the lowest flux density employed. Under these conditions he found a nearly constant value for the true exponent, but, as was pointed out in the discussion, if the exponent is calculated by the usual methods from his results, values decreasing with increasing flux density are obtained in most cases, particularly at high temperatures. This result, which is in contradiction to most of those already recorded, is open to doubt owing to the absence of any allowance or correction for variations in the form factor, which would be almost certain to occur under the conditions of the test.

Paglianti,* in a thorough investigation of the influence of silicon on the properties of steel, made a large number of measurements by the ballistic method of the hysteresis loss at flux densities from 7 000 to 16 000 on a series of annealed rods containing various percentages of silicon from 0·24 to 5·26. He determined for each value of hysteresis loss the value of the coefficient η, assuming an index of 1·6, and whilst he found great variations of the hysteresis, and hence of η, with changes in the percentage of silicon, he obtained in all cases very similar variations of η with B, viz. that η increased 25–50 per cent as B was increased from 7 000 to 16 000, the increase becoming particularly rapid above $B = 13\,000$. Values of the exponent between $B = 13\,000$ and $B = 16\,000$ ranged from 2·1 to 3·3.

A somewhat similar investigation of the properties of silicon-iron alloys containing various percentages of silicon was carried out by Yensen † in the course of his comprehensive study of iron and iron alloys prepared by melting *in vacuo*. His measurements were made ballistically, using the Burrows permeameter, and he also found a very high exponent of B for the hysteresis loss at high values of B, particularly in the alloys containing large percentages of silicon. For one specimen the exponent between $B = 10\,000$ and $B = 15\,000$ was as high as 3·2. Considerable doubt has been thrown, however, on the accuracy of the Burrows method of testing for such highly permeable materials, and tests on rings of the same material were found to give much lower values of the exponent, the results not departing very widely from the Steinmetz relation.

One of the most interesting papers dealing with the losses in sheet material at high flux densities is that by J. S. Nicholson,‡ on "The Magnetization of Iron at High Flux Densities with Alternating Currents." He points out that in testing total loss at high densities the chief difficulty is that, owing to the harmonics in the magnetizing current, the wave-form of induced E.M.F., even with an alternator giving a good sine wave on open circuit, becomes very distorted, and that in consequence the true maximum B may be much less than that indicated by the R.M.S. induced E.M.F. To minimize the error from this cause he adopted a

* See Appendix IV, (11). † *Ibid.*, (12). ‡ *Ibid.*, (13). § *Ibid.*, (14).

* See Appendix IV, (15). † *Ibid.*, (16). ‡ *Ibid.*, (17).

method which, although too complicated for general use, secures the elimination of the triple-harmonic component of the induced E.M.F. and of multiples thereof. To effect this he employs three similar cores, each with two magnetizing windings, one set of windings being star-connected to a three-phase supply and the other set mesh-connected to a single-phase alternator of triple frequency. Then by adjusting the phase and magnitude of the triple-frequency current until the voltage induced in three mesh-connected secondary windings and the power supplied by the single-phase machine are each reduced to zero, the third harmonic in the flux wave is eliminated and a sine wave of flux with only fifth, seventh and higher harmonics, which are usually very small, is obtained. Allowance was made for the fifth and seventh harmonics by analysing the E.M.F. waves, deducing the amplitudes of the flux harmonics from those of the induced E.M.F., and correcting the apparent value of the maximum flux density accordingly. A further correction was made for the flux in the air space within the secondary windings, using a permeability curve obtained ballistically.

The total losses in the three cores (built up of stalloy rings) were determined by measuring the three-phase input by a two-phase wattmeter at various values of the flux density (corrected as described above) and at frequencies of 15 and 22·5 periods per second. The resulting values of total losses were separated into hysteresis and eddy-current losses by the usual method based on frequency variation, and the hysteresis losses obtained were plotted logarithmically against B. The curve approximated to a straight line, indicating a constant index of about 1·58, even up to $B = 20\,500$. Prof. Baily, however, analysing the results in a somewhat different way (by calculating the eddy-current loss at each flux density from the mean value of the eddy-current coefficient, instead of using the values found from the results at that flux density only) found that the logarithmic curve connecting hysteresis loss and B was markedly convex to the axis of B, i.e. that the exponent increased with increasing B and rose to a value of approximately 3·5 above $B = 20\,000$. The results recorded in the paper thus appear to be rather inconclusive, but they seem clearly to indicate that there is no tendency for the hysteresis exponent for stalloy to decrease even at inductions as high as 20 500—a result directly contradictory to that found by Prof. Baily (see above), and, as he points out, hardly to be expected in view of the presumably constant value of the hysteresis loss when actual saturation is reached.

A recent investigation bearing on the variation of the iron losses at high flux densities is that carried out by Jouaust and Mlle Bourgoignon * at the Laboratoire Central de l'Électricité, on the losses in a large number of samples of sheet material at flux densities of 10 000 and 14 000. They used the Epstein tester as modified by Armagnat, and separated the losses by the usual method based on frequency variation, using values of total losses at 25 and 50 periods per second. They found that for some samples the exponent of B for hysteresis loss increased very much above the Steinmetz value—up to as high as 3·14 in one case—whilst for other samples considerably lower values indicating an approximation to a square law of variation with B were obtained. Their investigations appeared to show that the high values of the exponent were obtained on the group of specimens containing rather a higher percentage of silicon and having higher hysteresis loss and comparatively low permeability.

A still more recent paper bearing in some measure on the question under consideration is that by G. H. Cole * on "The Magnetic Properties of Silicon Steel in a Large Transformer." He measured the losses in the core of a 4 166-kVA single-phase transformer, built up of 4 per cent silicon-steel sheets, by both a d.c. method using the volt-second meter as described by Chubb and Spooner,† and an a.c. method involving the determination of the total losses at 25 and 60 periods per second from wattmeter measurements and from oscillograms of magnetizing current and voltage. The total losses found in the a.c. tests were separated into their two components by the usual frequency method, and the hysteresis losses thus obtained were found to be slightly greater than those given in the d.c. tests. The total losses measured on the transformer in this way were also found to be several per cent higher than those found by Epstein tests on the material of the core, the discrepancy being attributed to inferior annealing of the core material, greater pressure in the core causing increased eddy currents and, at high flux densities, fringing into the solid steel parts adjacent to the core. Although the hysteresis deduced from the a.c. measurements was slightly greater than that found from the d.c. tests, for both sets of tests the loss appeared to follow a similar law of variation with B. From the slope of the logarithmic curve connecting hysteresis loss with B a constant exponent of approximately 1·6 was deduced for values of B up to about 9 000, but above this density the exponent was found to increase continuously and more and more rapidly with B up to a value of 5 at $B = 16\,000$ (by a.c. tests) or at $B = 18\,000$ (by d.c. tests). This abnormally high value was almost certainly due in part to leakage of the flux, owing to the reduced permeability at high densities, into adjacent solid steel parts of the transformer, but it was shown that the effect of this would be inconsiderable below $B = 14\,000$, and a large increase in the exponent would therefore appear to be genuine. It is suggested that this may be due to the core material being unhomogeneous, e.g. to the presence of oxide scale.

From the foregoing résumé it is clear that experimenters on the losses at high flux densities are very far from being unanimous as to the nature of the law connecting hysteresis loss with flux density. The results obtained fall roughly into the three classes set out below :—

(1) *Results confirming Steinmetz's law,* in some cases even up to very high flux densities such as 20 000 or 22 000. In addition to the original results of Steinmetz this group includes the work of Stroude, MacLaren, Nicholson and, in spite of divergences at lower densities, of Ewing and Klaassen. In the case of Steinmetz, Ewing and Klaassen and, to some extent, Stroude, as has already been pointed out, the tests were made on

* See Appendix IV, (18).

* See Appendix IV, (19). † *Ibid.*, (20).

ordinary soft iron, not on the modern special brands of sheet material. It has also been suggested that Stroude's results are not so conclusive as they were made to appear, whilst the tests on stalloy were only carried up to $B = 12\ 000$; nevertheless, with these reservations they indicate at least a fairly close approximation to the Steinmetz law. MacLaren's results are, as previously stated, of doubtful accuracy, and in view of Baily's analysis the reliability of Nicholson's figures for stalloy, at any rate at the highest densities, is open to question. The latter's tests, however, would certainly seem to indicate that at about $B = 18\ 000$ the hysteresis index does not differ very widely from the Steinmetz value.

(2) *Results indicating an exponent of approximately 2 at high inductions.*—A large proportion of the investigators referred to above found that as the flux density was increased the hysteresis loss tended to rise rather more rapidly than was to be expected from Steinmetz's law—some obtaining an exponent of almost exactly 2, others slightly higher values such as 2·1, 2·2 or even 2·4. Of this group, the results of Wild, as has been indicated above, cannot be considered very reliable, whilst those of Wilson, Winson and O'Dell and of Baily were limited to one or two specimens. The remaining results in this class, however—those of Barrett, Brown and Hadfield, Gumlich and Rose, Czepek, Richter and Lloyd and Fisher—were obtained on a variety of specimens and do not seem open to any serious criticism as regards the accuracy of the methods employed.

(3) *Results indicating still higher exponents*, ranging up to 3 or more. Several experimenters have found, over certain ranges of B or for certain selected specimens, values of the exponent of 3 or more. These are Wooldridge, Paglianti, Yensen, Jouaust and Cole. Of these, the results published by Wooldridge are not given in sufficient detail to carry much weight, those of Yensen were obtained by a method of doubtful reliability when used for specimens with the properties of those tested by him, whilst those of Cole, being obtained on a complete transformer instead of on standard samples under exactly specifiable conditions of test, are subject to various sources of error and cannot be considered of very high accuracy. The tests of Paglianti and Jouaust, however, were carried out by standard methods and on a large number of specimens and, although the values found for the exponent differed considerably for different specimens, all gave very high values at high densities. Both these investigators obtained values of the exponent for silicon iron ranging up to about 3·2—in Paglianti's tests for the range from $B = 13\ 000$ to $B = 16\ 000$, in Jouaust's experiments for the range from $B = 10\ 000$ to $B = 14\ 000$.

Whilst, therefore, there is a large body of evidence that, at least for silicon-iron sheets, the losses increase rather more rapidly with the flux density at densities above 10 000 than at densities below that value where Steinmetz's law holds true, there is considerable disagreement between different investigators as to the extent of the deviation from the 1·6th power law, whilst two or three experimenters obtain results indicating that no such deviation occurs.

(3) Preliminary General Investigation.

Object and scope of tests.—The object of the tests to be described in this paper was to investigate the reasons for these apparently discordant results and to determine the true nature of the variation of the power losses with flux density at high densities.

In order to discover to what extent the law of variation differed for different commercial sheet materials or for different specimens of the same material, tests were made on a series of specimens provided by Messrs. J. Lysaght, Ltd., comprising samples of various thicknesses of their lohys, special lohys, high-resistance and medium-resistance grades. In each case tests were carried out at a number of values of B between $B = 5\ 000$ and $B = 15\ 000$. To provide a check against systematic errors inherent in the method of testing, parallel tests were made throughout by the ballistic and the a.c. wattmeter methods, the total power losses measured by the latter method being separated into hysteresis and eddy-current components, and the hysteresis thus deduced being compared with the static value obtained ballistically.

Methods of Testing.

(*a*) *Alternating-current tests.*—The alternating-current tests followed the usual lines of the wattmeter method of measuring total iron losses. A diagrammatic representation of the circuit for this is shown in Fig. 1, and

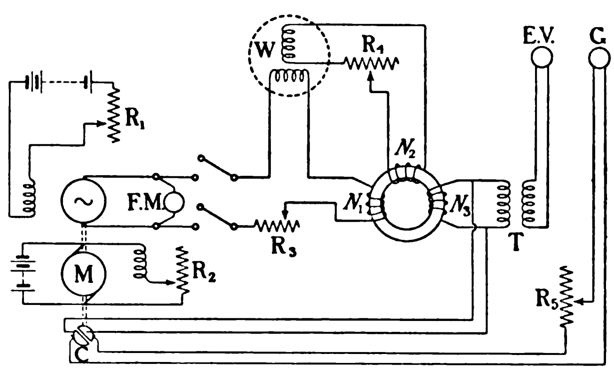

Fig. 1.—A.C. testing circuit.

the general principles of the method have been frequently described, for example, by A. Campbell * in his paper "On the Magnetic Testing of Iron with Alternating Current."

The samples used in these tests consisted of flat strips. Half of these were cut parallel and half perpendicular to the direction of rolling. They were built up into a square of the pattern due to Lloyd and Fisher † of the Bureau of Standards, Washington, but with certain modifications of their design introduced. One of the most important of these was an increase in the depth of windings to allow strips 7 cm wide to be inserted in place of the 5 cm strips used in the original apparatus. This reduces the effect on the results obtained of the higher losses in the material near the edges, caused by the cutting of the samples.

The square was wound with two primary (magne-

* See Appendix IV, (21). † *Ibid.*, (7).

tizing) coils of 640 and 160 turns respectively, and with secondary coils of 160, 80, 40 and 20 turns which could be connected to the wattmeter pressure circuit or to the voltmeters as required, to give convenient deflections. The square is indicated purely diagrammatically in Fig. 1, N_1, N_2, N_3 representing the three windings actually in use.

The wattmeter (W) was of the reflecting dynamometer type, designed to be of high sensitivity and constructed largely of marble to avoid eddy currents and thereby give accurate results at high frequencies. It had been found to be reliable up to 800 periods per second. A variable resistance (R_4) in series with the pressure coil gave a wide range of multipliers.

To determine the value of $B_{max.}$ it is necessary to measure the mean voltage induced in the secondary winding N_3, since

$$V_{mean} = 4fN_3B_{max.}A \times 10^{-8}$$

where f = frequency,
N_3 = number of turns in secondary winding,
A = cross-section of specimen.

For this purpose a Cambridge and Paul bifilar moving-coil reflecting galvanometer (G) with a high adjustable series resistance (R_5) was used, connected in series with a synchronous commutator (C).

An electrostatic voltmeter (EV), connected to the same or another secondary winding either directly or through a variable-ratio step-up transformer (T), measured the R.M.S. voltage and hence, in conjunction with the galvanometer G, gave the form factor of the induced E.M.F. wave. The voltmeter used was a low-reading Ayrton-Mather electrostatic voltmeter having a working range of 3–8·5 volts.

The source of supply was an alternator of about 5 kW rating, which gave a close approximation to a sine wave of voltage on open circuit, and the frequency and excitation of which were readily adjustable by means of the resistances R_1 and R_2. Its frequency was measured by a reed frequency-meter (FM) connected permanently to the supply terminals.

Before making any measurements the wattmeter and moving-coil galvanometer were always calibrated, as they were found to be liable to slight variations in sensitivity. To calibrate the wattmeter a direct current of exactly 1 ampere was passed through the current coil and through a standard resistance of 1 ohm, the potential terminals of which were connected to the pressure coil. A power of exactly 1 watt was thus applied to the instrument and the deflection noted. The current was then reversed and the deflection again noted, the mean of the two deflections being taken as the a.c. calibration. The galvanometer was similarly calibrated by connecting it to the potential terminals of the 1-ohm resistance. To adjust the current accurately to 1 ampere it was passed through a standard resistance of 1·0183 ohm, the P.D. on which was balanced against the E.M.F. of a Weston standard cell. This adjustment could easily be made to 1 part in 10 000.

The electrostatic voltmeter was not found to vary appreciably in its sensitivity and was therefore not regularly calibrated. It was checked at intervals on a potentiometer against a Weston standard cell.

In taking a reading, after setting the frequency to the required value, the alternator excitation was first adjusted to give approximately the desired flux density, and the brushes on the commutator were slowly rotated to give the maximum reading on the mean-voltage galvanometer. The final adjustment of this reading to the value corresponding to the desired flux density was made by means of the alternator field resistance, and the wattmeter and electrostatic voltmeter were then read.

In order to separate the losses into hysteresis and eddy-current components, readings were taken at the same values of B at two frequencies—25 and 50 periods per second. Then, if W_1 and W_2 are the total losses at frequencies f_1, f_2, for a given value of B, we may write :—

$$W_1 = \eta f_1 B^x + \xi f_1^2 k^2 B^y$$
$$W_2 = \eta f_2 B^x + \xi f_2^2 k^2 B^y$$
$$= 2\eta f_1 B^x + 4\xi f_1^2 k^2 B^y \text{ (if } f_2 = 2f_1)$$

whence

$$4W_1 - W_2 = 2\eta f_1 B^x = 2H_1 = H_2$$

if H_1, H_2 = hysteresis losses at frequencies f_1, f_2.

It is clear that this relation only holds if the form factor, k, is the same at both frequencies. This is not usually the case, particularly at high flux densities, unless special steps are taken to secure this condition. Consequently, in these tests all values of total loss were reduced to a sine wave of secondary induced voltage. For this purpose, for any values of B and frequency for which the form factor departed appreciably from the sine-wave value, a series of readings was taken with the form factor artificially varied by the insertion of series resistance (R_3) in the magnetizing circuit. Then from the above equations it is clear that for given values of B and f the curve connecting W and k^2 is a straight line, and by extrapolating to the value $k^2 = (1 \cdot 11)^2 = 1 \cdot 232$ the total losses for a sine wave of induced E.M.F. can be obtained. Using the values thus found, the above formula may be legitimately applied to separate the losses.

A correction on the apparent flux density must also be made for the flux in the air space enclosed by the secondary winding employed to measure B. Owing to the existence of this flux the value of B calculated from the mean voltage induced in the winding is too large by an amount equal to

$$H \times \frac{\text{Area of air space}}{\text{Section of specimen}}$$
$$= H \times \frac{\text{Mean area enclosed by coil} - \text{Section of specimen}}{\text{Section of specimen}}$$

The multiplying factor, being a constant for any given specimen and square, is calculated, once for all, from the known dimensions of the winding and specimen. The value of H for a given B may be taken from the permeability curve obtained ballistically, or may be directly measured by alternating current, as the results obtained by the two methods do not differ appreciably (see

Appendix 1). This correction becomes important only above $B = 10\,000$.

The values of loss obtained in the tests must also be corrected for the power lost in the instruments. The deduction to be made for the loss in the wattmeter pressure circuit is $V_W^2/R_{P.C.}$, where

$$V_W = \frac{N_2}{N_3} \times \text{R.M.S. voltage indicated on winding } N_3,$$

and $R_{P.C.} = R_4 +$ resistance of pressure coil itself.

This correction was always very small, particularly at high flux densities.

The loss in the moving-coil galvanometer circuit was in all cases negligible owing to the very high value of the series resistance R_5. It was usually less than $0 \cdot 01$ per cent of the power being measured.

Allowance for the reduction in the flux density, caused by the overlapping of the specimen and the corner pieces, was made in the way suggested by Lloyd and Fisher (loc. cit., p. 463), and in accordance with their formula, i.e. the loss per kg of material was determined by dividing the measured loss by an effective mass m given by

$$m = (m_1 + m_2)\,(1 - 1 \cdot 4c)$$

where m_1, m_2 = masses of specimen and corner pieces,
c = total length of overlapping portions of magnetic circuit, expressed as a fraction of the total length of the circuit.

When corner pieces of different material from the sample were used, an additional correction for the difference between the losses in the corner and the sample was necessary. This was made in accordance with the formula

$$W = W_1 + \frac{m_2}{m_1}(W_1 - w)$$

where W = true loss in watts per kg,
W_1 = apparent loss in watts per kg,
w = loss in corner pieces in watts per kg.

This formula, though only approximate, was sufficiently accurate provided the corner pieces resembled the test-specimen fairly closely in density, thickness and specific power loss. Where corners were cut from the same sheet as the specimen no such correction was made, it being known that the effect of the hardening due to bending of the corners was not serious.

(*b*) *Ballistic tests.*—The ballistic determinations of the hysteresis loops were made by the standard method, which is too well known to need any description. The test-set employed was the same, except for very minor alterations in certain details, as that described at length in the "Dictionary of Physics" article on "Magnetic Measurements and Properties of Materials." *

The ballistic galvanometer was a Sullivan moving-coil instrument having a resistance of approximately 600 ohms and a natural period in the field of about 10 seconds. It was fitted with adjustable shunts and series resistance to allow of the instrument being made direct-reading for B on any specimen. It was calibrated by being connected to the secondary of a Campbell inductometer in the primary of which a current of exactly 1 ampere was suddenly reversed. The current of 1 ampere was measured by a potentiometer and Weston standard cell as described above under "Alternating-current Tests."

The magnetizing current was measured by a Paul bifilar moving-coil galvanometer fitted with a range of suitable shunts and adjusted by varying a large series resistance to give direct readings of H. This instrument was calibrated by means of a Weston standard millivoltmeter with standard shunts.

The ballistic tests were made on rings of external diameter 15 cm and internal diameter 12 cm cut from the same sheets as the strips used for the a.c. measurements. It was realized that owing to the small width of these rings—$1 \cdot 5$ cm as compared with 7 cm for the strips—the effect of cutting would be much greater than on the strips, and that the values of hysteresis would, therefore, probably not be the same in both sets of tests; but as the investigation was directed rather to the nature of the variation of loss with B than to the determination of the actual values of the losses, it was thought that tests on the rings would furnish the confirmation of the a.c. results which was required.

TABLE 1.

No.	Material	Density	Measured thickness
			mm
1	Lohys	7·85	0·96
2	Lohys	7·85	0·46
3	Lohys	7·85	0·43
4	Lohys	7·85	0·37
5	Special lohys	7·80	0·45
6	Special lohys	7·80	0·40
7	High resistance	7·56	0·46
8	High resistance	7·56	0·35
9	High resistance	7·56	0·34
10	High resistance	7·56	0·32
11	Medium resistance	7·76	0·47
12	Medium resistance	7·76	0·38
13	Medium resistance	7·76	0·37
14	Medium resistance	7·76	0·37

The static hysteresis loops were plotted from the corresponding values of H and B and the hysteresis loss was calculated from their areas, measured by planimeter, in the ordinary way and expressed in watts per kg at 50 periods per second.

Results obtained.—A complete list of the materials tested is given in Table 1. From the sheets of each material, sets of strips and rings, for a.c. and ballistic tests respectively, were cut, as described above. The former were in each case denoted by the number of the material and the letter A, the latter by the number and the letter B.

As an example of the a.c. results obtained, the com-

* See Appendix IV, (22).

plete results for specimen 4A are given in Table 2. It will be seen that up to $B = 12\,000$ the form factor, k, of the wave of induced E.M.F. was practically that for to the apparent values of B is shown in Table 2A, the values of H being derived from the permeability curve shown in Fig. 2.

TABLE 2.

A.C. Results on Specimen 4A.

Mass $m_1 = 1\,232$ grammes. Cross-section of specimen, $A = 1{\cdot}569$ cm². Mass of corners, $m_2 = 66$ grammes. Overlap at corners = 4·5 mm. Effective mass, $m = 1\,229$ grammes. Magnetizing turns, $N_1 = 640$. Secondary turns (wattmeter), $N_2 = 160$.
Section of secondary coil = 20 cm², therefore correction for air flux $= [(20 - 1{\cdot}569)/1{\cdot}569]H = 11{\cdot}8\,H$.

a sine wave, but above this flux density it was not possible to obtain a sinusoidal wave and the losses for such a wave-shape were found by extrapolation on the curve connecting the wattmeter reading and k^2.

10 000	3·5	40	9 960
12 000	6	70	11 930
14 000	10	120	13 880
16 000	23	270	15 730

The method of deducing the corrections to be applied

The total losses obtained have been plotted against the corrected flux densities in Fig. 3, and from these curves the values used in the separation of the losses have been taken. The separation is carried out in Table 3, which also contains the hysteresis losses found by ballistic tests on specimen 4B and the exponents calculated between each pair of successive values of B both for hysteresis and eddy-current losses.

In Table 4 the results are given of a similar analysis of the measurements made by alternating current and ballistically on the remaining specimens detailed in Table 1. In certain cases, however, only two or three ballistic tests were carried out and determinations of the exponent for the same ranges of B as in the a.c. tests could not be made.

Discussion of results of preliminary general investigation.—These results appear to show definitely that above $B = 10\,000$ the exponent of B for hysteresis loss rises much above the Steinmetz value, 1·6, which applies below $B = 10\,000$. In several cases the exponent for

the range $B = 12\,500$ to $15\,000$ approximates to or even exceeds $2\cdot5$, and it would seem likely that, for smaller ranges of B near $15\,000$, values as high as $3\cdot0$ might be obtained. Such values were actually obtained for the range $B = 12\,500$ to $15\,000$ for material which was

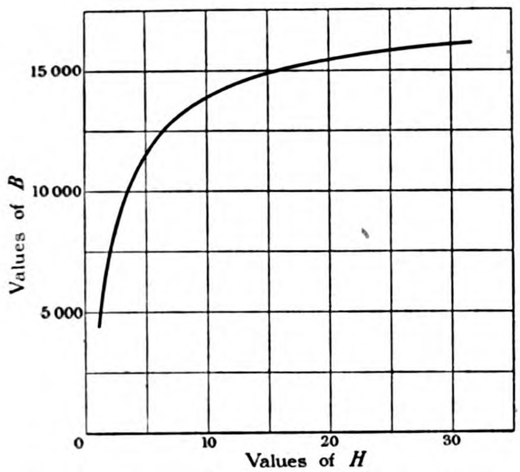

FIG. 2.—Permeability curve on specimen No. 4.

known to be defective. It will be seen that in all cases a fairly close agreement is obtained between the a.c. and ballistic tests. The increase in the exponent is less than the average for lohys, and slightly greater for special lohys specimens, but the number of specimens tested was too few to establish the existence of so small a difference.

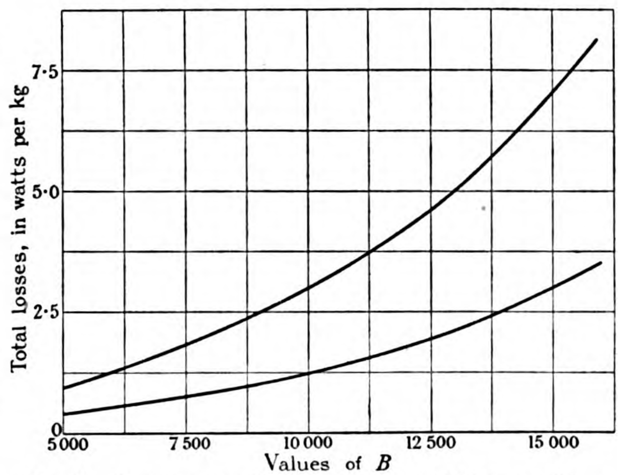

FIG. 3.—Curves connecting total losses and B for specimen No. 4.

The methods adopted in this preliminary general investigation were directed rather to obtaining comparative results on a number of specimens readily

quite definite in the ballistic results, though less marked owing to the hysteresis loss at flux densities near 10 000 (the region of maximum permeability) being increased much more than at higher flux densities by the greater effect of cutting on the narrow rings used in the ballistic tests. That this is the correct explanation of the lower exponents obtained in the ballistic tests was proved by a complete series of tests carried out on annealed rings and strips (see Appendix II) for which close agreement between the two methods of test was obtained.

The results for the four kinds of sheet material tested do not show any pronounced differences in the manner of variation of the hysteresis loss with B, the exponent increasing to approximately the same extent with B for each material. The increase appears to be slightly than to securing high absolute accuracy in any individual test. Thus the method of separating the total losses into hysteresis and eddy-current components assumes independence of frequency for the hysteresis loss per period, which, although a fairly close approximation, probably introduces some slight error into the a.c. values of hysteresis. At high flux densities, in particular, the results are liable to considerably increased errors, since the corrections to be applied for air flux and for form factor of E.M.F. wave become very large.

In view of the very large increase already observed in the exponent at high flux densities, it becomes of interest to examine the effect of testing at still higher flux densities, since, as no further increase of hysteresis is to be expected when saturation is reached, it would

* Owing to the thickness of the laminations of this sample, the eddy-current loss was very large and the temperature-rise so rapid at high inductions that reliable results could not be obtained. This also accounts for the apparently low value of hysteresis at $B = 12\,500$.

seem that the ratio of variation must at some point begin to diminish with increased B.

It was therefore decided to make a more accurate and detailed examination of the variation of losses on certain representative specimens, and to carry this examination to higher values of B.

(4) MORE DETAILED EXAMINATION OF CERTAIN SPECIMENS.

Construction of new square.—To allow of tests being made at higher flux densities a new Lloyd square was constructed in which, using the same general disposition and numbers of turns in the windings, the following improvements were introduced :—

(1) Cross-section of secondary coil was reduced from approx. 20 cm² on the old square to 8·5 cm², thereby reducing the air-flux correction to 40 per cent of its previous value. This is very important for tests at high flux densities.

(2) Resistance of primary winding was greatly reduced by winding with very much thicker wire. This reduces the distortion of the E.M.F. wave and hence the correction to be applied for departure of form factor from a sine-wave value. It is also of importance in diminishing the I^2R heating due to the magnetizing current, which is liable to become considerable at high flux densities and to affect the temperature of the specimen.

Method of testing and working out results.—Using this square, a further complete series of tests was made on specimens Nos. 3, 6, 8, 12, i.e. one each of lohys, special lohys, high-resistance and medium-resistance material.

As in the first part of the investigation, parallel tests were made throughout by the a.c. and the ballistic methods. The a.c. tests were carried out as before at frequencies of 25 and 50 periods per second and at a number of flux densities from 10 000 to the highest value that could be reached without excessive heating. Owing to the improved characteristics of the new square, it was possible to obtain satisfactory results for flux densities up to about 18 000 on the softer materials and 17 000 on the high-resistance material.

At the highest values of B attained, the I^2R heating, even with the new square, was sufficient to produce an appreciable rise of temperature in the time required to make the adjustments and take the readings. To minimize the effect of this, the temperature of the samples was read by a thermo-junction and the square was allowed to cool between successive readings so that the temperature when the readings were taken did not vary more than 1° or 2°.

The separation of the losses was carried out independently at each frequency from the curve connecting the power loss and the square of the form factor. This avoids the assumption that the hysteresis loss per period is independent of the frequency, but assumes that it is independent of form factor. From the fundamental formula

$$W = \eta f B^x + \xi f^2 k^2 B^y$$

it follows that if f and B are kept constant

$$W = A + Bk^2$$

i.e., the curve connecting W and k^2 should be a straight line.

In carrying out the tests a series of readings at different form factors was taken at each value of B by inserting various series resistances in the magnetizing circuit, and curves connecting W/f and fk^2 were drawn. (These curves are identical with curves connecting W and k^2, except for a change of scale for any series of tests at a given B and frequency, but they allow a direct comparison to be made between the eddy-current coefficients found from the 25- and 50-period tests.) These curves were found to approximate very accurately to straight lines, suggesting that the assumption of independence of form factor for the hysteresis loss is at least a close approximation to the facts. The slope of each of these curves was then found and must evidently be equal to ξB^y. Plotting the slopes logarithmically against the corresponding values of B, a curve is obtained the slope of which is the exponent of B for the eddy-current

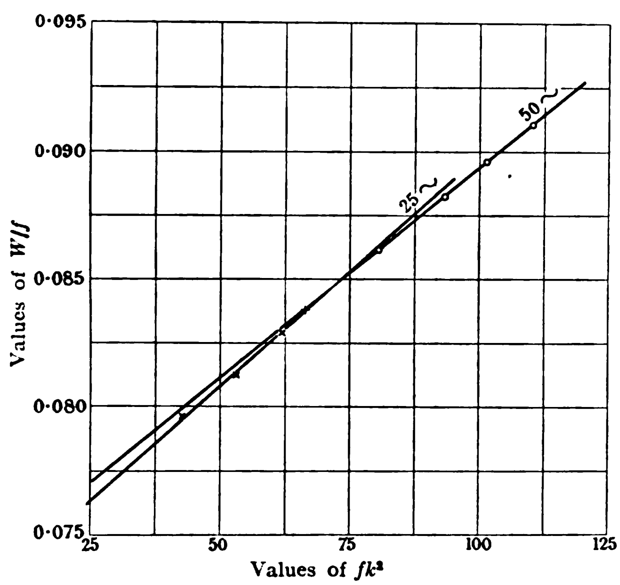

FIG. 4.—Curves connecting W/f and fk^2 for specimen No. 8A (high-resistance material) at $B = 16\,000$.

loss. In order to eliminate the errors of individual tests the separation of the losses was carried out by deducing the eddy-current loss for a sine-wave form for each value of B from the curve and then calculating the hysteresis loss by subtracting this value from the total loss for a sine-wave form, determined, as previously described, by extrapolation on the curve connecting W/f and fk^2.

The ballistic tests were carried out exactly as before, except that the tests were made on the same strips as were used for the a.c. tests while still built up in the Lloyd square instead of on separate ring specimens. The square was then treated as a ring, the magnetizing force being calculated from the primary current, and the flux density being measured by using one of the secondary windings as a search coil. This eliminates any discrepancy due to different effects of cutting, but may lead to some inaccuracy in the measurement of H owing to the magnetic circuit not being perfectly uniform. Comparative tests, however, showed that the error due to this was quite small (see Appendix 3).

Comparable values of hysteresis loss measured ballistically and by alternating current at 25 and 50 periods per second were thus obtained entirely independently and afforded a double check on the variation of loss with B.

Results obtained.—As in the first part of the investigation the complete a.c. results, for one sample No. 8A, are given in Table 5, the calculation of the air-flux correction to the apparent value of $B_{max.}$ being shown in Table 5A.

Curves connecting W/f and fk^2 were drawn from these results for each value of $B_{max.}$ at which tests were made, those for $B_{max.} = 16\,000$ being shown in Fig. 4. The slope of each of these curves was measured and is recorded in Table 6. The logarithms of the slopes are plotted against log B for both frequencies in Fig. 5, and it will be seen that the points for each frequency lie very nearly on a straight line the slope of which is slightly

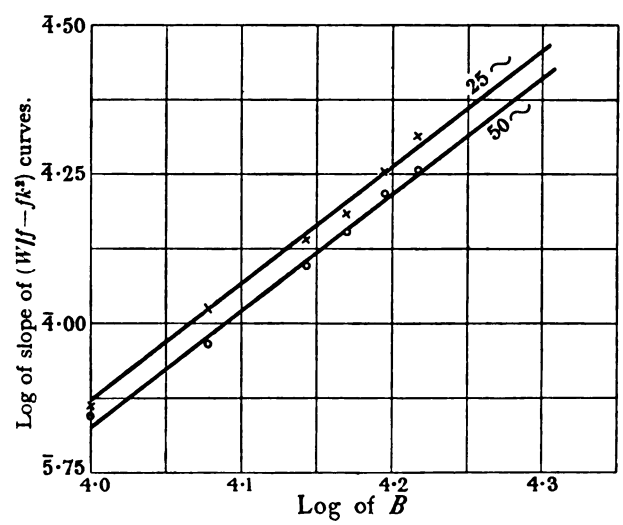

FIG. 5.—Logarithmic curves connecting slope of $(W/f\text{–}fk^2)$ curves with B for specimen No. 8A (high-resistance material).

less than 2, indicating a practically constant index of B of slightly less than 2. The curve for 50 periods per second, however, falls appreciably below that for 25 periods per second, indicating a lower value of the eddy-current coefficient, ξ, at the higher frequency.

Values of the slope corresponding to each value of B have been taken from these curves and are recorded in Table 6. The eddy-current loss for any given form factor may then be found by multiplying the value of the slope by the appropriate value of f^2k^2. For a sine wave $k^2 = 1 \cdot 232$, hence the values of W_E/f for a sine-wave form given in the table are obtained by multiplying the slopes by $1 \cdot 232 f$.

The corresponding values of total loss/frequency ($= W/f$) for a sine-wave form are read off the curves connecting W/f and fk^2 by making $fk^2 = 1 \cdot 232 f$.

Subtracting W_E/f from W/f the value of hysteresis loss/f ($= W_H/f$) is found, and hence the hysteresis loss may be obtained. Values of hysteresis

loss and total loss in watts per kg are given in Table 6 for each value of B at which tests were made, and for 25 and 50 periods per second. They are also plotted in Fig. 6, and from these curves the final values were read. The results are shown in Table 7, where the hysteresis loss at both frequencies has been expressed in watts per kg at 50 periods per second, and where the ballistic values determined from the areas of the static loops, also expressed in watts per kg at 50 periods per second, are given for comparison. The exponent of B for the hysteresis loss is also given for each set of results for various ranges of B. Results corresponding to those in Tables 6 and 7 are given for specimens No. 3A (lohys), No. 6A (special lohys) and No. 12A (medium resistance) respectively in Tables 8 and 9, 10 and 11, and 12 and 13.

TABLE 5A.

16 000	73	350	15 650
17 000	108	520	16 480

Discussion of results and conclusions.—The results obtained in the more thorough examination of the four representative specimens fully confirm the conclusions drawn from the preliminary general investigation and justify the suggestion made in connection with it that the exponent for limited ranges of B may reach values of $3 \cdot 0$ or more. In the case of specimen No. 12A the ratio between B = 15 000 and B = 16 000 even exceeds $4 \cdot 0$. It will be seen that the three sets of values of hysteresis loss, which have been obtained entirely independently, give exponents which are in very good agreement, the discrepancies between the three sets being apparently due only to incidental errors of measurement and not greater than are to be expected when deriving the exponent for such small ranges of B. Thus, although there are differences between the values of hysteresis loss obtained at different frequencies, probably

due to non-homogeneity of the material, it seems certain that the exponents represent fairly accurately the true values for the material. The results thus indicate a very rapid increase of the exponent in the neighbourhood of $B = 15\,000$, followed, as was anticipated, by a rapid decrease to quite low values above $B = 17\,000$. Too much reliance should not be placed on the figures for $B = 18\,000$, but since fairly close agreement was obtained between ballistic and a.c. results it may be assumed that the general shape of the curve, at any rate, follows the course indicated.

So far as the hysteresis loss up to $B = 16\,000$ is concerned, therefore, the results obtained appear to confirm those placed in the third group of the summary at the end of Section 2 as indicating ratios of variation considerably above 2·0, and although giving somewhat higher values they are not inconsistent with those in the second group which showed exponents of about 2. With the results in the first group confirming Steinmetz's law up to very high flux densities, however, the observations recorded in the paper appear to be in direct conflict. The most important of these are Nicholson's, which were obtained, as described above, by employing an altogether different method of allowing for distortion of the E.M.F. wave. This renders impossible a detailed examination of the points of difference between the two sets of observations, and there seems no obvious explanation of the discrepancy between them.

The significance of the departure from Steinmetz's law observed may be appreciated by calculating the loss at $B = 16\,000$ from that at $B = 10\,000$, assuming a constant exponent. The observed values at $B = 16\,000$ will be found to be 40–50 per cent higher than those calculated.

The rapid fall of the exponent at higher flux densities, although, as suggested, theoretically probable, does not seem to have been generally observed, and, as mentioned previously, the results of Baily, obtained by the calorimetric method and showing a similar effect, are of considerable interest in this connection. He found the decrease in the exponent to begin at about $B = 18\,000$. This is a rather higher value than that at which it was observed in this investigation, but it must be remembered that Baily's experiments were made about 1895 and, consequently, were carried out on soft-iron sheets instead of on the alloy materials now used, for which the saturation flux density is appreciably lower.

One effect of this successive increase and decrease in the exponent is that, where the losses are determined under such conditions that the flux density varies considerably in different parts of the circuit as in an actual machine, the exponent of B for hysteresis loss will appear to be much more constant than it really is. This will apply to such results as those recently discussed by E. Hughes.*

The curves in Figs. 4 and 5, and the results given in Tables 8, 10 and 12, show that the slope of the $W/f - fk^2$ curves is slightly less at 50 periods than at 25 periods, corresponding to a slightly lower value of the eddy-current coefficient. This holds fairly consistently for all specimens and at all values of B. It is quite a small effect and, like the apparent variation of hysteresis with frequency, is believed to be due to non-homogeneity of the material due to the presence of slight scale.

17 000	2·19	4·65	4·06	4·09	3·83			

The slopes of the logarithmic curves plotted from the results in Tables 6, 8, 10 and 12, of which Fig. 5 is an example, show that the eddy-current exponent is nearly constant for each specimen and is in general rather less than 2. This tendency at high flux densities has been noted by several previous observers.

To summarize the conclusions deduced from the results recorded, it has been shown that:—

(1) In all the principal types of commercial sheet material in use at the present time, the rate of increase of the hysteresis loss with B is considerably greater at flux densities above $B = 10\,000$ than is indicated by Steinmetz's law or than appears to have been generally realized. In most specimens over a small range in the neighbourhood of $B = 15\,000$ the variation is as rapid as the 2·5th power of B, and in some cases it exceeds the 3rd or even the 4th power of B.

(2) Above about $B = 16\,000$ the rate of increase falls

* See Appendix IV, (23).

off very rapidly and drops again to the 1·6th power or even lower.

(3) The eddy-current index at high flux densities is fairly constant and generally rather less than 2.

(4) The apparent values of hysteresis and eddy-current losses in ordinary commercial sheet material depend to a considerable extent on frequency. Experiments not recorded in the paper indicate that this is due to non-homogeneity of the sheet. These effects do not appreciably alter the exponents observed.

In conclusion the author wishes to express his thanks to Messrs. J. Lysaght, Ltd., for kindly supplying the samples of sheet material used in the investigation; to Mr. D. W. Dye, B.Sc., for his help and advice throughout the course of the work; and to Mr. L. H. Ford, B.Sc., for his assistance in carrying out the experiments described.

APPENDIX 1.

Comparison of Permeabilities Measured Ballistically and by Alternating Current.

Several tests were made in the course of the investigation to compare the values of permeability obtained by a.c. measurements with those given by the ballistic method.

For the a.c. tests the primary of a mutual inductance of 0·01 henry wound on a marble bobbin was connected

in series with the magnetizing winding of the square. Then after adjusting to any desired $B_{max.}$ by means of the V_{mean} reading in the usual way, the moving-coil galvanometer (G) was connected through the synchronous commutator to the secondary of the mutual inductance, the commutator was again adjusted to give the maximum reading and the value of V_{mean} indicated was noted.

Then $$V'_{mean} = 4fMI_{max.}$$

where M = mutual inductance, in henrys,
$I_{max.}$ = maximum value of magnetizing current, in amperes,
f = frequency, in periods per second,
V'_{mean} = reading of moving-coil galvanometer, in volts.

From this expression the maximum value of the magnetizing current in the square may be at once deduced and, treating the square as a ring in the way described in the paper, a simple calculation gives the value of $H_{max.}$ corresponding to the $B_{max.}$ at which the reading was taken.

Table 14 gives a few typical results obtained on specimen No. 3 with the ballistic values for comparison.

These results indicate clearly that at ordinary commercial frequencies the permeability ($B_{max.}/H_{max.}$) measured by alternating current is practically identical with that found ballistically. A considerable number of similar tests were made with the same results.

It seemed worth while to record these results, since N. W. McLachlan * in a paper on "The Magnetic

* See Appendix IV, (24).

Behaviour of Iron under Alternating Magnetization of Sinusoidal Wave-form" published results showing higher values of B, for given values of H, in a.c. than in d.c. (ballistic) tests.

This result, of which no theoretical explanation was suggested and which on theoretical grounds seems highly improbable, was obtained by making use of a much less direct method of measuring the a.c. permeabilities than that described above, involving the use of an oscillograph taking an appreciable current. His results also showed a marked change in the value of $B_{max.}$ for a given $H_{max.}$ when a small change in the wave-shape of the magnetizing current was made

(form factor of current-wave altered from 1·11 to 1·19), the frequency remaining the same.

This suggests that the effect observed is not due to a genuine difference between the d.c. and a.c. permeabilities, and the author thinks that the more direct measurements recorded above represent with much greater accuracy the true relation between the properties of iron sheet under direct and alternating magnetization.

APPENDIX 2.

Tests on Annealed Strips and Rings (to Eliminate the Effects of Cutting).

In order to determine the magnitude of the effect of cutting and to obtain satisfactorily comparable results, both ballistically and by alternating current on strips and rings, several complete series of tests were made at flux densities from 10 000 to 18 000 on the medium-resistance specimens Nos. 12A and 12B both before and after annealing.

The results of a.c. and ballistic tests on specimen No. 12A have already been recorded in Tables 12 and 13, and of ballistic tests on No. 12B in Table 4. A corresponding series of a.c. tests on No. 12B was made at 50 periods per second by the method described in the paper under "Detailed Examination of Certain Specimens."

Both strips and rings were then annealed together and the whole series of tests was repeated on both specimens. The complete set of results, with those obtained before annealing for comparison, is given in Table 15.

The results show clearly that the cause of the previous differences between the rings and strips was the greater effect of cutting on the rings. Annealing produced reductions in the hysteresis loss up to 25 per cent on the rings and up to 10 per cent on the strips, the reductions naturally being greater at $B = 10\,000$ than at higher flux densities. The resulting values for rings and strips will be seen to be nearly identical. The a.c. and ballistic results are also in very fair agreement, the a.c. values, however, as found in the results embodied in the paper, tending to be rather higher than the ballistic values. In the only case in which this rule is broken—the results at high flux densities on rings after annealing—it is to be noted that the a.c. results are not very reliable, as under these conditions the wave-shape is very distorted and a very large correction has to be made for the form factor.

APPENDIX 3.

Accuracy of Ballistic Tests on Square.

To check the accuracy of results obtained by treating the strips built up with corners in the Lloyd square as a ring for the purpose of making ballistic measurements, permeability curves on specimen No. 3A (lohys) were taken ballistically :—

(1) Treating the specimen as a ring as described in the paper.

(2) Measuring *H* by flat search-coils placed on either side of the strips near the middle of the magnetizing coils, and measuring *B* by search-coils wound on the same length of specimen as was covered by the *H* coils.

The results obtained are given in Table 16.

7·5	13 930	14 110
10·0	14 580	14 700
15·0	15 210	15 270
25·0	15 800	15 830
50·0	16 710	16 710

It will be seen that the discrepancy except for fairly low values of H is very small indeed, and that its maximum value is less than 3 per cent.

A further evidence of the accuracy of the method is given by results quoted in Appendix 2 for strips and rings annealed together. The close agreement between the ballistic results on the two sets of annealed samples again indicates that no serious error is involved in treating the square as a ring.

Discussion before The Institution, 17 December, 1925

Mr. H. S. Holbrook: It has been known for many years that in actual apparatus the core losses at high flux densities increase much more rapidly than would be expected from the Steinmetz formula but, as far as we know, no one has previously investigated the subject to the same extent as the present author. The paper is very opportune because, as the author mentions in his opening statement, there is a very definite tendency in modern practice to use higher flux densities in cores than has been customary in the past. It is interesting to note that our Continental and American competitors, in transformers at any rate, habitually run their cores at flux densities some 20 per cent higher than the average figures in British designs. This means not only that they are using smaller cores, but that due to the resulting reduction in mean length of turn of the windings they are able to get greater outputs for the same copper losses, or, alternatively, use a smaller tank for the same transformer rating. This is a contributory reason why orders are lost on price to American and Continental firms, and therefore the paper is of national importance. I was rather surprised that the author did not mention in his bibliography the work of Mr. John D. Ball as reported in the discussion before the American Institute of Electrical Engineers on his paper on the "Unsymmetric Hysteresis Loop."* He suggested that, as a result of his experiments, the variation in the Steinmetz exponent which had been noted by various investigators could be explained by the presence of scale on the steel. Mr. Ball stated that the scale tended to have a higher permeability than the steel itself but at the same time it had a greater loss coefficient. The flux distribution between the scale and the steel changes as the flux density is increased, and under such conditions one could not expect the total hysteresis loss to follow any regular law. Has the author considered Mr. Ball's work? In any case, of course, the scale on alloy steels, especially the 4 per cent silicon steel, is one of our most difficult practical problems. The author mentioned that at very high flux densities he found a decrease in the exponent. Some of our own curves show this, but in view of difficulties in making such tests I am afraid that I personally had been inclined to the view that the decrease represented some

* *Transactions of the American Institute of Electrical Engineers*, 1915, vol. 34, p. 2729.

error in the test-results. The author has obtained remarkable consistency in his experimental results. In Appendix 2 he gives some figures which illustrate the advantage of annealing alloy steels. The specimens on which he gives the results were of medium-resistance quality. Has he any figures in connection with the high-resistance steels? It is the present general practice in purchasing specifications and descriptive matter to compare electrical sheet steels on the basis of the total watts loss at 50 cycles and a maximum flux density of 10 000 lines per cm^2. When it was the practice to run transformer cores at flux densities around 9 000 lines per cm^2 a test at 10 000 was very useful, but now that the practice in England is to run cores between 12 000 and 14 000 lines per cm^2, whilst our foreign competitors are working at 15 000 and, in some cases, up to 15 500, I should like to suggest that if the data can be obtained it would be much more useful to compare steels in future by the total wattmeter losses at 15 000 lines per cm^2.

Mr. G. C. Marris: Steinmetz evolved his law as an empirical one to cover a certain range of flux densities, and he discusses very fully its defects in one of his books. The present paper appears to me to lead to the valuable and not unexpected conclusion that the Steinmetz formula does not apply except in the range which its author specified and which has been found by experience to be justified, namely between inductions of about 3 000 and 10 000 lines per cm^2. It is interesting to consider as a contrast the range of low flux densities which has been discussed by H. Jordan.* Jordan follows Rayleigh in his argument, basing the form of the hysteresis loop on the equation for permeability, but he provides an alternative expression for hysteresis losses in terms of quantities which are perhaps more fundamental from the point of view of the molecular theory of magnetism, and then shows how this new expression can be linked up with the Steinmetz formula. The main result of Jordan's argument as applied to these weak fields would appear to be that the coefficient in the Steinmetz formula can only be expected to remain constant over a region where the permeability is also constant or approximately so; and for weak fields the index would approximate to 3, which is borne out by experimental work. The permeability referred to is derived from the "tip-top point" curve of the hysteresis loops. From densities of about 4 000 to 10 000 lines, which is the region in which the Steinmetz law has been held to be true, the permeability is in many steels approximately constant, the variations being perhaps 30 or 40 per cent for a particular sample, but with densities as high as 16 000 or as low as 2 000 the permeability is changing more in the neighbourhood of 200 or 300 per cent. It is usually assumed that in the case of low flux densities the hysteresis loop is approximately an ellipse, and so analysis is possible. I think it would be very difficult to apply a similar analysis to the high-flux-density case. In conclusion it seems to me unwise to try to extend the use of the Steinmetz law outside the usually accepted range of flux densities, for an empirical law of this type becomes a source of confusion when its "constants" are allowed to change. It would be better to content oneself with a series of curves of loss and induction at one or two frequencies which would be usable, even if not quite so simply, as a basis for comparing materials.

* *Elektrische Nachrichten-Technik*, 1924, vol. 1, p. 7.

Mr. L. G. A. Sims: I cannot feel certain that the author has been able to place this matter beyond all further doubt, as when he states that his results are liable to increased errors at high flux densities he destroys our confidence in the results which he set out to achieve. He has obtained his correction for flux density in the air space by an arithmetical subtraction, taking simple multiples of the magnetizing force H, namely, $11 \cdot 8\ H$ in the first experiments and $4 \cdot 8\ H$ in the later experiments. At higher frequencies, when the result has been calculated at such high densities by voltage readings taken across the coil N_3, it would not be correct to employ such a correction. The voltage due to the air-space flux and the voltage due to the power loss in the iron are approximately in quadrature, but the effect is greater at higher frequencies, and the arithmetical subtraction cannot then give a correct result. Such an arithmetical method is only sound for tests using direct current, such as the ballistic tests, and not for a.c. tests. I should like the author to assure us that he has considered the question of phase angle at the test frequency in obtaining the voltage across the coil N_3 in Fig. 1. N_3 is not the magnetizing coil, but it is closed through a transformer and a galvanometer, and if there is no error there then a possibility of error in the wattmeter reading still remains. As the wattmeter voltage-coil is connected across N_2 and not N_1, with which the current coil is in series, it seems that there is an error either in the flux calculated from the voltage reading across the coil N_3 or in the reading of the wattmeter. The accuracy of a planimeter in integrating areas in a research of this kind seems questionable. The possibility of variable human error is too great, and it seems that errors of that kind have occurred in some of the results. This appears to be a weak point and diminishes our confidence in the accuracy of the ballistic results. The author might have given his reason why the wattmeter calibration, consisting apparently of one reversed direct-current observation, could not have been carried out on orthodox lines at the test frequency on such apparatus as the Drysdale a.c. bridge. Moreover, the practical value of his work would have been considerably enhanced if he had given experimental results for hysteresis cycles which are not symmetrical about the zero axis of flux density, by considering the case of iron magnetized by a steady current on which is superposed an a.c. component. No information is given as to whether his results apply to the case of rotating masses of metal, such as dynamo and motor armatures, etc. Transformers and choking coils are not generally worked at high flux densities, so it is difficult to see the practical application of the results, but this does not detract from their scientific value. I would suggest that the work be extended to cover the unsymmetrical cycles, and over a frequency band not limited by 50 periods per second, but by the upper audible, or even some higher, frequency.

Mr. H. W. Taylor: Machine designers are inclined to look upon the hysteresis exponent as an empirical

figure and to regard as more important a comparison between figures giving total losses in different qualities of material at specified flux densities. The addition of silicon to steel has three marked effects, (1) to increase the electrical resistance and so to lower eddy-current loss, (2) to lower hysteresis losses, and (3) to increase the permeability at low densities—which effect is more pronounced by the shape of the smaller hysteresis loop—and to lower the permeability at the top of the loop at higher densities. Curves showing loss tests on iron samples are usually based upon apparatus similar to transformers, and losses in this type of commercial apparatus are found to correspond closely to the results of tests made in this way. When, however, any of these materials are used in rotating machinery, and more particularly on turbo-alternators, it is well known that a multiplying factor has to be used to allow for the unequal distribution of the flux across the section of the core. One would, however, expect the total losses when different materials are used to the same design to bear some relation to the laboratory tests on the samples of the materials, but whilst an improvement is found with the higher silicon steels at low densities, at higher densities, say at 80 000 to 90 000 lines per sq. in. (this figure being stated as an average density across the core section), the results have been disappointing and the losses have been found to increase quickly, so that in many cases they show at these densities higher figures than in similar machines built with ordinary unalloyed sheet iron. The reason of this is somewhat obscure and worthy of further investigation, but it is believed that, owing to the peculiarities of permeability mentioned above, the already unequal distribution in the core is further disturbed at the higher mean densities, so giving rise to a considerable amount of high-frequency eddy-current loss.

Mr. Ll. B. Atkinson: I should like to endorse a remark that has been made by one of the speakers, and that was in regard to taking an exponential law with a constant index which fits, or did fit, some curve, and obtaining many deductions from it, but then proving that the so-called constant index is not constant, and being led through a series of evolutions and discussions which have no meaning unless it is constant. The value of any mathematical formula is two-fold, namely, to enable calculations to be made, or to throw some light on physical properties or actions; but when a law, stated to be exponential with a constant index, such as Steinmetz evolved, is taken, then it seems that no object is gained in using such a formula if throughout the curve a different index is required from point to point along the curve. It is clear that the formula will not allow calculations to be made, and it throws no light on any physical properties involved, and so I am of the opinion that the fact that Steinmetz's law is not true should be stated in the paper, as that is really the author's conclusion. Applied in a general manner, the law fits a curve for a little way, but I should have liked to see given in the paper a law which would fit the author's curves.

Mr. F. E. J. Ockenden: I am interested in the method of testing shown in Fig. 1. The use of resistance R_3 is not very clear to me. The author says that in all tests the induced E.M.F. wave in the search coils approximated fairly closely to a sine wave. I am rather surprised at this, having regard to the total resistance in the magnetizing circuit R_3, N_1, W. Would it not have been better to cut R_3 out and maintain the correct magnetizing current by extremely accurate adjustment of the generator voltage? Another source of error which appears likely to occur in this, and indeed in all wattmeter methods of measuring the power loss, is that due to the presence of large 3rd and 5th harmonics in the magnetizing-current wave, the former being likely to be of the order of 30 per cent of the fundamental. This component should of course be absent in the voltage wave consequently traversing the wattmeter as a wattless triple-frequency current, and it seems likely to bias the readings should there be any suspicion of eddy-current effect or of mutual induction between the fixed and moving coils. There is no mention of a condensive shunt being employed to compensate for this latter possibility. An excellent method of measuring power loss, devised originally, I believe, by Dr. C. V. Drysdale, in which the induced E.M.F. is measured on an a.c. potentiometer and compared with that in a standard mutual inductance, would appear to avoid all the aforementioned sources of error and would, I think, lend itself very well to the author's purpose. His method of ascertaining the peak flux by commutating the induced E.M.F. and measuring its mean on a d.c. voltmeter appeals to me as being both simple and ingenious, since, in the case of wave-forms differing much from a sine wave, I have always had to estimate the total flux from a graph of the E.M.F. wave. I think it would be better if N_2 and N_3 were in fact the same coil, since there must surely be some magnetic leakage between them. It must further be difficult to ensure that the commutator behaves perfectly. I mention this because I notice that in Table 2A the author takes the trouble to apply a correction figure of 20 to a B of 5 000, implying that he is sure of the peak flux within less than ½ of 1 per cent, which I should have thought to be a little optimistic.

Mr. A. Campbell (*communicated*): The paper appears to settle definitely the question of the inconstancy of the Steinmetz exponent for flux densities above 10 000. The good agreement between the results obtained by the two totally different methods (ballistic galvanometer and a.c. wattmeter) leaves little doubt that, for the materials tested, the exponent does not remain constant above $B_{max.} = 10\,000$. In a set of samples which I tested many years ago the exponent appeared to vary with a change of $B_{max.}$ much more in some than in others, and there appeared to be a connection between the "ageing" properties of the material and its exponent curve, so that one could predict how a particular sample would age, by merely testing the variation of the Steinmetz exponent. If such a relation could be confirmed it would form a useful criterion of ageing properties and save the trouble of tedious ageing tests. I am inclined to think that there are materials which would show a much more constant exponent than those tested by the author.

Mr. B. G. Churcher (*communicated*): With a few

minor exceptions, the whole of the ground covered by the author was investigated in the Research Department of the Metropolitan-Vickers Electrical Co. in the early part of 1925. The author rightly points out that the variation of the hysteresis "exponent" with induction is far greater than is commonly supposed. With 4 per cent silicon steel and using ring specimens we have found that in general the exponent increases from about 1·7 at $B = 10\,000$ to nearly 3 at $B = 15\,000$, rapidly decreasing values being obtained above $B = 16\,000$. Occasionally values as high as 4 are met with, but these are almost certainly abnormal. T. Spooner * shows that such high exponents are due to the scale which is often found on the surface of high-silicon steel. The scale has a low permeability and a high hysteresis coefficient. At low inductions the permeability of the steel is very high compared with that of the scale, so that the flux and hence the hysteresis loss in the scale is very small. As the induction is increased, the steel becomes saturated, causing the scale to carry an appreciable part of the total flux; hence the total hysteresis loss increases very rapidly. Spooner gives an example in which the exponent at $B = 15\,000$ was found to be 3·04. After the scale had been removed from the specimen by pickling, the exponent fell to 2·36. Further work on this matter is very desirable, using carefully pickled specimens and taking the induction up to $B = 18\,000$. A matter of great importance in the investigation of exponents at high inductions with ring specimens is that the ratio of outside to inside diameter should approach unity as nearly as is practicable. If this precaution is not taken, the values obtained for the exponents will be considerably in error owing to changing distribution of induction over the cross-section of the specimen, which takes place as the degree of saturation is increased. Also, the exponent of the hardened material at the edges of a narrow ring may be different from that of the rest of the material. To obtain accurate results on unannealed ring specimens rather large diameters are necessary and for this purpose we have used rings 73·5 cm outside and 63·5 cm inside diameter, giving a ratio of outside to inside diameter of 1·16 and a width of magnetic path of 5 cm. In my opinion far too much importance has been attached in the past by various workers on this subject to Steinmetz's value of 1·6 for the exponent. They seem to have assumed, without giving any reasons, that there is something fundamental about the value 1·6 and that any other value obtained is to be considered abnormal. The author draws attention to the large errors that can be obtained in using narrow rings or strips (such as those used in the Epstein apparatus) owing to the hardening effect of punching or shearing at the edges of the rings or strips. This is illustrated in Table 15. The effects of punching or shearing can, of course, be removed by annealing but not without altering the general quality of the material as well. For much experimental work and for all acceptance tests in connection with the purchase of sheet steel, the condition of having to anneal specimens before testing them is obviously one that cannot be accepted. For this reason I devised in 1918 an apparatus taking strips 10 cm wide, and the apparatus has been used by the Metropolitan-Vickers Co. for acceptance tests since that time. Besides possessing the required accuracy the apparatus has certain other advantages for routine testing, but these matters cannot be gone into here. With regard to the agreement between the values of hysteresis loss determined ballistically and with alternating current at 50 cycles, the author's observations (Table 15) show differences up to 7·9 per cent, the average difference being about 4 per cent. The a.c. results are consistently higher than the ballistic results. It seems very important that the identity or otherwise of the hysteresis loss at 50 cycles and that determined ballistically should be established, as further work on this subject would be much facilitated thereby. As the author remarks, it is very difficult to obtain a good accuracy in ballistic tests at high inductions owing to the compression of the extremities of the loop, apart from any question of the absolute accuracy in the measurement of B. However, we have found that by adopting a suitable procedure in making the observations and by attending to all possible sources of error, especially those arising in drawing and determining the areas of the loops, we have been able to obtain very consistent results and also good agreement between ballistic and 50-cycle values. The values obtained on a ring specimen of 4 per cent silicon steel are given in Table A.

* *Electric Journal*, 1925, vol. 22, p. 132.

TABLE A.

Hysteresis Loss in watts per kg.

$B_{max.}$	A.C. (50 cycles)	Ballistic	Percentage difference; (A.C. − D.C.)
10 000	1·25	1·24	+ 0·8
13 000	2·12	2·07	+ 2·4
16 000	4·70	4·72	− 0·4
18 000	5·90	5·96	− 1·0

Similar results have been obtained on other materials. Our experience leads us to believe that on materials not exceeding 0·4 mm in thickness (where it is known that the skin effect is small) the a.c. and ballistic tests should give similar results, such differences as are observed being due to experimental errors. The author's method of measuring $H_{max.}$ by means of a mutual inductance and the mean voltmeter is ingenious. If the total current traversing the magnetizing winding of the square be called the "magnetizing current," the R.M.S. value of this current will increase by a small amount for a given induction as the frequency is increased from zero to 50 cycles. This is due to the increase in the current component in phase with the applied E.M.F. and corresponding to the eddy-current loss. For "power" frequencies, and especially at high inductions, the eddy-current component is small and approximately in quadrature with the total current. Its effect on the maximum value of the "magnetizing current" will therefore be small, but, strictly speaking,

one would only expect $H_{max.}$ and H from ballistic tests to be identical for very low frequencies. The figures in Table 14 show that $H_{max.}$ measured by the author's method at 50 cycles is 3·8 per cent greater than H at $B = 10\,000$, but the difference steadily falls to 0·4 per cent at $B = 17\,000$. This is due to the eddy-current component becoming of smaller importance owing to the saturation of the steel. Thus, whilst the author's method is very convenient, it is well to bear in mind the distinction between $H_{max.}$ and the maximum value of what is usually regarded as the true magnetizing field, a quantity which is independent of frequency if skin effect is negligible.

[The author's reply to this discussion will be found on on page 432.]

South Midland Centre, at Birmingham, 27 January, 1926.

Dr. M. L. Kahn: The author's investigation proves that there is no definite relation between power loss in magnetic sheet material and flux densities which can be expressed in a mathematical equation with definite constants. The equation proposed by Steinmetz, on which the author has based his experiments, can only be used if the exponent is varied through the range of densities actually used in practice. Obviously, an equation with a varying exponent cannot be used for determining dimensions of machinery, or solving problems arising in connection with the calculation of electric machines or apparatus. Generally speaking, such a formula is not required, and it is quite sufficient to use curves for the relation of loss to the flux density in magnetic sheet material. Such curves have to be used in any case by the designer of electric machines, as the actual magnetic losses in finished machines or transformers are very much higher than the losses determined on specimens in the laboratory. Losses on specimens are merely of interest as they form a general criterion for determining the quality of the sheet material produced by the rolling mills. For this purpose, usually only the loss at a flux density equal to 10 000 and at 50 periods is taken into consideration, so that the shape of the loss curve is not considered. This actually implies that the losses at other densities are in a definite relation to the losses at a density of 10 000. As the paper clearly proves that this is not the case, it might well be considered whether it is not desirable to modify the present arrangement and to take losses at higher densities into consideration, all the more as the material is usually used more at densities above 10 000 than at densities below 10 000. In this connection I wish particularly to point out that the " marked tendency amongst designers of electrical machinery to employ higher flux densities in electrical sheet steel than have been customary in the past," which the author mentions in the introduction of his paper, is due not so much to the fact that machines are rated higher, as to the great improvements which have been made in the production of low-loss magnetic sheet materials. A further point must not be lost sight of in appraising the value of investigations concerning the relation of hysteresis loss and flux density. In practice the bulk of the iron losses is due to eddy currents and surface stray currents, whilst the hysteresis losses in the iron only contribute a comparatively low percentage of the total loss. On the other hand the general subject of power losses in magnetic sheet steel is of such great importance to the electrical industry that further investigations by the National Physical Laboratory would certainly be of great value. I should like to suggest that an investigation of the effect of annealing punchings after the stamping process would be of considerable interest. Although the laboratories of individual firms have carried out experiments on this matter, so far as I am aware no results have been published up to the present. Apart from this, it might be worth while to see whether it would be possible to develop a testing apparatus for iron losses, on which smaller specimens can be used and a sample of less weight can be tested than with the present standard testing apparatus. This would involve the investigation of the discrepancies introduced by the use of smaller samples. A thorough investigation of the subject may conceivably give definite results of allowance which can be made to account for these discrepancies, and a standard apparatus for smaller weights of material might be developed by the laboratories. With the apparatus at present usually employed, it is only possible to test samples of comparatively large area, so that this can only be used by manufacturers who buy their material in bulk and not for specimens cut out of material which is already punched. There is no doubt that the more investigations made on this important subject, and the more we get to know about it, the better it will be for all concerned, and it is to be hoped that investigations may lead to further improvements in the material available for manufacturers of electric machines and apparatus.

Prof. W. Cramp: The author has placed at our disposal the results of some careful work, but many of us who are designers will look at his results from a severely practical point of view. In this connection it should be remarked that the paper is intended to deal with losses at high flux densities, by which the author apparently means densities exceeding 10 000 maxwells per cm^2. His upper limit appears to be only about 18 000. Now in a.c. design it is seldom that the maximum density exceeds about 14 000, whilst in d.c. work 25 000 is reached in the teeth of traction motors. It follows that the losses discussed in the paper do not much concern the design of a.c. machinery, and on the other hand, for d.c. machines, the density has not been carried nearly far enough to be of practical service. It is well known, for instance, that in traction motors the chief part of the iron loss arises from the teeth, but apart from indicating the probability of a much larger hysteresis loss in this region than would follow from the Steinmetz law, the paper gives no definite help. We must hope that the author

will continue his researches up to a density of, say, 26 000. The fact that these densities occur in d.c. apparatus only, introduces another question, with which the author has not dealt. I refer to the difference between the loss when rotating a mass of iron in a magnetic field and the loss when the iron is stationary and the field has a harmonic variation. The difference between the two cases is generally assumed to be very large. With regard to the general form of the Steinmetz equation, the author's results seem to question the existence of any such law. It is not in accordance with any physical conception of the cause of hysteresis that the loss should be proportional to a fixed power of the density, and it seems to me that the adoption of the Steinmetz expression has, on the whole, held back any real knowledge of the phenomena. All the results given in the paper indicate that the index of B is no more constant at low densities than at high values, and consequently it seems to be time that some new expression, based upon a physical picture of the conditions in the iron, should be developed. Such an expression must lead rather to the loss being dependent upon the intensity of magnetization than upon the density; and it is interesting to note that the author has considered this point, which will become of more and more importance as he deals with higher densities. With regard to the methods of measurement, it is disappointing to find that the wattmeter was only calibrated on one value of direct current. The difficulty of getting accurate readings with a wattmeter on low power factors is well known, and it would have contributed to reliance upon the results if this instrument had been calibrated throughout its range on a Drysdale potentiometer. The resistance marked R_4 in Fig. 1 is also very important, and it would be interesting to know what steps were taken to make sure that the wattmeter calibration did not change on alternating current, as this resistance was increased or decreased. With respect to the use of an electrostatic voltmeter supplied through a transformer, I have found on similar tests that such an instrument is liable to considerable errors. Its capacity, slight though it may be, appears to influence the secondary of the transformer to which it is connected, and it is difficult, unless the wave is of a pure sine form, to get two electrostatic voltmeters on the secondary of the same transformer to read precisely the same value. Again, in connection with the areas of the hysteresis loops, the use of the planimeter gives scope for considerable errors, which can often be eliminated by the use of Newton's rule or other graphical means for determining areas. In stating on page 417 that his results are liable to "considerably increased errors," the author shakes our faith in his figures to an extent which I should think is not justified in view of the care taken. He does not justify his treatment of the Lloyd square as a ring, but possibly he can tell us the magnitude of the errors involved in this assumption. Since so great a difference was observed between the results with the wide as compared with those on the narrow strips, it seems hardly reasonable to regard the effect of cutting as negligible; but in any case this effect would be much reduced as compared with that which exists under normal conditions, since the insulation between the stampings in the tests was so thick. On the whole the paper marks a real advance in our knowledge of the hysteresis loss, but I do not think that any more accurate prediction of this important quantity at varying densities is likely to be reached so long as there is a persistent attempt to put the results in the form given by Steinmetz.

Mr. C. E. Webb (*in reply*): The points raised in the discussion may, I think, be conveniently grouped under five or six heads and I shall, therefore, deal with them in this way rather than by replying to individual speakers.

Accuracy of methods.—Several speakers have suggested possible sources of error arising from the methods employed. Most of these had received consideration and been found to be negligible, whilst in one or two cases the speakers appear to be under some misapprehension as to the operation of the test-set.

Mr. Sims criticized the arithmetical subtraction of the air-flux correction from the apparent flux density in the iron. This is, however, correct to a very high degree of accuracy, for the measurement is based on the reading of V_{mean} obtained by rectifying the secondary voltage. This voltage is made up of two parts, one dependent on $B_{max.}$ and the other on $H_{max.}$, and provided the rectification of each component is complete an arithmetical subtraction is justified. This requires that the two component E.M.F. waves pass through zero simultaneously, i.e. that H and B reach their maxima simultaneously. This condition was assumed to be very nearly fulfilled at ordinary power frequencies, an assumption which was experimentally confirmed in the measurements of a.c. permeability described in Appendix 1, when it was found that the commutator brushes required only a very slight angular displacement between the settings for reading $B_{max.}$ and $H_{max.}$.

The errors suspected by Mr. Sims, due to the effect on the reading of one instrument of the load applied by connecting another on a different winding, were tested for by disconnecting all instruments except one in turn and noting whether the reading of the remaining instrument was affected. No observable effects were detected except when the high-ratio transformer T (Fig. 1) was used, and then a very small effect was noticed. When the transformer was used, therefore, the remaining readings were taken with the transformer disconnected, and it was then switched on for the form-factor measurement only. Prof. Cramp also suggested a possible error due to the influence of the electrostatic voltmeter on the high-ratio transformer. No such effect was noticed, although checks were made using two voltmeters of different patterns and of widely different ranges with various ratios on the transformer. As a matter of fact, however, most of the measurements and all those above $B = 14\ 000$, in which the most distorted waves were likely to occur, were made without the transformer and with the voltmeter connected directly to a secondary winding of the square. Checks between these results and those obtained using the transformer also showed no appreciable discrepancy attributable to the influence of the voltmeter on the transformer.

Mr. Sims and Prof. Cramp have both criticized the

use of the planimeter and the use of a d.c. method for calibrating the wattmeter. On the first point it should be mentioned that the loops at high values of B, which are the most irregular in shape, were all plotted in two, three or even four sections, suitable scales for H and B being chosen for each section. Further, the possibility of variable human error was practically eliminated by running round each loop at least three times, rejecting any markedly discrepant result and averaging the remainder. The variation between successive readings was normally considerably less than 1 per cent. The planimeter method was also checked in several cases by the laborious but unassailably reliable method of counting squares, and again agreement was obtained to about ½ per cent, which is definitely within the limits of accuracy of the measurements. With reference to the calibration of the wattmeter, it should be pointed out that the method employed allows of greater accuracy being obtained than an a.c. potentiometer, since the calibration of the latter depends in the last resort upon exactly those standards which were used directly in the method of wattmeter calibration described. It is true, however, that the wattmeter calibration might be different on alternating current from the d.c. value, and it should have been made clear that this had been investigated previously and the instrument found to give concordant results by direct current and alternating current within a fraction of 1 per cent, and that the calibration referred to was only intended to allow for the day-to-day variations in the sensitiveness of the instrument due to temperature and other variable conditions. A closely related point mentioned by Prof. Cramp is the purity of the wattmeter pressure-coil resistance R_4. This was a specially prepared resistance, and it was checked first by replacing it by other resistances known to be of high purity, including a Duddell-Mather anti-capacity resistance, and secondly by taking the same reading under actual working conditions using different wattmeter multipliers (i.e. various values of R_4) and simultaneously altering the number of turns in the secondary winding, N_2, to give the same wattmeter deflection. No perceptible error due to R_4 could be detected by either of these tests.

Mr. Ockenden has questioned the use of a series resistance R_3 in the magnetizing circuit. It is, however, pointed out in the paper on page 414 that the adjustment to the correct magnetizing current was made, as he suggests, by varying the alternator field, and that the resistance R_3 was introduced deliberately to distort the E.M.F. wave. In fact, at each value of frequency and B a reading was first taken with R_3 cut out to give as close an approximation to a sine wave of induced E.M.F. as was obtainable, and then a series of further readings was obtained with increasing values of R_3, and consequently increasing form-factors, to enable a curve connecting watts per kg and (form-factor)^2 to be drawn and an extrapolation made to give the loss for an exact sine wave of E.M.F. Mr. Ockenden also referred to the effect of third and fifth harmonic components of the magnetizing current. The wattmeter takes proper account of these components and measures the losses due to them on the sole condition that the wave-shape of B is not re-entrant, i.e. that there is no subsidiary loop on the main loop. Error might, of course, be caused, as Mr. Ockenden suggests, by the presence of eddy currents or mutual induction between the wattmeter coils, but the former were avoided by the absence of metal from the case of the instrument and the latter by suitable adjustment. Tests made at much higher frequency showed that any effect from these causes with a fundamental of 50 periods per sec. must be very small. The potentiometer method of measuring iron losses is, I believe, really due to Mr. Campbell, and makes use of a mutual-inductance bridge; but this method suffers from the very defects which Mr. Ockenden suspects in the wattmeter method, since the losses are referred to the fundamental component of the flux wave whilst the true $B_{max.}$ cannot be determined, since the wave cannot be definitely adjusted to be a sine wave. The wattmeter method and the a.c. potentiometer method really have different spheres of usefulness. The latter method commences where the former method becomes inaccurate on account of lack of sensitivity. The border line occurs in the region where $B = 200$. At lower values of B than this amount, the changes of permeability are not very great, so that B does not differ much from a sine wave with a sine wave of H. It is in this region of low values of B that the a.c. potentiometer methods are specially useful.

With reference to Mr. Ockenden's remarks on the use of the commutator, he is correct in assuming that very great care is needed to secure satisfactory behaviour, but with constant attention to the brushes and continuous lubrication during operation it is believed, from the results of tests carried out, that the error on the determination of $B_{max.}$ does not exceed 2 parts in 1 000. The correction of 20 with $B = 5\,000$ is therefore justifiable as being definitely greater than the probable error of measurement, but the further correction of 10 on 10 000 given in Table 5A is within the limits of experimental error and is only stated to show the magnitude of correction involved at this value of B.

Prof. Cramp's query as to the justification for treating the Lloyd square as a ring is dealt with in Appendix 3, and, as pointed out there, the very close agreement between the ballistic results on strips (in the Lloyd square) and rings, after annealing together, indicates that the error involved in such treatment is not greater than the errors of measurement—about 1 per cent.

Both Prof. Cramp and Mr. Sims referred to the disquieting effect of the suggestion that "at high flux densities the results are liable to considerably increased errors." Possibly the expression was an unfortunate one to use, but it should be noted that it had reference to the tests on the preliminary investigation carried out on the original Lloyd square—in the new square alterations in design were made to reduce to a minimum this tendency to increased errors at high flux densities. Actually a comparison between the results given in Table 4 using the old square and those in Tables 7, 9, 11 and 13 for the same specimens using the new square shows that the former were not very seriously in error due to these causes. The statement was introduced, however, because it was particularly desired to emphasize the fact that a test-set giving thoroughly reliable results at low flux densities may be subject to quite

serious errors at higher flux densities unless certain corrections, which are negligible in the first case, are carefully made.

Whilst, therefore, the methods employed are believed to be not open to serious criticism on *a priori* grounds, a conclusive justification of their accuracy is provided, as pointed out by Mr. Campbell, by the very close agreement between the results obtained by two such entirely distinct methods. I was also very much interested to learn that Mr. Churcher had obtained results so closely agreeing with those given in the paper.

Influence of scale.—Mr. Holbrook and Mr. Churcher both referred to the influence of the presence of scale on the variation of the exponent of B for the hysteresis loss. I was aware of Mr. J. D. Ball's suggestion, but did not mention it as the reference to the subject in his paper was very brief and not supported by full data. Mr. Spooner's work, which is given in greater detail, had escaped my notice. Moreover, my own tests on this point, though unfortunately very limited in range, did not confirm their conclusions. To investigate the effect of scale, specimen No. 3A was very carefully pickled and the complete tests on it were repeated. The final results are given in Table B, which is directly comparable with Table 9.

It will be seen from this comparison that the effects of removing the scale are :—

(*a*) To reduce the apparent loss—due of course to the removal of the low-permeability scale, the more uniform distribution of the flux across the section of the remaining plate, and the consequent lower flux density in the high-permeability steel.

(*b*) To reduce to a negligible amount the discrepancies between the ballistic, 25-period and 50-period results. This suggests that the rather large discrepancies (up to 7·9 per cent) between ballistic and a.c. values of hysteresis loss, also pointed out by Mr. Churcher, are due to the presence of scale and are not inherent in the method of testing. Presumably the flux distribution is different in the ballistic and a.c. tests when scale is present.

(*c*) The maximum values of the exponent of B for hysteresis loss are not appreciably less than before, but the increase in the exponent takes place at rather higher values of B. This is accounted for, as in (*a*), by the actual flux density being somewhat higher than the apparent value when scale is present.

TABLE B.

Comparison of Results on Specimen No. 3A after pickling.

B	Total loss in $\frac{\text{watts}}{\text{kg}}$		Hysteresis loss in $\frac{\text{watts}}{\text{kg}}$			Exponent of B for hysteresis loss		
			At 50 ~ per second					
	At 25 ~	At 50 ~	From 25 ~ results	From 50 ~ results	From static loops	25 ~	50 ~	Static
10 000	1·11	2·67	1·68	1·69	1·70			
						1·82	1·74	1·78
12 000	1·52	3·69	2·34	2·32	2·35			
						2·19	2·18	2·06
14 000	2·10	5·09	3·28	3·25	3·23			
						2·58	2·60	
15 000	2·50	5·97	3·92	3·89	—			2·76
						2·81	2·72	
16 000	2·94	6·99	4·70	4·64	4·67			
						1·74	1·77	1·69
17 000	3·30	7·78	5·22	5·16	5·17			
						1·17	1·30	—
18 000	3·58	8·45	5·58	5·56	—			

It therefore appears from these tests that the increase in the exponent is not a spurious effect due to the presence of scale but a genuine property of the material, although a larger number of tests on this point would be desirable to confirm the results obtained on specimen 3A.

Effects of cutting and annealing.—I should like to endorse very strongly Mr. Churcher's remarks on the importance of using wide specimens to minimize the effect of cutting on the magnetic properties of the material. It is believed that the width of 7 cm used at the National Physical Laboratory is sufficient to reduce such effects to a very small percentage, but any departure from this width should certainly be in the direction of increasing rather than decreasing it.

Mr. Holbrook asked whether similar information to that given in Table 15 for the effect of annealing medium-resistance material after cutting was available for other material. No such complete data have been obtained on high-resistance material, but a few isolated tests that have been made indicate results of a very similar nature.

Conditions of testing material.—Dr. Kahn and Prof. Cramp have both pointed out that the losses in machines are much greater than and, to a considerable extent, of a different nature from those resulting from the alternating magnetization applied in the test-set. This was, of course, fully realized, and also the fact that an extension to flux densities above 18 000 was very desirable. At the same time, the methods used in the investigation are those by which the suitability of material is gauged in practice, whilst it seems reasonable that results up to 18 000 should give a better indication of the behaviour of the material under densities of 20 000–25 000 than values at 10 000 only. It is hoped later to carry the tests up to still higher values of B, but the experimental difficulties of making these measurements under standard conditions become very great above about $B = 18\,000$.

It seems doubtful whether any change in the general method of testing sheet material for losses can be satisfactorily made, but I agree with Mr. Holbrook and Dr. Kahn that the results in the paper point to the desirability of testing material to be used at high flux densities at, say, $B = 15\,000$ in addition to $B = 10\,000$. Dr. Kahn's further proposal of tests on smaller samples deserves careful consideration, although such methods would probably only be suitable for rough workshop tests and not for high-accuracy standard tests.

The further work suggested by Mr. Sims on unsymmetrical cycles, rotating hysteresis and losses at telephonic frequencies, would be of great value but lies outside the scope of the present paper. Mr. Campbell's results relating to "ageing" are of great interest, but I have had no experience on this point and cannot therefore offer any confirmation of them.

With reference to the method of measuring a.c. permeability described in Appendix 1 to which Mr. Churcher draws special attention, I should like to mention that the idea of this was suggested to me by Mr. D. W. Dye. It is, of course, theoretically open to the objection pointed out by Mr. Churcher, but normally the alteration produced by the eddy-current component is exceedingly small. The figures given in Table 14 were obtained when very little experience had been gained with the method, and it is believed that the discrepancies in the ballistic values were largely due to one or two small errors not inherent in the method which have since been eliminated. Later results show an agreement to within 1 per cent between the a.c. and ballistic permeabilities.

Law of variation of hysteresis loss with B.—Several speakers have drawn attention to the fact that Steinmetz's law is admittedly an empirical one only applicable between fairly narrow limits of B and not to be expected to hold true outside those limits, and that, in practical designing, reliance must be placed on curves of loss. This was, of course, fully appreciated, but I felt that it was desirable to emphasize the departure of the law of variation of hysteresis loss with B from Steinmetz's law at high values of B, because I am strongly of the opinion expressed by Mr. Churcher and Prof. Cramp that the 1·6-power law has been given altogether undue importance and that this has probably done a great deal to retard progress in our knowledge of the subject.

I hope and believe that I have not been guilty of the mathematical solecisms suggested by Mr. Atkinson. The exponential form of stating the results was employed for the purpose just mentioned of emphasizing the magnitude of the deviation from the Steinmetz law, and I do not think any unjustifiable deductions have been drawn from this form of statement. The ratio of variation, or exponent as I have called it, may be used quite legitimately to show the way in which loss varies with B over any definite range of B.

I fully agree that a law of a different type which will fit the curves obtained is urgently needed to enable prediction of losses at higher values of B to be made, but although I have attempted to discover such a formula I have not succeeded in evolving any reasonably simple expression which will accord with the experimental results and I have, therefore, thought it better not to introduce any tentative formula which might only be misleading. Jordan's work at low flux densities, referred to by Mr. Marris, is of interest in this connection, but I agree with him that it is unlikely that the same principles could be applied satisfactorily at high values of B.

Results which I have obtained also indicate that for other magnetic materials the exponent is much more constant, as suggested by Mr. Campbell. For such materials, therefore, Steinmetz's law may be safely used, but it is probable that if a new form of law based on the physical actions taking place can be discovered, it will be applicable by a suitable choice of constants both to such materials as those tested in this investigation and to those having a much more constant exponent of B.

ANNUAL DINNER, 1926.

The Annual Dinner of the Institution was held at the Hotel Cecil on Thursday, the 11th February, 1926, when the President, Mr. R. A. Chattock, presided over a gathering numbering about 580 persons.

Among those present were: The Rt. Hon. Neville Chamberlain, M.P. (*Minister of Health*), The Rt. Hon. Sir A. Steel-Maitland, Bart., M.P. (*Minister of Labour*), The Rt. Hon. Lord Hewart (*Lord Chief Justice*), The Rt. Hon. The Viscount Falmouth (*Member of Council*), Air Chief Marshal Sir H. M. Trenchard, Bart., G.C.B., D.S.O. (*Chief of Air Staff, Air Ministry*), Sir H. Hirst, Bart., Sir F. Mills, Bart., D.L. (*President, Iron and Steel Institute*), Sir John Snell, G.B.E. (*Past-President, I.E.E., and Chairman, Electricity Commission*), Rear-Admiral Sir A. E. M. Chatfield, K.C.B., K.C.M.G., C.V.O. (*Third Sea Lord and Controller of the Admiralty*), Sir S. Chapman, K.C.B., C.B.E. (*Permanent Secretary, Board of Trade*), Brig.-Gen. Sir W. T. F. Horwood, K.C.B., D.S.O. (*Chief Commissioner, Metropolitan Police*), Maj.-Gen. Sir W. Childs, K.C.M.G., K.B.E., C.B., Sir P. Nash, K.C.M.G., C.B., Sir W. S. Abell, K.B.E. (*Chief Ship Surveyor, Lloyd's Register of Shipping*), Sir J. Devonshire, K.B.E. (*Vice-President*), Sir H. Fowler, K.B.E. (*Vice-President, Institution of Mechanical Engineers*), Sir L. Macassey, K.B.E., K.C., M.A., LL.D., Sir A. B. Gridley, K.B.E., Sir J. E. Petavel, K.B.E., D.Sc., F.R.S. (*Director, National Physical Laboratory*), Sir H. Gibson, Bart. (*President, Incorporated Law Society*), Sir H. Haward (*Vice-Chairman, Electricity Commission*), Sir M. Hughman, Colonel Sir J. Nall, D.S.O., T.D., M.P. (*President, Institute of Transport*), Sir W. Noble, Sir E. Rutherford, O.M., F.R.S. (*President, Royal Society*), Sir St. Clair Thomson, M.D., F.R.C.S. (*President, Royal Society of Medicine*), Sir O. E. Warburg, O.B.E., M.A., J.P. (*Chairman, London County Council*), The Hon. H. P. Colebatch, C.M.G. (*Agent-General for Western Australia*), The Hon. John Huxham (*Agent-General for Queensland*), Col. E. Snowden (*Agent-General for Tasmania*), Mr. C. T. Allan (*Hon. Secretary, Western Centre*), Mr. P. F. Allan (*Hon Secretary, North-Eastern Centre*), Mr. Ll. B. Atkinson (*Past-President*), Councillor H. K. Beale (*Chairman, Birmingham Electric Supply Committee*), Colonel R. E. B. Crompton, C.B. (*Past-President, Honorary Member and Faraday Medallist*), Mr. R. N. Eaton (*Hon. Secretary, Irish Centre*), Lieut.-Col. K. Edgcumbe, R.E. (T.A.) (*Vice-President*), Mr. A. R. Everest (*Chairman Designate, British Electrical and Allied Industries Research Association*), Dr. S. Z. de Ferranti (*Past-President, Honorary Member and Faraday Medallist*), Prof. C. L. Fortescue, O.B.E. (*Member of Council*), Mr. H. Cecil Fraser (*Hon. Secretary, North Midland Centre*), Mr. G. R. Freeman (*President, Institute of Chartered Accountants*), Mr. R. W. Gregory (*Chairman, North-Eastern Centre*) Mr.R.Grierson (*Member of Council*), Mr. H. H. Harrison [*Past Chairman, Mersey and North Wales* (*Liverpool*) *Centre*], Mr. H. Hastings (*I.E.E. Local Hon. Secretary for Spain*), Mr. J. S. Highfield (*Past-President*), Mr. W. E. Highfield (*Member of Council*), Mr. H. Hooper (*Hon. Secretary, South Midland Centre*), Mr. G. W. Humphreys, C.B.E. (*Chief Engineer, London County Council*), Mr. J. E. Kingsbury, Prof. H. Lamb, M.A., D.Sc., LL.D., F.R.S. (*President, British Association*), Mr. H. C. Lamb (*Past-Chairman, North-Western Centre*), Monsieur M. Leblanc (*Vice-President, Société Française des Electriciens*), Mr. E. Leete (*Member of Council*), Mr. G. C. Lloyd (*Secretary, Iron and Steel Institute*), Mr. A. L. Lunn (*Hon. Secretary, North-Western Centre*), Mr. A. MacGregor, M.D. (*President, Electro-therapeutic Section, Royal Society of Medicine*), Mr. S. Machin, J.P. (*President, Association of British Chambers of Commerce*), Mr. S. W. Melsom (*Member of Council*), Mr. L. W. Migotti (*Past-Chairman, Argentina Centre*), Mr. R. B. Mitchell (*Past-Chairman, Scottish Centre, and President, Incorporated Municipal Electrical Association*), Mr. E. W. Monkhouse (*Chairman, Association of Consulting Engineers*), Colonel R. K. Morcom, C.B.E. (*Chairman, British Electrical and Allied Manufacturers' Association*), Mr. W. M. Mordey (*Past-President*), Brig.-Gen. M. Mowat, C.B.E. (*Secretary, Institution of Mechanical Engineers*), Mr. A. Page (*Vice-President*), Mr. R. W. Paul (*Member of Council*), Mr. S. L. Pearce, C.B.E. (*Electricity Commissioner*), Col. T. F. Purves, O.B.E. (*Member of Council, I.E.E., and Engineer-in-Chief, G.P.O.*), Mr. W. R. Rawlings (*Vice-President, Illuminating Engineering Society*), Mr. C. Rodgers, O.B.E. (*Member of Council*), Mr. P. Rosling (*Member of Council*), Dr. A. Russell, M.A., D.Sc., LL.D., F.R.S. (*Past-President*), Mr. E. H. Shaughnessy, O.B.E. (*Member of Council*), Mr. F. E. Smith, C.B.E., F.R.S. (*President, Physical Society of London*), Mr. R. T. Smith (*Past-President*), Mr. E. F. C. Trench, C.B.E. (*Vice-President, Institution of Civil Engineers*), Mr. S. J. Watson (*Member of Council*), Mr. W. B. Woodhouse (*Past-President*), and Mr. P. F. Rowell (*Secretary*).

The President read the following message from Monsieur Legouez, President of the Société Française des Electriciens:

> "I thank the Institution very heartily for its very kind invitation to the Annual Dinner which, to my great regret, I am not able to attend. Our Vice-President, Maurice Leblanc, will represent the Société Française des Electriciens, and I join him in offering to you the fraternal greetings of the electrical engineers of France and in expressing their desire for an ever closer and still more cordial co-operation."

The Toasts of "His Majesty the King" and "Her Majesty the Queen, His Royal Highness the Prince of Wales, and the Other Members of the Royal Family" were proposed by the President and loyally received.

The Rt. Hon. Neville Chamberlain, M.P. (*Minister of Health*), in proposing the toast of "The Institution of Electrical Engineers," said: "I believe that it is

some 55 years since the foundation of the Society of Telegraph Engineers, which was, I am informed, the original title of this Institution. During that half-century the growth in its membership, in its usefulness and in its influence, has kept pace with the remarkable and manifold developments in the use of electricity itself. I am told that the membership now exceeds 12 000, and that you are actually the largest Institution in this country. I do not know whether there is any agent on behalf of which so many extravagant claims have been made as on behalf of electricity—not, I need hardly say, by the members of this Institution, but by a public whose enthusiasm is only equalled by its ignorance. All the same, however, if we look back I do not know but that the reality is pretty well equal even to the anticipation. In domestic lighting, electricity is now unrivalled; in transport, it is rapidly taking a leading place, and for the ease of its transmission and its freedom from smoke and noise, it is becoming the most popular form of power in almost every branch of manufacture; whilst the development of telephony and of broadcasting shows that electricity is entering into the lives of the whole community, and one is tempted to ask where it is going to stop. Will it leave us any privacy whatsoever? Apparatus has been produced which photographs our insides, and the other day I saw in an illustrated paper a picture of apparatus which, it was stated, would enable anyone to see what was going on in the next room through a lath and plaster partition. It only remains—and I fancy that electrical engineers are capable of it—to invent a new camera which will photograph our thoughts. If you do that, whilst we already know what you think of us, we politicians will have some satisfaction in realizing that you will know what we think of you. It has long been obvious to the Government, in view of these considerations, that it would be necessary in self-defence to find you something else to do, and accordingly we have announced that we are going to bring in an Electricity Bill. I do not know what you think of it, but the first sketch of the proposals has been welcomed by the public with a unanimity that has rather alarmed me. The only thing which consoles me is that the Bill is praised quite as much for what it does not do, as for what it does do. To begin with, there is no subsidy, and there is to be no nationalization; there is to be, in fact, as little State interference as is compatible with the purposes we have in view. I think I may, from the layman's point of view, express our purpose as being threefold: to provide for a concentration of production, for the pooling of power reserves, and for the standardization of equipment. I believe that if we can achieve these three things we may hope to see throughout the country a considerable cheapening of electricity, and certainly a very much more available supply. I hope it will be agreed that aims of that kind are worth a serious national effort. We cannot, of course, make such changes without interfering with local and personal interests. Certain stations will have to be closed; there will be a certain amount of dislocation and change, and possibly an abolition of existing offices. What we desire, however, are changes which we believe to be in the national interest and of benefit to the community as a whole, and what is of benefit to the community as a whole must sooner or later percolate right through to every individual part of it. In the carrying out of our proposals after they have been passed through Parliament we shall look to electrical engineers for assistance, and I feel confident that we shall receive it. I only want to say further that I have been especially looking forward to being here to-night, because I knew that Mr. Chattock would be in the Chair. He is an old friend and colleague of mine. During the early part of the war, he was in charge of the Electricity Supply Department of the City of Birmingham and I happened to be Lord Mayor. It was my duty to share in his responsibilities in what was a very difficult time. We had turned our city into a munition factory; the demands on us came every day with increased vehemence. Our difficulties in connection with staff and with fuel were overwhelming, and it was an enormous satisfaction to me to see the courage and the determination with which Mr. Chattock faced those difficulties and ultimately won through to success. He is in the seat of the mighty to-night, and I wanted to see him there and pay my tribute to his worthiness to occupy it. I ask you to drink the health of the Institution of Electrical Engineers, coupled with the name of its President, Mr. R. A. Chattock."

The President, in responding, said: "I want to thank you for the very hearty way in which you have received this Toast. We have been told for many years that we are still in our infancy, but I think we ought to grasp the fact that we are now considerably over 50 years of age. In spite of our age, however, we are still growing. The Institution has now in the scientific world a standing and importance which are second to none, and I am very glad indeed to know how its members are supporting it and what a great deal they think of it. It is only by devoting ourselves to the work of the Institution that we can further its interests, and that devotion is to me very apparent in all its members. I know that there are one or two grumblers; occasionally one hears the remark: 'What has the Institution done for me?' Well, we are the Institution, and when a question like that is asked we can only say: 'What are we doing for ourselves?' I have no patience with those who want others to do for them things which they should do for themselves. I want to thank the proposer of this Toast for the very kind and appreciative way in which he spoke of the Institution and also of myself. I can assure him that this Institution is willing and anxious to do everything it can to further the interests of the great industry which we represent, and if we can help the Government in any way I am sure that we shall do so to the best of our ability. Approximately one hundred years ago the steam age commenced, and that age revolutionized all the ideas and habits of those days. We are now inaugurating the electrical age, and it would be a bold seer who would prophesy what will be the ultimate changes which this age will bring to us. I feel that we are only on the fringe of enormous developments. Mr. Neville Chamberlain referred to the marvels of wireless telegraphy, and in that connection I should like to

mention that last month the Marconi Company sent by wireless my signature and greetings to the American Society of Engineers across the Atlantic. The resulting photograph was forwarded to me the other day, and I can testify that the signature has not been forged. I am particularly pleased that Mr. Neville Chamberlain was able to find time to come here to-night and I want to extend a very hearty welcome to him and to Sir Arthur Steel-Maitland, who is another Birmingham stalwart chosen by the Prime Minister to assist him. Mr. Chamberlain referred to his connection with me in the Birmingham Corporation. We had great difficulties in those days, and I should like to take this opportunity of thanking him again for brushing them away in a manner that only he could do. In doing that, he enabled us to construct and equip a 10 000-kW generating station in nine months, which I think was an excellent performance during that difficult time. Mr. Chamberlain is now in charge of the health of this country, and I am certain that he is fully cognisant of the extraordinary influence that electricity is having on the amelioration of the conditions under which we live and work. He has mentioned cheap and quick transport and the abolition of smoke, but I want to remind him that electric homes are bright and clean, and that electric cooking is wholesome and excellent; with electric cooking the nutritious part of the food is not dissipated up the chimney as in other methods. Workshops are made healthy by the abolition of fumes in their furnaces and processes. These are only some of the blessings which electricity brings. The direction of it is in our hands and we must follow it up and make the fullest possible use of it. I cannot let this occasion pass without referring to the youngest activity of the Institution—its Wireless Section. I have attended several of the meetings of that Section, and have been impressed by the very great enthusiasm and intelligence which are brought to bear on the conduct of its meetings and the reading of its papers. I wish it the greatest success in London and throughout the country."

Mr. W. B. Woodhouse (*Past-President*) then proposed the Toast of "Our Guests," to which the **Rt. Hon. Sir Arthur Steel-Maitland, Bart., M.P.** (*Minister of Labour*), and **Sir Lynden Macassey, K.B.E., K.C.,** responded.

A reunion was subsequently held in the Victoria Hall of the Hotel.

RECENT IMPROVEMENTS IN THE INSULATION OF ELECTRICAL MACHINERY.

By K. G. Maxwell and Allan Monkhouse, Members.

(*Paper first received 28th January, and in final form 30th March,* 1925; *read before* The Institution 23*rd April and before the* North-Eastern Centre 14*th December,* 1925.)

Summary.

The paper constitutes a review indicating the more recent developments in the manufacture and use of insulating materials. A survey of the prominent characteristics of such materials is followed by a summary of process improvements. In handling this subject the authors put forward a strong plea for standardization of nomenclature and of test methods for determining essential properties of insulating materials. The paper is accompanied by eight appendixes, which include examples of standardizing of material terminology and a considerable amount of data obtained by test methods as adopted by the E.R.A.*

During the past 20 years singularly little change has been observable in the general nature of the insulating materials available for the insulation engineer's requirements. Perhaps the only really outstanding new materials are those which have resulted from the introduction to electrical work of synthetic resins of the phenolaldehyde type. As evidence of this statement—if any is required—we have here a book of samples drawn from standard insulating materials in use in 1903, beside which are mounted examples of the best corresponding products available at the present day.

It must not, however, be inferred that there has not been any improvement in the insulation of electrical machinery and apparatus during the same period. On the contrary, the past few years have been marked by:

(1) Clearer understanding of the theories of insulation, resulting in a more scientific use of the materials available.

(2) Closer knowledge of the properties of the various materials under extreme thermal, mechanical and electrical conditions.

(3) A definite movement to develop standardized methods of ascertaining and expressing values for the properties of the various insulating materials.

(4) Organized effort to produce refinements in the quality of insulating materials.

(5) Improvements in the method of applying insulating materials in the electrical manufacturers' works, involving close scientific control for insulating processes.

It is proposed to deal with each of the above phases of development under the following headings:—

1. Theories bearing on insulating problems.
2. Data in regard to properties of insulating materials.
3. Standardization of methods of testing insulation.
4. Progress towards improvement of insulating materials.
5. Improvements in processes of application of insulating materials.

* British Electrical and Allied Industries Research Association.

1. Theories Bearing on Insulating Problems.

The literature bearing on the behaviour of dielectrics when under electrical stresses has been appreciably enriched during the past few years by valuable contributions by investigators in almost all countries where electrical development is in progress. Appendix 8 is a bibliography of the more important treatments of this subject. In addition to the work done by the investigators, whose writings are referred to in the bibliography, much organized research is being undertaken by various national research institutions. The Committee on Electrical Insulation of the Division of Engineering of the National Research Council (of America) has issued a report outlining its extensive programme of systematic research, noting the problems connected with electrical insulation. According to the annual report of the British Electrical and Allied Industries Research Association, a similar investigation on less extensive lines is already under development in this country.

Much that has been published is more of academic interest at the moment than of actual practical value to the industry, and it is therefore not proposed to deal further with this phase of the subject.

2. Data in Regard to Properties of Insulating Materials.

The temperatures and general conditions under which insulating materials have to operate are very largely determined by the various national and international rating rules now in force. Appendix 2 sets forth a scheduled comparison of the better-known rating rules. These rules, so far as Great Britain is concerned, are only now emerging from the melting-pot. B.E.S.A. Specification No. 168 has recently superseded the old Specification (No. 72) and has helped partly to fill a badly felt need for standard information on insulating materials. A specification is now in preparation which will further supplement the information available. In the meantime, however, it is clear that the electrical industry as a whole is awaiting reliable information with regard to the behaviour of insulating materials offered as insulators under the extreme electrical, thermal and mechanical conditions permissible in electrical machinery and apparatus. It is

perhaps reasonable to anticipate that one of the results of the valuable work now being done by the E.R.A. will be to provide the industry with this information.

In the preparation of such data the question of ageing and life tests should be considered as being of prime importance. The effects of continued exposure to conditions representing operating conditions in machines has only been superficially dealt with in the past. It is here suggested that tests of this nature should include a study of the effects of vibration, moisture and sustained electrical and mechanical stresses, all at the extreme temperatures likely to occur in practice. In Appendix 1 an endeavour has been made to set forth in tabular form some of the properties of the insulating materials in general use.

3. Standardization of Methods of Testing Insulation.

While discussing the provision of standard data on insulating materials, the necessity of standardized methods of test cannot be too highly emphasized. Such methods are now being published by the E.R.A., and it is to be hoped that the methods recommended will rapidly be adopted by all who test insulating materials. So far, however, these test methods are only applicable to raw materials and not as a general rule to finished apparatus. Some definite policy in regard to the latter is very necessary, particularly in respect to the so-called high-pressure or flash tests. The generally accepted practice at the present day is to apply to insulation a flash test of 2 to $2\frac{1}{2}$ times nominal full voltage for a period of several minutes while the machine or apparatus is still hot after its initial trial run. At no time in the life of a machine is its insulation so vulnerable as when it has just completed its first temperature run. The windings—particularly end windings—contain certain volatile matter which rapidly dries up in service, but which during an initial 6 hours' run has just had time to leave the hotter portions of the material and concentrate where the windings are coolest. A flash test then breaks down what is probably a perfectly sound machine, and thus necessitates a "re-wind" where a "drying out" is all that is necessary. The leakage-loss test described by Hartshorn * appears to afford an ideal way of avoiding many unnecessary failures in testing large plant and apparatus. The suggestion made by Mr. Hartshorn to use a bridge method of measuring leakage losses on such apparatus gives a practical solution of the problem which, in the authors' view, could never have been solved by using wattmeter methods. In a test of this kind, a disproportionate rise in a leakage current gives an indication of a failure commencing in time to check an actual breakdown, and thus gives the insulation a chance of another "drying out" before applying the full test.

Before passing from the subject of standardization as applied to insulating materials, the authors wish to draw attention to Appendix 3, which gives a classification of insulating materials with both trade and abbreviated standardized names. This table was developed by a British firm in 1922 to permit the employment of one set of material designations on drawings, specifications and in the shops. It is included as a sample of successful standardization although it is recognized that many of the terms then adopted do not agree with those more recently adopted by the E.R.A. The universal adoption of a complete list on this basis will go far towards eliminating the present confusion which exists between the producers of insulating materials, manufacturers and users of electrical plant. Up to date, there is no detailed classification of insulating materials under the E.R.A. class recognized by the B.E.S.A. The only guide is the general indication which has been given by the International Electrotechnical Commission rating rules. It is announced in the appendix to B.E.S.A. Specification No. 168 that the E.R.A. now have in hand a standard grouping (and nomenclature) which sooner or later will become available.

* *Beama*, 1923, vol. 13, p. 89.

4. Progress Towards Improvement of Insulating Materials.

(*a*) I.E.C. Class O and Class A Materials.

The development of oil-immersed transformers and switchgear has given a great impetus to the improvement of materials of this class.

(1) *Papers and Pressboards.*—Until the latter part of the war, comparatively little scientific study had been given in this country to the production of high-grade insulating papers and pressboards. The pressboard used in the manufacture of shell-type transformers was frequently the common board made for the wool-finishing industry and similar work. Recent research, however, has resulted in perfectly definite conclusions being reached as to the relative superiority of various commercial vegetable fibres for electrical work, and also as to the most suitable methods of converting the same into boards for the requirements of the industry. Table 1 shows the average results of a very large number of tests on the behaviour of special papers made from various fibres. The overwhelming superiority of cotton for high-temperature work is clearly demonstrated, and as cotton is the only fibre of those tested which is entirely free from lignin in its structure, this result might be expected. The highly lignified fibres, including jute, deteriorate seriously at temperatures over 80° C.

Another most interesting development is the manufacture of pressboards possessing widely differing properties, making them applicable to specific requirements. Table 2 shows some characteristic figures taken on various special pressboards which have already been produced on a commercial basis. The authors consider that finality in this direction has not by any means been reached and that insulators of the pressboard class may ultimately largely replace those belonging to the so-called laminated-paper class. Efforts to introduce leather cuttings, rubber latex and other similar materials into the manufacture of pressboard for electrical work has not so far been

attended with success, due to the inability of these materials to resist high temperatures without ageing.

(2) *Fabrics, tapes, etc.*—With the exception of one or two isolated cases, the electrical industry has been content to carry on with such fabrics, tapes, etc., as the dealers in this class of goods have been able to offer. Speaking generally, the materials in use are not of high quality, and improvement in this direction can hardly be expected until manufacturers in general are prepared to pay the additional price for a superior article. A recent innovation is the introduction of artificial silks, but the application of this material to the electrical industry is at the moment too much in its infancy to predict whether it will become general. One thing which is certainly in favour of this material is its low moisture-absorption figure.

(3) *Coverings for wires.*—Cotton, silk, paper, enamel and asbestos are all extensively utilized as coverings for wires in electrical work. Artificial silk and so-called "spun glass" (glass wool) are also being tried for this purpose.

Cotton, however, remains the most important wire-covering material, and it is regrettable that so little has apparently been done to attempt to improve the insulation value of the cotton yarns which are applied to wires. Possibly this is due to the fact that the majority of engineers regard the cotton covering on wires merely as a spacer, and calculate the electric strength of the covering as being that of an equivalent air film. Experiments have clearly shown that this is not the case, and that by paying strict attention to the selection and treatment of the yarns employed, appreciable improvement can be made in electric strength, which is also accompanied by an enormous improvement in insulation resistance. In telephone and similar work this latter improvement is of prime

TABLE 1.

Table Showing Superiority of Cotton Base Papers for High-Temperature Work.

Volts per mil in oil at various temperatures on papers made from various fibres.

Class of paper	Volts per mil at following temperatures:					
	20° C.	40° C.	60° C.	80° C.	100° C.	120° C.
Cotton	780	740	700	660	580	190
Sulphate wood pulp	680	640	590	410	340	—
Hydrated chemical wood	700	660	530	400	—	—
Manilla	700	520	230	180	—	—
Jutes	500	475	430	160	—	—

Note rapid deterioration of jute at 80° C.

TABLE 2.

Tests on Special Pressboards.

Special pressboard made from	Density	Moisture absorption, per cent	Electric strength in volts/mil at		Remarks
			20° C.	90° C.	
Cotton	1·15	95	245	240	Good ageing properties
Wood pulp	1·15	90	220	120	Ages rapidly
Jute and hemp	1·15	125	260	100	Ages rapidly and becomes very brittle

High-class boards, consisting mainly of cotton fibre, should have the following characteristics :—

Density	24 hours' oil absorption, per cent	24 hours' water absorption, per cent	Volts per mil. at 90° C. in air	Remarks
Approximately 0·9..	30	150	240	Soft board for oil immersion
Approximately 1·15	20	100	260	Suitable for slot liners
Approximately 1·3..	2	70–90	300	For h.t. oil-immersed work

importance. The authors have recently devoted considerable attention to this problem, and the following details of the work accomplished may be of interest.

The investigation commenced with a study of the botanical nature of the chemical composition of cotton fibres, bearing in mind the fact that the fibres as applied to insulated wires are, generally speaking, in exactly the same state as they left the cotton plant, since in the processes associated with the production of yarn they do not pass through any chemical or wet process which might remove their natural wax or other impurities. A preliminary survey brought to light the work of Lister,* who carefully analysed the wax and the soluble impurities in cotton, and pointed out that some of the latter are extremely hygroscopic, even up to 32 per cent of their own weight. Matthews, in his book on *Textile Fibres*, suggests that the hygroscopic nature of the untreated cotton fibre (approx. 7 to 8 per cent) is probably due to this constituent. As electrical characteristics usually largely depend on the amount of moisture present, it was decided to dissolve out the impurities present, using various solvents for the preparation, and then make electrical tests. The test-results shown on specimens of specially prepared unbleached cloth treated in various ways have clearly indicated the improvement procurable, although they are so far insufficiently conclusive to establish the exact nature of the process to be employed. It would appear, however, that a treatment of the cotton yarns and fabrics for a short period in a very weak solution (approximately 0·5 per cent) of caustic soda followed by washing is all that is required to render a very considerable improvement in the electrical properties of the cotton. Table 3 shows the results obtained in the tests made.

In addition to these results, experiments with specially prepared cotton yarns have been carried out, using a subsequent treatment of basic dye and further washing, the results of which are summarized in Table 4. These experiments are consequent upon collaboration upon this subject with the British Cotton Industry Research Association, who have also been engaged upon this development.

In view of the results contained in Tables 3 and 4, it is reasonable to hope that one of the lines along which further industrial research will be directed will be that leading to the commercial application of the improvements indicated above as possible in cotton coverings on wires.

Paper insulation on wires is another comparatively recent development. Paper-insulated wire has much in its favour, particularly for use on high-tension transformer work where immersed in insulating oil, since it can be built up to a considerable thickness very much more readily than the insulation applied in the form of yarn.

For cable work also, paper insulation has definitely established itself and development is now proceeding on the lines of improved treatment of the paper to produce dielectrics commercially for the high voltages now being employed.

Enamel-insulated wires are growing in favour on all classes of work. In the past, enamel insulation was largely confined to small wires, and the present B.E.S.A. Specification No. 156 only covers wires up to 0·048 in. diameter. Enamel insulation, when properly carried out, is exceedingly good, and the main difficulty at the moment is that the demand apparently exceeds the supply of good wire, with the result that some very inferior wire is being placed upon the British market.

Asbestos as a wire covering should properly be regarded as a class B material, but for the purpose of convenience will be dealt with here. Asbestos coverings present themselves in three distinct forms, of which the oldest is that in which the asbestos is applied as a paper tape lapped on to the wire and protected with a single cotton covering. This product has been in use for many years on traction work, but more recently the practice has been growing of using wire in which the asbestos is applied to the wire in a wet pulp form, "felted on" and afterwards smoothed over by specially constructed irons. This second class of asbestos-covered wire gives extremely satisfactory results, as it is much more readily bent to coil shapes, etc., without damaging the insulation. A third form of applying the asbestos is in the form of yarn, but this procedure is not common, except as an outside braiding on certain cables which have to pass a flame-proof test, on flexible heater cables and similar work. The serious disadvantages of asbestos are its capacity for taking up moisture and its liability to contain conducting fibres of magnetite. There is hope that both these shortcomings may be largely remedied in the future, in the first case by adopting a suitable water-resisting size, and in the second case by a treatment along the lines of the oxalic acid treatment, details of which were originally published in British Patent No. 24259/1911.

(4) *Varnished-paper products.*—Under the heading of varnished-paper products the various shellac-paper and bakelite-paper materials may be included, together with a limited number of materials in which bitumastic varnishes are employed as binders.

Boards and tubes of the bakelite-paper class are a development of the past 10 or 12 years as far as this country is concerned, and at the moment there is probably no insulating material which causes its producers so much anxiety in manufacture as this particular one. When carefully made by properly and scientifically controlled processes, bakelite-paper products constitute an extremely good Class A insulation and possess the advantage over shellac-paper products that they may be raised to temperatures over 100° C. without appreciable deterioration or softening. The popular idea that bakelite-paper products may be used at temperatures up to 160° C.–180° C. without deterioration is erroneous. The paper constituent loses its nature at temperatures of 100° C. to 120° C., depending on the raw fibre from which the paper is made. Bakelite asbestos, however, may safely be used up to 150° C. without its strength being impaired.

In many quarters bakelite products have earned for themselves severe criticism. In the authors' view this is, however, largely due to the number of pro-

Note.—The last column shows the improvement maintained under humid conditions after basic dye treatment.

prietary grades of bakelite paper on the market which fall far short of what is required in a first-class insulator. The only serious disadvantage possessed by the better grades of bakelite-paper products is the phenomenon known as "tracking." When a bakelite material has once been under the influence of any form of disruptive discharge, whether it be a power arc or only a flash over the surface during a pressure test, the path followed by the arc becomes a conducting path even at a comparatively low voltage. This is generally referred to as "tracking," and when once started on a bakelite product of any kind is extremely difficult to eradicate. All organic fibrous materials naturally char in the presence of an arc, but there is an enormous difference in the extent of the damage done. The figure shows specimens of (1) bakelite-paper board, (2) shellac-paper board, (3) hard pressboard, (4) linseed-oil-impregnated wood, (5) micanite, and (6) vulcanized fibre, all of which have been subjected to the E.R.A. standard fuse-wire test as described in their publication A/S9. The number of times the test was made before the photograph was taken is marked below each sample.

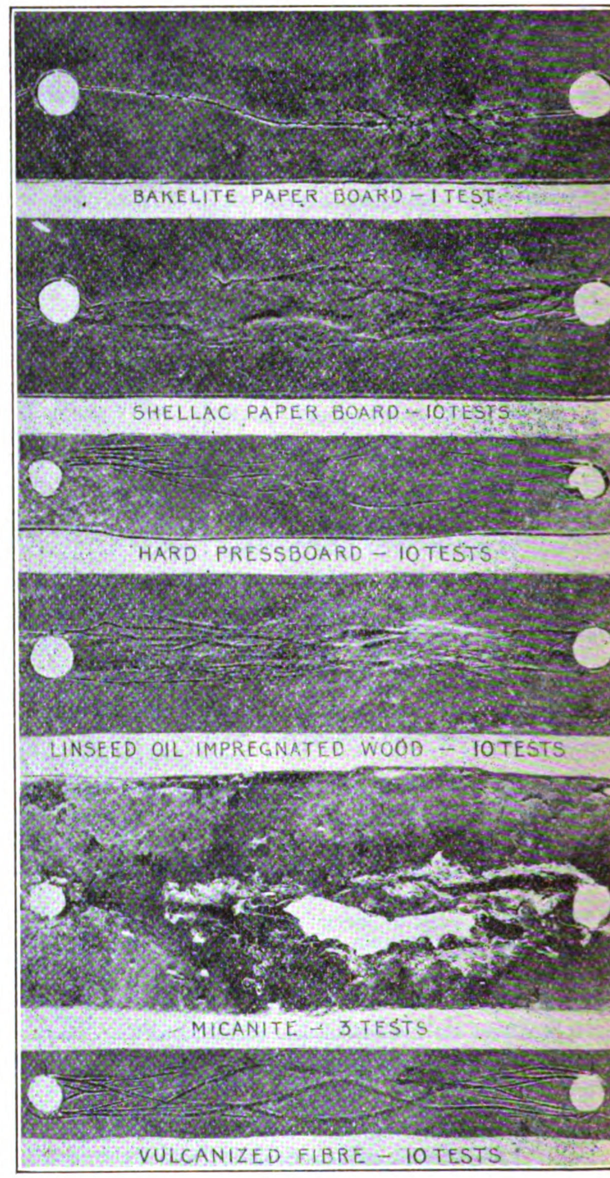
Under this test bakelite-paper materials, unless protected by special varnishes, almost all invariably failed on the first application of the test, whereas all other fibrous insulating boards withstood from 6 to 20 applications before failure. Vulcanized fibre shows up singularly well in this connection, proving its suitability for use as a fuse carrier. It has been pointed out by Moureu and Dufraisse * that the presence of small quantities of antioxygenes (as, for instance, hydroquinone) prevents auto-oxidation in substances of the phenol and aldehyde groups. Experiments made with bakelite resins which contain traces of hydroquinone have shown a marked improvement with regard to the tracking defect previously referred to.

Possibly the development and application of this discovery, or the adoption of special protective varnish films with which considerable improvement has been obtained, will remove one of the most serious shortcomings in an otherwise extremely useful material.

Shellac-paper products are limited in their use by their tendency to soften at temperatures above 80° C. unless subjected to an extended "curing" treatment. One development in electrical manufacture, however, has been the application of shellac-treated paper to the manufacture of condenser terminals. It is this development which has done much to render possible the manufacture of electrical plant for transmission line pressures up to 220 000 volts, and terminals have already been produced capable of dealing with one million volts. It may be interesting to note that the dimensions of such terminals are in the neighbourhood of 42 in. diameter and of 20 ft. length. A certain tendency has developed to blend shellac and synthetic varnishes with the object of obtaining the better characteristics of both in the finished product. In the authors' opinion, however, the risks of accentuating some of the bad characteristics in either constituent render this practice a doubtful one.

The bitumen-paper group of materials possesses distinct advantages on low-temperature apparatus, due to the extremely high electric strength and water-resisting properties of good-grade bitumens. The use of such materials, however, is very limited, due to their low softening points, although this is frequently counteracted by an outer reinforcing layer of bakelite-paper material.

* *Comptes Rendus*, 1922, vol. 174, p. 258.



Results of E.R.A. fuse-wire tests.

The processes involved in the production of varnished-paper products are amongst the most highly technical which an insulation engineer is called upon to contend with, and call for the closest possible scientific control and technical supervision.

(5) *Vulcanized fibre.*—Vulcanized fibre is shown by laboratory tests to be one of the poorest insulating materials in modern use, but nevertheless it has given

most excellent results for many years in a varied number of applications, including rail-joint insulation, fuse holders, slot wedges, packing and spacing blocks, contact carriers on low-tension switches, etc.

Unfortunately, post-war supplies of vulcanized fibre have not been comparable with the high-quality product available 10 years ago. The general acceptance of vulcanized fibre as a second-grade insulator only, and its disuse as primary insulation on anything but the lowest-voltage work is the most marked advance which has been made in the industry with respect to this material. It might be mentioned here that the V.D.E. rules have definitely specified that vulcanized fibre shall not be used in positions where the voltage across the material exceeds 15 volts per mil. A recommendation of a similar nature has been put forward by the E.R.A. limiting the stress to 20 volts per mil in dry situations. Leatheroid, which is classified as a grade of vulcanized fibre, affords an excellent material for slot-lining purposes, but in many instances is now being replaced by tough flexible pressboards, since the latter possess better ageing characteristics.

(*b*) I.E.C. Class B Materials.

(1) *Mica products.*—The effect of temperatures, within the range met in electrical machines, on Class B insulation is a question which is capable of considerable discussion and should probably be the subject of considerable further investigation before any very definite conclusions can be arrived at. Mica itself does not begin to disintegrate until raised to temperatures well in excess of those encountered in electrical plant, but the bonds used in building it up into micanite, and also the paper and fabric "carriers" which are frequently employed as a backing for mica, are in most cases affected by temperatures in the neighbourhood of 100° C. The I.E.C. rules permit Class B insulation to contain Class A material for structural purposes only and specify that only where such material may be destroyed without impairing the insulating or mechanical qualities of the combined material may the latter be considered as Class B insulation. There seems to be some considerable latitude in interpreting this rule, and it might be suggested here that in a future revision of the B.E.S.A. Specification some definite values should be specified as a minimum for the percentage by volume of truly fireproof material (as, for instance, mica, asbestos, etc.) that a Class B insulation should contain. Micafolium wraps not infrequently contain only 25 per cent of mica by volume—figures as low as 14 per cent by volume have been found in wraps made by certain foreign manufacturers—and yet such a wrap is frequently looked upon as a Class B insulation. For large machine work a figure in the neighbourhood of 35 to 40 per cent of mica by volume in mica-wrapped insulation would probably be a reasonable figure for a Class B insulation.

In setting the above figure, it might here be pointed out that much misunderstanding has frequently been caused by the use of percentage-of-mica figures based on weight and not on volume; such figures are of course very much higher and quite misleading. When expressing percentage-of-mica figures in mica wraps on, for instance, alternator bars, figures by volume higher than 45 per cent are almost unobtainable commercially, but such figures expressed as a percentage by weight may be 65 to 75 per cent of mica, depending on the specific gravities of the paper and bond employed. In micanite plate (in which no fibrous material is employed as a "carrier") it is not difficult to obtain percentages of mica by volume of 85 per cent.

The selection of splittings used in building up mica products also requires more close attention, particularly on high-voltage work. It is to be regretted that at the moment the electrical manufacturer is so hopelessly in the hands of brokers in selecting splittings, and there is no definite specification for the purchase of this important material. Brokers' grade numbers vary enormously, and of recent years certain large consumers have found it necessary to abandon the use of grade numbers entirely and employ suitable standard grade names. Splittings are then bought to blue-print drawings, depicting the size and thickness of the flakes in an average handful of the material to be supplied. This arrangement has worked extremely satisfactorily and has eliminated a very considerable amount of confusion.

The bond used in built-up mica insulation constitutes, as already stated, the weakest part. Shellac, when carefully selected and free from rosin and other impurities, yields to treatment which renders it an excellent bond, but calls for the strictest observance of technical detail in carrying out the processes where it is employed. Improper treatment or impurities in the bond may easily produce volatile matter at the high temperatures met with in machines, with deleterious results.

Among the more recent improvements introduced into the building of mica products, the use of machine building in place of hand building should be mentioned. The authors' experience is that machine-built micanite is mechanically and electrically superior to that built by hand, even when lower grades of raw splittings are employed in the machine-built material. Machine-built micanite is naturally cheaper to manufacture. Another important development has been the general introduction of what is known as "cushion pressing," i.e. placing a resilient material such as thin felt or heavy cloth between the sheets of micanite whilst being pressed. This results in an even distribution of bond and mica and produces beautifully uniform sheets, free from the light patches familiar in micanite made between solid metal platens.

The synthetic resin group of varnishes lend themselves to certain classes of work in connection with Class B insulation, but not as a rule in conjunction with mica wraps, since they cannot be successfully dealt with in the ordinary Haefely wrapping machine. They also possess the disadvantage that when dry they are exceedingly brittle. In any case their use is not advisable in any position where a disruptive discharge is liable to occur. In conjunction with asbestos fabrics, however, they are used to produce a laminated board which is essentially a Class B material and is extensively used for packing blocks where high temperatures and heavy mechanical stresses are encountered.

(2) *Asbestos products.*—Asbestos products enter the field of insulating materials in several forms. As a covering for wires and as a base for varnished fabric boards, asbestos has already been referred to.

In the form of paper, asbestos is extensively used as an insulation between turns in strap windings. Unfortunately, asbestos papers are generally weak mechanically, and the special treatments so far applied to improve electric strength (as, for instance, the oxalic acid treatment) by removing the magnetite fibres from the asbestos tend still further to reduce the mechanical strength of the material. It is to be feared that the raw fibre used in paper making is too frequently residue material and contains many impurities. Probably the use of high-quality spinning fibres would go far to remedy this defect without greatly increasing the cost.

Asbestos tapes are becoming more extensively used than previously in place of cotton tape in coil insulation which is called upon to meet a Class B specification. The chief disadvantage of using such tape at present is the difficulty in securing thin tape. The majority of tapes on the market at anything like a reasonable price, vary in average thickness from 12 to 20 mils. The difficulty in making a thinner tape is entirely in the production of fine asbestos yarns without the introduction of cotton. There seems little doubt that if manufacturers' specifications would permit a comparatively small percentage of cotton (e.g. 10 or 15 per cent) to be included with the asbestos, these tapes could be produced down to average thicknesses of 7 to 8 mils. For the majority of work it is probably permissible to regard an asbestos tape with 15 per cent of cotton in its structure as coming within the limits of a Class B specification.

The various asbestos arc-shield materials are, it is suggested, classifiable under the heading of Class B insulation. The E.R.A. have recently subdivided these materials into a number of classes, and their classification is followed in Appendix 1. All the materials of this kind which the authors have had the opportunity of examining—some 54 in all—fall far short of the ideal, and particularly with regard to the requirements necessary for high-tension direct-current traction work. It is questionable how far asbestos itself constitutes an ideal filler for a high-tension arc-resisting material, except when added in small quantities as a mechanical reinforcement. It is probable that an arc-resisting material with a low-melting-point (500° C.–600° C.) vitreous binder, and employing powdered mica, asbestos, pumice or chalk as a filler may supply the want now badly felt. At least one such material has been produced experimentally and has proved most promising.

(c) I.E.C. Class C Materials.

The I.E.C. rules define Class C materials as fireproof and refractory materials, such as pure mica, porcelain, quartz, etc.

(1) *Block mica.*—Block mica finds considerable use in the electric heater industry and is to a certain extent still employed on high-class commutator work, but by reason of its high cost it is replaced wherever practicable by micanite.

(2) *Porcelain.*—With the increase of high-tension work, porcelain is becoming the centre of much attention, and extensive research work is now in hand with a view to improving this material both on the Continent and in the United States. British manufacturers do not seem to have devoted the same attention to the scientific development of electrical porcelain, involving, as it does, a complete study of the clays utilized, grain size, blending, and of the problems of close temperature control during firing. Porcelain and pottery making is one of the oldest industries for which Great Britain is famous, and it is to be hoped that the conservative attitude of those in charge of this particular industry will not exclude British products from the high-grade electrical porcelain market of the future.

(d) Materials Unclassified by the I.E.C. Rules.

(1) *Varnishes.*—The manufacture of high-grade insulating varnishes in this country has made very definite progress of recent years. The main efforts of most varnish makers have been directed towards reproducing the original varnishes which were introduced into this country, largely from America, when the electrical industry was enjoying its first boom. Electrical manufacturers also have closely followed the practice of earlier days in the use of these materials. In Appendix 4 a general classification of insulating varnishes in use is embodied. Probably by far the most important of the classes of varnish named are those with a linseed oil base, which constitute the bulk of insulating varnishes at present in use for dipping and impregnating purposes.

The development of outdoor apparatus, particularly in connection with outdoor substation work, has called for special insulating varnishes, capable of protecting organic insulation against extreme weather conditions. No generally accepted practice in this connection is evident at the moment. In considering this problem, however, the figures given in Table 5 are of general interest as indicating the relative protecting power of various classes of varnish.

(2) *Moulded compositions.*—Moulded compositions are a form of insulation the value of which is becoming more appreciated as the art of making mouldings becomes better understood. The most formidable difficulty in this class of work is that of producing moulds at a reasonable cost. The classification in Appendix 3 indicates the general subdivisions into which insulation of this kind can be classified. Of these, the synthetic resin group of moulded products have certainly come as a boon to engineers, since they are capable of retaining their form and strength at temperatures where rubber and bitumen mouldings soften. The use of synthetic resin mouldings for magneto work, small distributors, commutators and similar parts is now quite general. Here again, however, the danger of " tracking " must be taken into account in introducing these materials into electrical designs.

Mouldings with a rubber base are chiefly applicable to high-grade instrument work and radio specialities.

The bitumen class of mouldings is probably more in general use than any other, as it includes a very large number of products, such as switch handles, terminal blocks, cable-rack insulators, etc., all of which can be made from a very cheap grade of raw materials, particularly as the fillers employed may readily be prepared from factory waste.

Casein forms the binding base of another group of moulded materials which, although comparatively little used in this country, is becoming considerably more widely used on the Continent of Europe. One of the most striking features of the recent Trades Exhibition in Vienna was the number of products of this type exhibited. Galolith is one example of this type of material.

Amongst other materials which may be regarded as moulded materials are a group of cold-moulded products, using cement, lime and other natural clays as binders. The majority of these materials are particularly applied for arc shields and similar work, and bear a close relation to the asbestos arc-resisting boards already referred to.

TABLE 5.

Protective Powers of Various Varnishes against Penetration of Moisture.

Varnish	Number of coats	Moisture absorption, per cent
Untreated sample	0	145
Black finishing varnish ..	1	104·3
Black finishing varnish ..	2	94·0

Bakelite varnish	2	95·3
Grey insulating varnish ..	1	114·9
Grey insulating varnish ..	2	93·42

(3) *Insulating oils.*—The use of insulating oils has increased enormously of recent years with the rapid growth of transformer and high-tension switchgear work.

In pre-war days a large amount of Russian oil was used in Great Britain, since this class of oil is singularly free from sludge, being what is known as a bitumen-base oil. The complete cessation of supplies from Russia, which lasted until a few months ago, caused the transformer builders to depend on America for their supplies. Unfortunately American oils are petroleum-base oils, and unless very carefully refined and produced have a serious tendency to sludge. The difficulties encountered with sludging became so real that electrical manufacturers have been compelled to spend very large sums of money in endeavouring to perfect methods of testing for sludge. The B.E.S.A. Specification 148 outlines the test, devised by Dr. Michie, which is at present recognized as a standard test. This test is unquestionably good, but apart from the fact that it takes extremely careful handling to obtain consistent results, it takes 48 hours to complete. Such a long period is frequently extremely inconvenient in actual practice, and to obviate this difficulty a very simple and apparently reliable method has recently been suggested by Mr. W. H. Nuttall.* This short test depends in principle on the fact that oils containing large amounts of unsaturated hydrocarbons (and therefore having a strong tendency to sludge) exhibit a very much stronger interfacial tension towards water than that shown by oils which contain no unsaturated hydrocarbons. This is due to the enormous affinity that unsaturated hydrocarbons have for water. The test consists of allowing a known quantity of oil to rise in bubbles through distilled water from a standard small orifice. The drops are expelled from the orifices under a definite head of oil. Oils which contain a large amount of unsaturated hydrocarbons will rise through the water in small bubbles, whereas the good non-sludging oils rise in large bubbles. The number of bubbles per unit volume of oil is claimed to afford a direct measure of the sludging properties of the latter. The various properties of insulating oils commonly in use are set forth in Appendix 5.

With reference to the electric strength, it may be pointed out that although B.E.S.A. Specification 148 definitely lays down that the electrodes should be horizontally arranged, recent research has quite definitely established that with oils of the purity referred to in that specification, where all other conditions are equal, the question as to whether a horizontal or a vertical arrangement is employed affects the test results to an absolutely negligible extent.

(4) *Bituminous materials.*—It is probably not generally realized what a large number of different materials are available under the heading of bitumens, using the word in its widest chemical sense. Appendix 6 is intended to convey some indication of the wide field covered by this group, showing electrical properties where they apply. Many of the materials possess extremely satisfactory electrical characteristics, whereas others are far from satisfactory. There is little doubt that the practice of regarding materials which have a black bituminous appearance as bitumen has resulted in much trouble to electrical engineers in the past.

For impregnating work and as a filling for high-tension apparatus the quality of the bitumen employed has to be very carefully checked, particularly with regard to electrical characteristics and to the so-called "dropping point." Unfortunately there is no standard specification for this material. In view of the importance which is undoubtedly attachable to this group of materials, it is suggested here that the tests, of which the results are given in Appendix 6, might be regarded by users as effecting a satisfactory criterion to cover purchasing requirements. These tests should cover electric strength, dropping point, shrinkage, ash content, and nature of fracture. The dropping-point test is best carried out either in accordance with the ball and ring method specified by the American Society

* *World Power*, 1924, vol. 2, p. 92.

for Testing Materials in their Specification No. D36–21, or by the Kramer-Sarnow mercury-globule method. The electric tests are conducted in accordance with the rules laid down in the previously mentioned A/S2 document of the E.R.A., on sheets of bitumen prepared under pressure between amalgamated brass platens. Whilst pressing out into a sheet, the material should be at a temperature not more than 10 degrees below its dropping point. The whole field covered by these materials is now being investigated by the E.R.A.

One material which is singularly interesting is vulcanized bitumen. This material has the appearance and general characteristics of rubber, and yet is absolutely unaffected by continued exposure to hot transformer oil. Cable manufacturers have utilized vulcanized bitumen for some years, but its use in other classes of electrical apparatus does not appear to have been adopted to any extent.

(5) *Rubber and gutta-percha products.*—Rubber and gutta-percha are probably the oldest commercial dielectrics, and although used extensively in the cable industry and also in the manufacture of ebonite and similar materials for the manufacture of scientific instruments, telegraph apparatus, radio equipment, etc., are not used to any great extent in heavy machine work. No appreciable developments are noticeable in recent years, except the efforts which have been made to produce an oil-resisting rubber. Experiments have been made with rubber in the form of rubber latex with the idea of improving papers and pressboards, but for electrical work there is nothing in its use to recommend it, since the paper in which it is incorporated unquestionably ages rapidly at temperatures exceeding 80° C. Gutta-percha—found so satisfactory in early cable work—is not used extensively in the industry as a whole at the present time.

5. Improvements in Processes of Application of Insulating Materials.

Since all insulating materials are admittedly the weakest point both electrically and mechanically in any piece of well-designed electrical plant, it has been necessary to compensate as far as possible for their inherent weaknesses by improving the processes included in their application. The past four years have witnessed considerable progress in the improvement of insulating processes employed in manufacturing electrical machinery. This work has ceased to be a series of rule-of-thumb operations, but in the majority of large factories is carried out to definite specifications prepared under highly trained technical supervision and employing up-to-date scientific methods for controlling and recording temperatures, pressures, specific gravities of liquids, etc.

These improvements fall generally under the following headings :—

(*a*) Improvements in machinery.
(*b*) Improvements in processes resulting from better knowledge of the properties of various materials.
(*c*) Technical control of processes—process specifications.
(*d*) Training of specialized operatives.

(*a*) Improvements in Machinery.
(*b*) Improvements in Processes resulting from Better Knowledge of the Properties of Various Materials.

These two subjects are so closely allied that they will be dealt with together in relationship to the use of the various materials already mentioned in Part 4 of the paper. It may be pointed out here that such improvements in processes as are specifically applicable to the manufacture of materials dealt with in the earlier part of the paper have been already considered in dealing with the materials themselves. The following paragraphs cover the application of the various materials to finished electrical machinery. Generally speaking, manufacturers have at last appreciated that the majority of insulating processes are specialized operations requiring suitably designed machinery, and that the struggle to perform these difficult operations with machine tools constructed for other purposes very seldom pays in the long run. The number of firms now specializing in the manufacture of machinery for insulation work bears ample testimony to the truth of this latter assertion.

In connection with cell-insulating methods, the controversy as to the best form of insulation for long bar conductors in high-speed generating plant still continues, although the practice of inserting micanite tubes in the machine slots and afterwards drawing in the conductors and wedging them into position appears to have been abandoned in long-slot machines by those who advocated it. The use of soft cells in which varnished cloth was used has also not found favour recently.

Modern practice is divided between :—

The use of mica-silk tape applied by hand throughout on both slot portions and end windings.

Machine-wrapped bars (usually known as the Haefely wrap) in which micafolium is used on the slot portion and the end connections taped with mica fabric tape, etc.

Green cell insulated bars in which wet mica cells built on fine jap paper are applied by hand.

In all these cases the bars are pressed to shape after insulating. There has not been much improvement to record in these processes of recent years except in regard to the more careful selection of the materials used and the improvements effected in pressing dealt with later.

Coil insulation.—The chief changes in the insulation of armature and field coils have been brought about by the frequent use of square and rectangular conductors. In many cases bare conductors are now bent and formed to shape and the insulation afterwards inserted between conductors in the form of micanite, treated paper, pressboard, treated asbestos, etc. The coil is then served with special enamels and insulated with plain or mica-fabric tapes. This practice requires much greater skill and attention to the processes and materials employed than did coil formation with the d.c.c. wires of former days, but has the advantage of an

improved space factor. These remarks are equally applicable to transformer coils.

In small apparatus coils it is of interest to note the automatic machinery recently introduced for winding small coils. The Leesona coil winder may be taken as typical of this class. Such machines in proper hands can put up wonderful output records but need skill in operation and must be fed with very carefully selected raw materials.

Pressing.—Under this heading several distinct modern advantages may be mentioned.

The use of hydraulic presses is considered the best practice for pressing mica plate, built-up varnish-paper products of all kinds, and similar work where it is essential that the platen shall be at a temperature of 100° C. to 150° C. Such presses have been greatly improved of recent years and the general adoption of the drilled steel platen in place of the more cumbrous cast-iron platen has resulted in an increased press capacity both because more platens can be inserted in the limited "daylight" of the press and because the small amount of metal in the platens allows more rapid heating and cooling. Presses of this type are also equipped with cold-water cooling direct from a water supply.

For commutator **V**-ring work, heavy moulded composition parts, etc., presses are used with no heated platen, but in this case special provision is made to heat and water-cool the moulds themselves. The adoption of this practice has greatly increased the output per press.

The class of press, however, to which most attention has been given is the screw-operated clamp press in general use for steam-pressing long insulated bars and similar work. The design of such presses in order to get quick heating and cooling with no distortion, calls for considerable skill. The object of steam-pressing is to obtain a hard wrap on turbo-bars and such parts to definite dimensions with no soft places, blisters or air-spaces, and it is in the proper selection of materials and careful control of temperature, time and pressure that most improvement has been obtained with these presses. A divergence of opinion exists as to whether insulated bars in these presses should be pressed to size against stops or should be pressed with a definite applied pressure, relying on the correct amount of material having been wrapped on the bars to produce the required size.

Varnish treatment.—Two distinct trends of opinion exist with regard to the correct varnish treatment for electrical machinery and windings. The mere dimensions of the machines of course decide the point as to whether the windings should be varnish-treated before or after assembly. It is quite usual practice to wait until small machine parts are completely wound before treating with varnish. The whole machine is treated in this case, including the iron parts, which are afterwards wiped clean. Parts and coils for large machinery, on the other hand, are of necessity varnish-treated before being inserted into the machines. The point of difference, however, lies in the actual method of varnish treatment, i.e. whether vacuum impregnation or hot dipping results in the best product. Although some authorities still hold a brief for vacuum impregnation it is more generally recognized that hot dipping methods give results at least as good and often better at less cost in time and equipment. One of the most salient disadvantages of vacuum impregnation is the fact that the depth of varnish impregnation entails the use of either a slow-drying varnish in order to prevent the air surface drying too rapidly and preventing the access of air to oxidize the varnish in the interior, or a varnish containing an excess of internal driers. Both these types of varnish tend to release acid compounds which deteriorate the insulation. In the hot dipping process a 24 hours' baking at 120° C. before dipping leaves the insulation extremely dry, and if it is immediately transferred hot to a varnish tank and immersed in varnish until cold, practically all the advantages of a vacuum treatment are obtained.

On removal from the varnish and after draining, the insulation should be transferred back to the oven, as in this case a quicker-drying varnish can be used because, even should the outer film oxidize, the presence of oxygen in the interstices of the material accelerates internal drying. In vacuum treatment, of course, very little, if any, oxygen is present in these interstices. The chief change of practice of recent years to be noted is therefore the falling into disuse of vacuum impregnation.

Baking.—Great improvements have recently been made in baking and drying equipment. The scientific principles of the quick removal of moisture during drying, and quick oxidation of varnish during baking, have been closely studied and the ovens modified accordingly. In many factories the "through" type of oven is in use, ensuring a definite and gradual rise of temperature as the parts pass through on a conveyor until a maximum is reached, followed by a gradual reduction of temperature before removal. Thermostatic control and temperature recorders are almost everywhere employed since engineers have realized how much depends upon a close adherence to times and temperatures in baking insulating materials. Air circulation has been greatly improved in modern oven designs. The futility and, in fact, bad effect of "stewing" varnished products in their own varnish fumes have been realized by all, and the totally enclosed oven is a thing of the past. Electric heating of the air supplied to baking ovens is employed to a limited extent. In certain instances the recovery of the solvents from drying ovens has been considered, but such a scheme is hardly practicable except in specialized factories making one range of products only, from which ovens with a small ratio of total volume to volume occupied by the products being treated can be built.

A special application of baking processes is the so-called bakelization of synthetic resin products. According to the original ideas of treating the products, the final condensation process was carried out by baking at 150° C. in strong steel vessels under 120–160 lb./sq.in. pressure of air. Modern experts practically all agree that such high temperature and high pressure baking is quite unnecessary. With recent phenol-aldehyde varnishes bakelization can be

produced equally well with a prolonged baking of 40 to 60 hours at 115° C. to 120° C., which is a temperature far less likely to do any permanent damage to the organic constituents of the insulation.

Assembling, taping, etc.—In the assembly of insulated parts no appreciable changes can be discerned except perhaps in the special case of insulating parts of rotating machines running at speeds up to 3 000 r.p.m. A particular instance of this is a commutator for such speeds in which micanite insulation is tested to the utmost. Commutator work in general calls for very special treatment, but the methods of checking for truth during building, tightening and seasoning, have not appreciably changed during recent years. Block mica is hardly ever employed in modern commutators and in its place a segment micanite containing only 3 per cent, or at the most 5 per cent, of bond is used. A recent innovation is the checking of all mica parts for thickness under a definite pressure comparable with that met with in the finished commutator.

Finishing.—Finishing has been the subject of much attention of recent years, and the high finish on insulated parts exhibited at Wembley by various specialist firms is an eloquent testimony of the steps that have been made. To secure good finishes, cleanliness and complete absence of dirt and moisture are essential. Many firms have taken the precaution of providing special dust-excluding ventilation, oiled floors, double doors, etc., to their varnish-finishing departments.

Transport and storage.—Probably more insulation failures are due to careless handling and damage in transport than to any other cause. Considerable attention is being given to these details by most manufacturers, and practice has shown that the provision of special bogies and transport facilities usually more than compensates for their initial cost and upkeep.

(*c*) Technical Control of Processes—Process Specifications.

In paragraphs 4(*a*)(4) and 4(*b*)(1) above, specific cases have been cited of the necessity for the strictest control of every detail in the process of insulating modern electrical equipment and plant. So varied are the many stages through which a material passes, depending upon its physical and electrical characteristics and upon the ultimate part it is to play as insulation, that modern practice has developed the use of process specifications which take the form of detail shop instructions covering all essential shop points upon which the successful manipulation of the material may depend. Appendix 7 gives a typical sample of a process specification.

In spite of the fact that operatives are more highly specialized and therefore can be trained in detail operations, these process specifications have been rendered more necessary of late years in this country, partly because modern design has developed the use of a wide range of insulating materials, more nearly as their ultimate electrical properties permit, and partly because there is a greater tendency to develop the use of special machines which may be operated by semiskilled workers rather than to rely upon the dexterity and experience of highly trained workmen.

The contents of process specifications naturally depend upon the type of plant and personnel in dealing with a particular material, and only those variables which fall outside the broad knowledge of the personnel employed need be recorded. In many cases information sheets giving temperatures, times, pressures, speeds, etc., may be hung at a machine, oven or bench.

By means of such specifications or information sheets electrical insulating processes may be more easily and safely checked and controlled. At the same time new methods and materials may be developed outside the manufacturing areas and then introduced to full production with a minimum of manufacturing difficulties.

(*d*) Training of Specialized Operatives.

Modern firms have proved the necessity of adopting a definite scheme of training operatives, including both the manual training of apprentices by means of instructors and the special training of operators on all machines where the technical significance of each operation is of importance. This training is now extended to the personnel for supervising production, inspection, testing and erecting staffs wherever they are in direct contact with insulating materials, as it has been found that the complexity of such materials demands precise knowledge at each stage at which parts may be handled, transported, erected, etc. In addition, modern practice calls for the development and training of specialists qualified to undertake investigational work into shop problems, design features and test-bed methods. The process engineer of to-day is the outcome of the necessity for the closest shop supervision over insulating work and the need for intelligent investigation into shop problems apart from production work. Only by such means can the latest developments in special machines and materials be satisfactorily tried out and applied on a production basis.

In conclusion, the authors' experience is that such improvements in the insulation of electrical machinery as have been effected of recent years, have arisen from experience gained through either deliberate development or the intelligent observation and study of defects. A strong plea is made for the complete classification of insulation materials and methods of testing them, and also for closer co-operation between users and manufacturers of electrical plant so that a study of present-day requirements may lead to developments in method and material and permit of full investigation into service and ageing effects as well as into failures that occur.

The authors wish to express their thanks to the Metropolitan-Vickers Electrical Co., Ltd., and to the British Electrical and Allied Industries Research Association for their kind permission to make use of much of the data given in the paper and appendixes, and, in particular, to Mr. A. P. M. Fleming, C.B.E., without whose advice and guidance much of the research work referred to would not have matured.

APPENDIX 1.—SOME PROPERTIES OF THE CHIEF INSULATING MATERIALS.

Type of insulation	B.E.S.A. class	Usual thickness	Chief particulars			Remarks
		in.	Tensile strength (lb. per 1 in. width) Warp	Weft		
Untreated cloths :						
Cotton cambric	O	0·003	20	15		Used for a backing for cells and tapes
Unbleached linen	O	0·012	105	100		Used for protecting coils
Duckcloth	O	0·020	100	50		Used for motor armature caps
Sized calico	O	0·005	35	20		Used for insulation between layers
Jap silk	O	0·0015	15	12		Used for silk mica tape
Asbestos	B	0·020	—	—		Used for fire-proofing coils
Treated cloths :			Tearing strength (double tear), oz.	Electric strength, V/mil		
Black empire cloth	A	0·007	14	1 000		Used for slot liners
Yellow empire cloth	A	0·007	14	1 000		Used for slot liners
Empire silk	A	0·005	10	1 000–1 400		Used for coil insulation
Mica cambric	B	0·008	—	—		Used chiefly in the form of tape
Mica empire	B	0·010	—	—		Used for cell and washer work
Untreated tapes :			Tensile strength (lb. per 1 in. width)			
Cotton	O	0·005	43			Used for bonding purposes, and as a carrier for varnish
Linen	O	0·007	60			
Surgical	O	0·012	100			
Webbing	O	0·020	120			
Asbestos paper	B	0·008	8			Used for insulating conductors
Asbestos woven	B	0·015	48			Used for insulating coils
Cable paper	O	0·005	25			Used for paper-insulated wires
Treated tapes :			Tensile strength (lb./1 in. width)	Electric strength at 20° C., V/mil		
Black bias	A	0·007	30	1 000		Used for sealing the ends of coils
Yellow bias	A	0·007	30	1 000		Used as above where greater flexibility is required
Adhesive	A	0·015	45	—		Used for various purposes
Para	A	0·015	—	—		Used for waterproof joints
Rubber	A	0·010	—	—		Used for waterproof joints
Impregnated asbestos	B	0·010	12	—		Generally used between high-temperature windings
Mica silk	B	0·008	—	—		Used for insulation of turbo coils
Mica paper	B	0·006	—	—		Used for insulation of railway armature coils
Asbestos mica	B	0·012	10	—		Used for insulation of resistance units, etc.
Untreated papers :			Warp	Weft		
Kraft	O	0·003	20	11		Used for laminated synthetic boards
Greaseproof	O	0·002	22	12	Usually em-	Used for laminated synthetic boards
Sylphite	O	0·003	25	11	ployed as	Used for laminated synthetic boards
Bank	O	0·003	9	7	carriers of oil	Used between turns of fine wire coils

Tissue	O	0·001	4	1	trical value	Used for mica cell manufacture
Core disc	O	0·001	3·5	2	will vary	Used for papering laminations
Asbestos	B	0·007	8·6	6·8		Used for insulating fuse boxes

Continued on pages 452 and 453.

APPENDIX 1, *continued*.—SOME PROPERTIES OF THE CHIEF INSULATING MATERIALS.

Type of insulation	B.E.S.A. class	Usual thickness	Chief particulars		Remarks
Treated papers:		in.			
Synthetic varnished sulphate (Kraft)	A	0·005	These materials may be regarded as a semi-finished product, and therefore no electrical value is given		Used for laminated boards and tubes
Synthetic varnished sulphite (greaseproof)	A	0·004			Used for laminated tubes
Shellac varnished sulphate ..	A	0·004			Used for laminated boards and tubes
Shellac varnished sulphite (greaseproof)	A	0·004			Used for laminated tubes
Shellac varnished cable	A	0·005			Used for h.t. insulators
Synthetic varnished asbestos ..	A	0·010			Used for laminated boards and tubes
Linseed oil impregnated	A	0·015	Electric strength, 200–800 V/mil		Used for washers, etc.
Boards and sheets:			Density	Electric strength at 90° C., in V/mil	
Pressboard: grade A	O	$\frac{1}{16}$, $\frac{1}{8}$, $\frac{1}{4}$	1·15	218	Ordinary electrical usage
Pressboard: grade B	O	$\frac{1}{32}$, $\frac{1}{16}$, $\frac{1}{8}$	0·9–1·15	205	Soft and absorbent, used for oil immersion
Pressboard: grade C	A	$\frac{1}{32}$	Impregnated	500	Used for impregnated boards
Pressboard: grade D	O	$\frac{1}{32}$, $\frac{1}{16}$, $\frac{1}{8}$	1·3	255	Extra dense. Low moisture absorption
Pressboard: grade E	O	$\frac{1}{32}$	1·15	230	Used for slot linings
Laminated shellac	A	$\frac{1}{16}$–2	1·33	200 (at 20°)	Terminal boards, etc.
Laminated synthetic	A	$\frac{1}{16}$–$2\frac{1}{2}$	1·33	150 (at 90°)	Terminal boards, etc.
Leatheroid	A	$\frac{1}{64}$, $\frac{1}{32}$	—	—	Slot liners
High-grade fibre	O	$\frac{1}{64}$–2	1·15–1·35	75	Slot wedges, etc.
Asbestos millboard	B	$\frac{1}{16}$ up.	1·17–1·18	—	For embedded iron arc shields
Ordinary asbestos cement	B	$\frac{1}{4}$ up.	1·6–1·9	—	Cubical barriers, etc.
Compressed asbestos cement ..	B	$\frac{1}{4}$ up.	1·9–2·0	—	Fireproof chambers
Arc-resisting asbestos cement ..	B	$\frac{1}{4}$ up.	1·9–2·1	—	Arc shields
Bakelized asbestos board	B	$\frac{1}{4}$ up.	1·4	35–50	High-temperature insulation
Impregnated asbestos board ..	B	$\frac{1}{4}$ up.	1·9–2·1	50	High-temperature insulation
Ebonite	A	To thicknesses as required	1·207	200–350	High dielectric at low temperatures
Micafolium board	B		—	400–500	Insulation washers
Hard micanite (Muscovite) ..	B		—	700–900	Used for commutator segments
Flexible micanite	B		—	600	Used for protecting coils and leads
Bakelized cambric sheet	A		1·36	150 (at 20° C.)	For mechanical and electrical work
Flexible mica sheet	B		—	—	Used for insulating leads, etc.
Tubes and cylinders:					
Shellac paper	A	From $\frac{1}{16}$ wall to thickness as required	1·15–1·35	350 (at 20° C.)	Used for low-temperature work
Bakelite paper	A		1·25–1·35	325	Used for high-temperature work
Asbestos	B		1·17	50	Used for high-temperature work
Pure mica	B		2·3	500	High-stress and high-temperature work

APPENDIX 1, *continued*.—Some Properties of the Chief Insulating Materials.

Type of insulation	B.E.S.A. class	Usual thickness	Chief particulars			Remarks
Tubes and cylinders—continued:		in.	Density		Electric strength at 20° C., in V/mil	
Protected mica	B	From $\frac{1}{16}$	2·0		300	Medium-stress and high-temperature work
Micafolium	B	wall to	1·6		400–500	Low-stress and high-temperature work
Bakelite cambric	A	thickness	1·36		250	Mechanical and electrical work
Fibre	A	as required	1·15–1·35		75	For mechanical reasons only
Rods:			Density		Tensile strength, lb./sq. in.	
Bakelite paper	A	$\frac{1}{8}$ up to $2\frac{1}{2}$	1·3		—	High-tension trip gear
Fibre	A		1·15–1·25		8 000	Low-tension trip gear
Ebonite	A		1·2		4 000	Low-temperature high electrical stress
Bakelized cambric	A		1·36		8 000	Switchgear lifting rods
Moulded compositions:			Density	Approximate softening point, ° C.	Electric strength, in V/mil, at 20° C.	
Rubber base (ebonite)	A	General	1·2	70–90	200–350	Low-loss and low-temperature work
Synthetic base	A	moulding	1·2	100–150	–250	Medium low- and high-temperature work
Casein base	A	work	1·3	70–90	200–300	Low-temperature coloured work
Celluloid base	A		1·6	70–100	300–600	Low-temperature coloured work
Bitumen base	A		—	60–90	50–300	Usually black, cheap mouldings
Portland cement and asbestos ..	B		—	—	5–50	Fireproof work
Fireproof and refractory materials:					Electric strength, V/mil	
Porcelain (wet method)	C	—	—		150–200	High-tension insulators
Porcelain (dry method)	C	—	—		80–120	Medium tension
Marble	C	1 to $2\frac{1}{2}$	—		40–80	Switchgear and switchboards
Slate	C	$\frac{1}{2}$ to 2	—		5–20	Low-voltage switchboards
Heavily spotted green mica ..	C	Thin mica	—		1 100	Not recommended for use
Medium spotted green mica ..	C	splittings	—		1 200	Occasionally used on low-grade work
Medium spotted brown mica ..	C		—		2 000	Suitable for mica cells
Clear ruby mica	C		—		2 250	Suitable for condensers
Clear brown mica	C		—		3 500	Used for moulding micanite
Canadian amber mica	C		—		3 800	Used for commutator segments
Clear white (Muscovite)	C		—		3 000	Used for micanite

APPENDIX 2.

Comparison of Temperature Rating Rules of Various Countries.

[Note.—Unless otherwise indicated all figures are maximum permissible temperature-rises.]

			B.S.S. No. 72			B.S.S. No. 168			B.S.S. No. 173 (Traction motors)			V.D.E. (1923)			I.E.C. (1919)

—	—	—	—	—	—	—	—	—	—	—	—	55	70 shunt	

D = Measured by thermo-couples or similar detectors.

‡ This figure is for impregnated windings. If compound-filled 80 deg. C. is permitted.
§ Only applies to windings with two coils per slot. Windings with single coil per slot 5 deg. C. lower when temperature measured by detector.

OTHER RATINGS.

Norway.

The Norwegian Rules are substantially the same as the V.D.E. (1923) Rules.

Traction motor insulation after 1-hour test must not exceed 70° C. for cotton, 80° C. for paper and 100° C. for class B insulation.

France (*R.G.E., 28th May*, 1921).

The French Rules agree with the I.E.C. Rules, with exceptions :—

1. No limit specified for mica, asbestos, etc.
2. Specify 60 deg. C. rise on soldered joints, and at switch contacts, etc.
3. Following limits are set for composite materials :—
   Bakelite, etc., 200° C. max. temp.
   Ebonite, etc., 60–100° C. max. temp.
   Shellacs and gums, 60–100° C. max. temp.
   Marbles and slates, 100° C. max. temp.

Italy.

The Italian Rules differ from I.E.C. in that :—

1. Temperature allowed on rotating armature and on a.c. windings in slots is 5 deg. C. lower than in the I.E.C. Rules.

Sweden (*Schwedische Technalogen Verein*, 1919).

The Swedish Rules differ from V.D.E. in that :—

1. Ambient temperature = 35° C.
2. Varnish-paper products are allowed to reach 105° C. max. (70 deg. rise).
3. Short-circuited non-insulated windings are allowed to reach 115° C. max. (i.e. 80 deg. rise).
4. On transformer oil, when able to come into contact with air : 50 deg. C. rise. When shut off from air : 60 deg. C. rise.
5. Bearings are allowed 40 deg. C. rise.

Spain and Switzerland.

The V.D.E. Rules are, generally speaking, applicable in Spain and Switzerland.

Russia.

The Russian Rules (1923–4) are based on V.D.E. Rules.

APPENDIX 3.

Sample of Standard Grouping and Terminology of Insulating Materials.

TABLE A.

B.E.S.A. Class A and Class O Materials.

Class A Materials include cotton, silk, paper and similar materials when impregnated or immersed in oil of varnish. They also include enamelled wire.

Class O Materials include cotton, silk, paper and similar materials when unimpregnated, unvarnished, or not used under oil.

	Usual trade name	Recommended standard name
(I) *Fabrics*		
(*a*) Untreated cloths..	Cotton cambric	Cambric
	Unbleached linen	Linen
	Cotton duckcloth	Duckcloth
	Sized calico W7070	Sized calico
	Jap silk	Jap silk
(*b*) Treated cloths ..	Varnished cotton cloth	Black empire cloth
	Varnished cotton cloth	Yellow empire
	Varnished silk	Empire silk
(*c*) Untreated tapes ..	Egyptian cotton tape	Cotton tape
	Linen tape	Linen tape
	Surgical cotton webbing	Surgical tape
	Special linen webbing	Linen webbing
(*d*) Treated tapes ..	Black adhesive tape	Adhesive tape
	Bias-cut varnished cotton tape	Black bias tape
	Bias-cut varnished cotton tape	Yellow bias tape
	Varnished cotton cloth	Empire tape
	Varnished silk cloth	Empire silk tape
(*e*) Untreated sleeving	Glace tubular cotton braiding	Glace sleeving
	Tubular cotton braiding No. 1 white and special	Cotton sleeving
(*f*) Treated sleeving ..	Varnished cotton tubing	Empire tubing
	Varnished silk tubing	Empire silk tubing
(*g*) Untreated cords ..	Manilla rope	Manilla cord
	Loom twine	Loom twine
	Gilling's twine	Gilling's twine
	Cotton braiding	Cotton braiding
	Finishing twine	Finishing twine
	Barbour's No. 3 twine	Shoe thread
	Sea Island yarn	Cotton yarn
(*h*) Treated cords ..	Gilling's treated twine	Gilling's treated twine
(II) *Papers*		
(*a*) Untreated papers	Red rope paper	Rope paper
	Strong soda woodpulp wrapping paper	Kraft paper
	Hydrated chemical woodpulp greaseproof paper	Greaseproof paper
	Machine glazed sulphite woodpulp paper	M.G. sulphite paper
	Sulphite woodpulp unsized cable paper	Cable paper
	Bond paper	Bond paper
	Pure Japanese tissue paper	Jap paper
	Tissue paper	Tissue paper
	Core-disc paper	Core plate paper
	Homogeneous typing paper	Bank paper
(*b*) Treated papers ..	Shellac treated bear paper	Shellac kraft paper
	Shellac treated gramme paper	Shellac greaseproof paper
	Synthetic varnish treated bear paper	Bakelite-kraft paper
	Synthetic varnish treated gramme paper	Bakelite-greaseproof paper
	Shellac treated sulphate woodpulp cable paper	Shellac cable paper

TABLE A (*continued*).

	Usual trade name	Recommended standard name
(III) *Boards, rods, tubes and cylinders*		
(*a*) Boards	Flexible pressboard	Flexible pressboard
	Presspaper (on rolls)	Presspaper
	Soft pressboard	Grey pressboard
	Dense pressboard	Dense pressboard
	Ordinary pressboard	Ordinary pressboard
	Shellac paper board	Shellac paper board
	Synthetic varnish paper board	Bakelite paper board
	Fibre boards	H.Q. fibre
	Leatheroid (and leather paper)	Leatheroid
(*b*) Tubes and cylinders	Shellac paper tubes	Shellac paper tubes
	Shellac paper cylinders	Shellac paper cylinders
	Synthetic varnish paper tubes	Bakelite paper tubes
	Synthetic varnish paper cylinders	Bakelite paper cylinders
	H.Q. fibre tube	H.Q. fibre tube
(*c*) Rods	Synthetic varnish paper rod	Bakelite paper rod
	H.Q. fibre rod	H.Q. fibre rod
(IV) *Moulded composition and rubber*		
(*a*) Boards	Ebonite	Ebonite
(*b*) Tubes	Ebonite tube	Ebonite tube
	Soft rubber tube	Soft rubber tube
(*c*) Rods	Ebonite rod	Ebonite rod
	Soft rubber cord	Soft rubber cord
(*d*) Sheets (i.e. flexible —distinct from " Boards")	Thick rubber sheet	Rubber
	Oil-resisting synthetic rubber	Oil-resisting rubber
	Cork composition	Cork composition
(*e*) Tapes	Type " N " rubber tape	Admiralty rubber tape
	Para rubber tape	Para tape
(*f*) Special mouldings	Ordinary arc-resisting moulded composition parts	Ord. arc-resisting mould
	Special arc-resisting moulded composition parts	Special arc-resisting mould
	Standard-grade moulded composition parts	Ord. grade mould
	High-grade synthetic resin arc-resisting moulded composition parts	Special bakelite mould
	High-grade synthetic rubber arc-resisting moulded composition parts	Special ebonite mould
(V) *Varnishes, oils, etc.* (*not including insulating oils*)		
(*a*) Insulating varnishes	Shellac (0·975) varnish	Shellac varnish (0·975)
	Lacwatt No. 49 varnish	Lacwatt No. 49
	Grey insulating varnish	Grey insulating varnish
	Thinner for grey insulating varnish	Thinner for grey insulating varnish
	Synthetic insulating varnish	American bakelite varnish
	Synthetic insulating varnish	Formite (bakelite) varnish
	Baking coil varnish	Baking coil varnish
	Baking cloth varnish	Baking cloth varnish
	Flexible black baking varnish	Flexible black baking varnish
	Black finishing varnish	Black finish varnish
	Flexible mica sticking varnish	Flexible mica sticking varnish
	Glossy air-drying varnish for meter coils	Air-drying coil varnish
	Hard-drying copal varnish	Copal varnish
(*b*) Gums, etc. ..	Hydrolene gum, grade " B "	Impregnating bitumen
	Special elastic bitumen, grade " G "	Special elastic bitumen
	Texacto No. 130 filling compound	Cond. terminal compound
	Paraffin wax	Paraffin wax
	Sticking compound	Chatterton compound
	Resin	Resin
	Manilla gum	Manilla copal gum

Continued on page 458.

TABLE A (*continued*).

	Usual trade name	Recommended standard name
(V) *Varnishes, oils, etc.* (*not including insulating oils*)—*continued*		
(*c*) Oils, etc.	Raw linseed oil	Raw linseed oil
	Boiled linseed oil	Boiled linseed oil
	Double-boiled linseed oil	Double-boiled linseed oil
	Thin fluxing oil for hydrolene gum	Thin flux oil
	Methylated spirits	Methylated spirit
	Genuine American turpentine	Genuine American turps
	South American turpentine	South American turps
	Turpentine substitute	Turps substitute
	Venice turpentine	Venice turps
	Castor oil	Castor oil

TABLE B.

B.E.S.A. CLASS B MATERIALS.

Mica, asbestos, and other materials capable of resisting high temperatures. If Class A material is used in conjunction with Class B material for structural purposes only and may be destroyed without impairing the insulating or mechanical qualities of the combined material, then the material may be considered as Class B.

	Usual trade name	Recommended standard name
(I) *Mica products*		
(*a*) Sheets	Micafolium	Micafolium
	Mica cambric	Mica cambric
	Mica empire	Mica empire
	Machine-built commutator micanite	Machine commutator micanite
	Flexible micanite	Flexible micanite
	Segment micanite	Segment micanite
	Moulding micanite	Moulding micanite
(*b*) Tubes	All-mica tube	All-mica tube
	Protected mica tube	Protected mica tube
	Micafolium tube	Micafolium tube
(*c*) Tapes	Mica-silk tape (0·005 in.)	Mica-silk tape (single layer)
	Mica-silk tape (0·006 in.)	Mica-silk tape (2 layers)
	Mica-silk tape (0·008 in.)	Mica-silk tape (3 layers)
	Mica-paper tape	Mica-paper tape
(II) *Asbestos*		
(*a*) Boards	Bakelized asbestos boards	Bakelite asbestos
	Asbestos millboard	Asbestos millboard
	Semi-compressed asbestos, slate, or semi-compressed Uacolite, or Everite or Asbestone	Ordinary asbestos cement board
	Compressed "C" Uacolite	Compressed asbestos cement board
	Natural Syndanyo, or transite asbestos wood	Arc-resisting asbestos board
	Ebony Syndanyo, or ebony asbestos wood	Impregnated asbestos board
(*b*) Tubes	Asbestos tube	Asbestos tube
(*c*) Tapes	Asbestos paper tape (cut from asbestos paper)	Asbestos paper tape
	Asbestos woven tape	Asbestos woven tape
(*d*) Sheets	Asbestos paper	Asbestos paper
	Asbestos cloth	Asbestos cloth
(*e*) Cords	Asbestos cord	Asbestos cord
(*f*) Packings	Asbestos wool	Asbestos wool

TABLE C.

B.E.S.A. Class C Materials.

Fireproof and refractory materials such as pure mica, porcelain, quartz, etc.

	Usual trade name	Recommended standard name
(I) *Refractories*		
(*a*) Mica	Block mica	Block mica
	Amber mica splittings	Amber mica split
	Tower mica splittings	Tower mica split
	Moulding mica splittings	Moulding mica split
	Micafolium mica splittings	Micafolium mica split
	Flexible cell mica splittings	Flexible cell mica split
	Admiralty mica splittings	Admiralty mica split
(*b*) Porcelain	High-grade porcelain	High-grade porcelain
	Dry-process porcelain	Dry-process porcelain
(*c*) Natural mineral insulators	Slate	Slate
	Marble	Marble
	Lava	Lava

APPENDIX 4.

Classification of Commonly used Insulating Varnishes.

	Drying hours		Specific gravity at 15·5° C.	Redwood viscosity at 15·5° C.	Electric strength, in V/mil
	Oven	Air			
Oil Varnishes :					
Linseed oil, China wood oil blended with resins, gums and driers and thinned with hydrocarbon solvents (Petroleum naphtha, benzene, turpentine substitute, etc.)					
1. Baking coil varnish	6		0·855–0·875	30–50	700–900
2. Baking cloth varnish	8		0·830–0·875	30–50	700–900
Asphaltum varnishes :					
Native asphalts dissolved in benzine and frequently blended with linseed and wood oils, thinned with hydrocarbon solvents.					
1. Black plastic varnish	15		0·830–0·860	45–55	900–1 200
2. Black baking japan	6		0·870	—	600
Spirit varnishes :					
Lacs, gums and synthetic resins dissolved in denatured alcohol, acetone, etc.					
1. Black finishing varnish	5–10 min.	½	0·870–0·930	40–70	600
2. Clear finishing varnish		3	0·945–0·955	20–30	500
3. Mica sticking varnish		2	0·850–0·870	—	—
4. Shellac as a binder		2	0·975	60–70	900
5. Hard copal, for finishing, etc.		12	0·800–0·900	5–10	500
6. Synthetic for finishing	2–6	10–30 min.	0·980–1 000	60–80	200
7. Synthetic for paper treating	2–6	10–30	0·980	60–65	350
Pigmented varnishes :					
Oil varnishes loaded with lithopone or other pigments to improve their thermal and filling characteristics.					
1. Grey enamel	2–3	8–10	1·2–1·4	60–160	450

APPENDIX 5.

Physical Properties of Insulating Oils required to fulfil B.S.S. No. 148.

Grade	Sludge (Michie)	Loss by evaporation	Flash-point (Pensky-Martens)	Viscosity (Redwood), at 15·5° C.	Viscosity (Redwood), at 20° C.	Viscosity (Redwood), at 60° C.	Cold test	Disruptive strength	Acid value	Saponification value	Sulphur	General
	per cent	per cent						kV				
A (light) ..	0·1	2·0	170° C. ± 5° C.	$\not>$ 175	$\not>$ 145	$\not>$ 45	− 5° C. ± 5° C.	22	$\not>$ 2 mg KOH	$\not>$ 4 mg KOH	nil	The oil of each class shall be a pure hydrocarbon (mineral) oil, clean and sufficiently free from moisture or other matter likely to injure its insulating properties and shall satisfy the requirements set forth.
A (medium)	0·1	2·0	170° C. ± 5° C.	175–250	145–195	45–50	− 5° C. ± 5° C.	22	$\not>$ 2 mg KOH	$\not>$ 4 mg KOH	nil	
B (light) ..	0·8	3·0	155° C. ± 5° C.	$\not>$ 175	$\not>$ 145	$\not>$ 45	− 5° C. ± 5° C.	22	$\not>$ 2 mg KOH	$\not>$ 4 mg KOH	nil	
B (medium)	0·8	3·0	155° C. ± 5° C.	175–250	145–195	45–50	− 5° C. ± 5° C.	22	$\not>$ 2 mg KOH	$\not>$ 4 mg KOH	nil	
C	—	3·0	155° C. ± 5° C.	$\not>$ 300	$\not>$ 250	—	− 20° C. ± 5° C.	22	$\not>$ 2 mg KOH	$\not>$ 4 mg KOH	nil	

It is under consideration to modify the above clauses in certain respects with the possibility of admitting a wider range of oils having, for instance, slightly lower flash-points and higher loss by evaporation, but the tendency is to increase the value of the disruptive strength.

APPENDIX 7.

Specimen Specification.

METROPOLITAN-VICKERS ELECTRICAL CO., LTD.
TRAFFORD PARK. MANCHESTER.

Process Specification No. 22365.

Varnish Treatment of Coils in Instrument Transformer Department.

General.—This specification details the process to be followed in the drying and dipping of coils in instrument transformer department.

Material.—Baking coil (0·875) varnish. P.S.* 1065
Motor spirit No. 3. P.S.* 1168-A

Varnish.—The varnish shall be thinned down with No. 3 motor spirit to a specific gravity between 0·870 and 0·875. This gravity shall be checked every day by means of a hydrometer and no coils shall be dipped if the specific gravity of the varnish is not correct.

Drying out of coils before dipping.—All coils for dipping shall be dried out for 8 hours in an oven at a temperature between 100–120° C. Care shall be taken when loading the oven that no coils are placed in contact with the steam pipe as this will damage the insulation.

Dipping and draining of coils.—The coils shall be removed from the oven and immediately dipped in the baking coil (0·870–0·875) varnish.

They shall remain below the surface until all bubbling has ceased or for a period of 5 minutes, should bubbles cease to rise to the surface of the varnish before this time has elapsed.

The coils shall then be removed from the varnish and hung up on the rack provided where they shall remain until all surplus varnish has drained off.

Second drying.—After draining the coils shall be replaced in the oven and dried at a temperature between 100–120° C. for 15 hours.

Subsequent dipping, draining and drying.—In cases where more than one dip is called for, the coils shall be redipped, drained and dried as detailed above. The second and subsequent dip shall take place immediately after the drying period which follows the previous dip.

* The British Electrical and Allied Industries Research Association.

DISCUSSION BEFORE THE INSTITUTION, 23 APRIL, 1925.

Mr. E. B. Wedmore: Very great progress has been made in the last few years in insulation practice. Since manufacturers and users have co-operated through the Electrical Research Association in standardizing and improving their nomenclature and methods of testing, the precision with which insulating materials are selected for particular purposes has been greatly improved, as has also the quality of the materials. The development and use of improved and more precise methods of testing, simple and empirical as they may often appear to be, inevitably result in additions to our knowledge, and ultimately in improvements of products. The methods and results given in this paper are almost wholly of the type so much favoured by engineers, bordering on the empirical rather than on the methods of pure science. The engineer is daily faced with problems which will not submit at once to the methods of pure science, but which can be dealt with effectively for the immediate purpose by the empirical engineering method. I want, however, to insist upon the very great importance of fundamental research and the use of methods more searching and illuminating than those indicated in so many cases in the paper. The fuse test is a case in point. It is admirably adapted to give the engineer just the information he wants about materials used for a certain purpose, just as a foot rule is used

to pass men into the Guards. The foot rule was effective for the particular purpose but left us with a C3 population to be discovered during the European war. The fuse test and others like it will not prevent our having C3 insulating materials. Scientific methods, however, take time to develop and can best be discovered by people co-operating together and combining their facilities. Even with an establishment of the magnitude of Messrs. Metropolitan-Vickers Co. the expense is too great; but when large firms and small firms join together then we are able to tackle, on fundamental scientific lines, problems which the individual manufacturer finds beyond his means. Ultimately that is the only way in which rapid progress and far-reaching improvements will be made in the development of insulating materials. That there is room for improvement by such methods there can be no question. Some persons doubt the value of pure scientific work in a problem of this kind. It is true that one must always have the engineer to apply the results and even to advise the directions in which the research is carried on the industrial side; but anyone who has had close contact with problems of insulation will realize that there is a very great lack of knowledge as to the nature of the phenomena with which we are constantly faced. In the atmosphere of the works, stress is placed on continuous production of sound products. Bad samples and unexpected results are set aside as being something of no value immediately the stream of production can be made to flow smoothly. In engineering concerns the engineers do not realize how much new evidence passes under their eyes and is unnoticed because they are not wanting it immediately. In the calmer atmosphere of the Electrical Research Association we are able to turn these things over in our minds. There is no question that there is a great lack of fundamental data with regard to the nature of insulation and of conductivity in solids. If one takes such a simple case as conductivity in metals, when one looks into it one finds that there are conflicting theories as to the nature of conductivity there, and no one has yet been able to devise crucial tests to determine which of those theories is mostly right. Conductivity in non-metallic elements—pure elements—is a much more complicated phenomenon. What then may we expect in a commercial insulating material? Seldom do we even know what is in it. I am sure, however, that these difficulties will give way before methods of scientific attack. For our encouragement we have the clear analogy of the case of metallic alloys, the state of the art in which has been revolutionized by the scientific elucidation of the underlying physical phenomena. On page 439 the authors refer to fundamental research which it is hoped the Electrical Research Association will carry out on this subject, and they refer also to work which is in contemplation or in progress elsewhere. This Institution is the representative body of the industry, and whether we are going to do fundamental research in this country on a less extensive or on a more extensive scale than has been done elsewhere is for the members to say, and I hope they will show their sense of responsibility in the matter. This country has never lacked brains capable of dealing with pure scientific problems in an effective way. After all has been said, however, manufacturers in this country, including Messrs. Metropolitan-Vickers themselves, have no reason to be ashamed of the products which they turn out from day to day.

Mr. J. Rosen: I agree with Mr. Wedmore in regard to certain of the phraseology used in the paper, especially in regard to the statement that comparatively little scientific study has been given in this country to the production of high-grade insulating papers and pressboards. With regard to the tests proposed by the authors to be carried out on insulation, I would suggest that they should also consider the difficulties which arise due to repeated expansion and contraction, or to differences in expansion and contraction between the copper and the insulation. I find that in some cases after many years mica insulation apparently shrinks, but whether it actually does so or whether it powders I am not quite certain. This point is worthy of investigation. In regard to the specification for mica splittings —which I think is the generally accepted term—I agree with the authors that there is considerable difficulty in obtaining standard splittings. To give an example of the remarkable difference in the types of splittings, on one occasion we obtained an excellent splitting at a price of 1s. a pound. We had previously paid 2s. 6d. a pound. It was found that the splittings at 1s. a pound were far superior to those at the higher price. That is rather unusual, and I think that if steps were taken to get in touch with the suppliers more uniform material might be obtained.

Mr. A. R. Dunton: In Table 1 attention is drawn to the superiority of cotton-base papers for high-temperature work. These results could have been equally emphasized by mechanical tests. Further on we are told that the values of electric strength given on page 440 for pressboards are for tests carried out in air; but if the insulation had been thoroughly dried and impregnated in transformer oil, the values could with ease have been increased by approximately 100 per cent; and these would more closely correspond to the possibilities of this material for modern transformer practice. The authors also call attention to the use of paper-insulated conductors. This is rather a new development, and here again most remarkable results can be achieved by the use of properly selected papers. On page 442 the opinion is expressed that the adverse criticism against bakelite has been due to the large number of inferior grades of this material on the market. I would rather attribute this to the misuse of good material in many instances. Practically all bakelite boards and tubes may roughly be divided into three classes. I do not think many engineers actually realize this, because bakelite materials of the wrong class are often found in quite unsuitable places. We have numerous cases of bakelite materials which are really most absorbent and which are admirably suited for oil-immersed work, but of course will not do for open-air work of any nature whatever, unless they are adequately varnished. In another class of bakelite the paper has been so thoroughly impregnated with bakelite as to be impervious to humid conditions; and this is the class for use in air. Many people think that all bakelite is non-hydroscopic. This is incorrect. Certain classes

of bakelite are really excellent, and if engineers would use them properly they would get the results they desire. The E.R.A. fuse-wire test shows the deterioration of the various products resulting from this test; but it should be borne in mind that the test is extremely severe, and, although bakelite fails after the first test in actual practice, if suitable varnish protection is employed the material is quite capable of withstanding repeated flash-over tests without "tracking." Reference is made in the paper to the use of shellac-paper products for extremely high-voltage terminals. Whilst agreeing that this is possible where absorbent paper is used, equally good, if not better results can be obtained by the use of specially selected synthetic varnishes combined with non-porous papers of the greaseproof variety. In this case the paper used constitutes the main factor in withstanding the electrical stresses involved. The use of a non-absorbent paper calls, however, for very special scrutiny of the materials used, the important feature of which is to select the material at a stage in its treatment when all surplus vapour has been expelled, and yet sufficient adhesion has been retained, finally to produce a solid article. When this is done it is possible to eliminate the pressure baking mentioned on page **449**. At one time it was assumed that bakelite products could not be made without air pressure, but it is possible to do so if the materials are in the proper condition. For that reason I agree that the authors' statement on the subject is quite correct, but I would point out that the elimination of the pressure baking can only be carried out satisfactorily if the surplus gases have not been trapped in the material during the process of winding.

Mr. A. Collins: The manufacture of varnish-paper materials is now well established in this country but, as the authors have pointed out, in many quarters bakelite products have earned for themselves severe criticism. For a number of reasons this is not surprising. In the first instance there is the large number of proprietary grades on the market, both British and foreign. It is inevitable that there should be various qualities. There is also the question of the synthetic resin used in the manufacture of the material. Again, there are a number of proprietary grades on the market. The manufacture of this resin is a specialized chemical process, which has necessitated close co-operation between the manufacturing chemist and the insulation engineer. There are many qualities of synthetic resin, some of which are satisfactory, many indifferent, and some useless. The next point is the process of manufacture of varnish-paper products. It has been the practice of some manufacturers of electrical machinery to manufacture a certain amount of their own varnish-paper materials. They generally buy their raw material in a semi-finished condition, such as, for example, paper already treated with one or other of the many resins on the market. Whilst there are notable exceptions, in general it is unreasonable to expect the user of insulating materials to produce results comparable with the product of the specialized firm. There is a fourth point which has already been touched upon by Mr. Dunton. Those firms who may be regarded as the successful manufacturers of varnish-paper material find it necessary to manufacture several different grades, because the properties of the material have to be deliberately varied to meet different applications. This point is not fully appreciated, and it is by no means unusual to find engineers employing the wrong grade. I entirely agree with the authors' statement that the processes involved in the production of varnish-paper products are amongst the most highly technical with which the insulation engineer is called upon to contend. The work certainly calls for closer technical supervision than the manufacture of other insulating materials. I do not, however, agree with the authors when they state that there is probably no insulating material which causes producers "so much anxiety." I feel that the authors had no intention of creating in the minds of users the impression that such a remark may possibly convey. I am confident that, in the case of a specialized firm which has realized that proper scientific control and technical supervision are necessary for such a process, and has organized itself on proper lines with a view to the production of the material in large quantities, the atmosphere which prevails is not one of undue anxiety. It is a general belief that the extent of "tracking" is dependent upon the class of bakelite employed, and it would be useful if the authors would explain whether the tests illustrated on page **444** are typical of the results obtained on a large range of bakelite boards, or whether the behaviour of one grade only is shown. Whilst it may be difficult to eliminate the causes of tracking in special cases such as controller work—particularly oil-immersed controllers—this phenomenon is not such a serious matter so long as bakelite paper materials are correctly applied. In the class of varnish-paper insulators used in transformers and switchgear for which bakelite resin is considered a suitable material (and this excludes, according to the best practice in this country and the United States, very high-voltage terminals, for which natural resin is used) the design and conditions of test should be such that there is no possibility of tracking. The effect of a flash-over is entirely a question of the amount of power available. With sufficient power it is possible to damage any insulating material. I think that the authors are creating an unnecessary atmosphere of alarm when they suggest that a flash-over on the surface during a pressure test may create a conducting path. With the average testing equipment used in commercial work for testing switchgear and transformer insulators of the type and voltage manufactured in bakelite paper, there is little risk of such an occurrence when the flash-over occurs in air. I have seen many bakelite-paper insulators flashed over for demonstration purposes on an ordinary commercial testing plant without being damaged. The conditions under oil, of course, are more severe. One British firm of specialists can supply a varnish-paper board with a special surface which behaves very well under the fuse-wire test, and yet retains the mechanical properties of the bakelite-paper board. Commutator micanite—that is to say, the micanite used as separators between commutator bars—is a material in which many improvements have been made during the past few years. An impression still prevails in some quarters that a tolerance on the thickness of

plus or minus 1 mil, i.e. a difference of 2 mils between the maximum and minimum thickness, can easily be obtained. Present-day practice admits, however, that first-class commutator micanite may have a total variation between the maximum and minimum measurements of not more than 3½ to 4 mils at any point when measured with a micrometer having a head ⅜ inch in diameter. Closer figures can be obtained, but only at an increased cost which is not only commercially undesirable but unnecessary when suitable arrangements are made during commutator construction. What may be described as the average tolerance on the set of separators used for a commutator is a matter of considerable importance, because inaccuracies in individual separators accumulate to an extent which may be embarrassing in view of the number of separators required to make a commutator. Provided the commutator separators are purchased ready cut to size, modern methods of gauging and checking enable the specialized firm to keep the total tolerances on the whole set of separators within very fine limits. This feature constitutes a great advantage to the commutator builder. On page 448 the authors enumerate three leading methods of insulating stator conductors. Whilst the hand application of mica-silk tape leads to a higher mica content than the "Haefely wrap," the former method must, of necessity, be more expensive. It would be interesting to learn, therefore, whether in the authors' opinion the increased cost is likely to prejudice the more extended application of the mica-tape method, in spite of the technical advantages of the increased mica content.

Mr. H. C. Silver: One of our great difficulties in testing dielectrics is the complicated nature of the material. The electric strength of paper depends on several factors besides thickness and temperature, for instance the process of manufacture and the moisture content. Testing in oil introduces another factor, viz. porosity, and it is probable that the order of merit of the papers shown in Table 1 would have been altered had the tests been carried out in air. The authors hope that the Electrical Research Association will issue reliable data on the behaviour of insulating materials. That is a very difficult task, in view of the enormous variations one finds in testing insulating materials. The Electrical Research Association adopts the policy of preparing proposals for specifications which are based on the results of a large number of tests, and then the limits are set so as to eliminate the inferior materials. Those of us in close touch with the work of that Association realize fairly clearly the lines on which improvements can be made and, speaking entirely for myself, I am convinced that a stage has been reached in which the problem is not so much a technical as a psychological one. For instance, it is generally understood that bleaching affects the mechanical strength of paper. I was told recently, however, by a paper-maker that one is more likely to obtain superior paper made from a bleached pulp than a corresponding paper made from unbleached pulp, for the reason that the paper-maker takes more care in the manufacture of bleached paper than he does in the manufacture of unbleached paper. Another difficulty is the question of price. Electrical insulating paper should be regarded as a material altogether apart from ordinary paper, and if a user wishes to secure a really good insulating paper he must be prepared to pay an increased price for it. He can obtain improved papers if he is willing to pay for them.

Mr. W. P. Digby: The authors refer to the proposed standardization of the nomenclature of insulating materials. I was aware that the British Engineering Standards Association had been giving some attention to that matter. I think that the sooner a standardized list is issued the better it will be for the industry. Whether it will follow the lines of the authors' Appendix 3, I should be inclined to doubt. Some of the terms suggest the use of trade names, with which the B.E.S.A. does not wish to identify itself; and it would probably be better in one particular case to have used such an expression as "a woven fibrous material of the cotton type" than to have employed the name by which that particular varnished fabric is known in the shops. The question of the standardization of nomenclature is rather an old one. In a paper read before the Institution of Civil Engineers in 1910-11 the author of that paper, after urging the standardization of nomenclature, suggested that the standard of minimum insulation resistance of the machine on test should not take into account merely the pressure and the output of the machine, as is done to-day, but should also take into account the question of speed, because if the stator of the large, low-speed machine is compared with the stator of the 3 000-r.p.m. turbo-alternator, and if the clause given in the latest B.E.S.A. specification is applied, the insulation on the low-speed machine would have to be very much better than that on the high-speed machine, simply because the specification does not take into account slot areas. On page 440 the authors deprecate the standard high-pressure test when the machine is warm at the end of its test run, but those who test machines, as I frequently have to do, are in a rather difficult position. We can make an insulation-resistance test, and if we find the resistance low we can say, "Very well, take the pressure test another day." Ordinarily the time when we want to take a pressure test is when the machine is at the maker's works, not necessarily to find any fault with the drying out, which can easily be cured or which would even cure itself in practice, but in order to track down as quickly as we can any defects due to the carelessness of the winder, through any abrasion of the material or cutting through fibrous insulating materials. The only place in which we can take a pressure test is at the maker's works, and it will be very little satisfaction to a purchaser if he is expected to take a pressure test after delivery. It would be very much less satisfactory, I fancy, to the average manufacturer. One or two speakers have deprecated the references in the paper to the development work in this country, and I feel that probably the authors would wish to revise their references on page 446 to the porcelain manufacturers here. These manufacturers are working under conditions of considerable difficulty, but they are working under and delivering high-tension insulators complying with the British Standard Specification—a specification which is quite as severe as that of any other manufacturing country. They are fully

alive to the necessity of, and are fully desirous of, developing further. In some cases there is a deficiency of high-tension testing equipment; but in dealing with such questions as the chemistry of clays and the physics of the materials they use, my own impression is that the manufacturers are fully alive to the problems; and I think that the authors may wish to modify that particular remark. Generally, with regard to the insulation of electrical machinery, I should say that, up to the outbreak of war, there were two parallel developments in progress. In this country we were developing moulded mica insulation for extra-high-tension machinery, and were leading the Continent in the quality of our work. On the other hand, for low-tension machines, in regard to the use of compressed fibrous materials, my impression is that the Continent was ahead of us. In 1913 I visited a large German works and was shown with pride their latest insulation on a 6 000-volt alternator. They assured me it was the first machine on which they had used that method, but it was the standard moulded mica insulation which was being turned out in this country five or six years before that. So that I feel that even if we did lag behind in regard to the compressed fibrous materials, our woven and pressed fibrous materials were quite as good as any produced on the Continent, and our practice in regard to the use of moulded mica was far in advance of theirs. The authors speak of the necessity of co-operation between the user and the manufacturer. This is well recognized, but it has only been within the last few years, and with the increasing use of embedded temperature detectors, that intelligent co-operation has been possible. In the modern power station, with its thermocouple embedded in the windings, it is possible to keep a proper life history of the machine, and in due course, if trouble does arise, we can see whether or not the insulation is to blame. An examination of the insulation of some of the machines which were built 20 years ago, when insulation was rather a matter of rule-of-thumb, shows that the fibrous insulation has become quite brittle, and it is surprising that the machines have withstood working pressures of 200 or 500 volts for so long. Many of the younger of those present are likely to die of old age before the generators being built to-day in this country break down through failure of insulation, always provided that the loads are not in excess of the specified limits to which the machines have been built.

Mr. H. D. Symons: There has been steady and marked improvement in methods of insulating during the past few years, not always accompanied by an improvement in the materials used. Indeed the reverse is often true, and one experiences many instances where service has only been met by intelligent and careful use of material. The need for standardized methods of tests for insulating materials is becoming increasingly urgent, and the Electrical Research Association is doing sterling work in this direction. Referring to the insulation test on page 440, it is often of great service to study the materials which have been used in the construction of machines and apparatus, as an aid in determining what insulation tests should be applied. The authors' proposal that the nomenclature of insulating materials should be standardized has my hearty support, but I would urge the great desirability of the adoption, or at least the serious consideration, of the use of numbers. Numbers are just as easy to memorize as names, and moreover they have the distinct advantage that they allow of future developments. For the sake of example, the grading of insulating materials, such as papers, under insulating paper No. 1, insulating paper No. 2, and so on, instead of the authors' list of names given in Appendix 3, would allow for extension to any extent. This idea can be applied to each separate class of product. The subdivision can be varied and the number of materials of any given class can steadily be added to without confusion. It has also the advantage of eliminating the use of such expressions as "special quality" and other similar phrases which give no indication whatever of the material. Unless something like this is seriously attempted the list of materials in use in 25 years' time will commence to tax our vocabulary. The results given in Table 3 are very interesting, but I cannot quite share the authors' enthusiasm for the treatment of the cotton cloth with a weak solution of caustic soda, as the figure given shows very little improvement over that obtained with boiling water. The treatment with varnish of synthetic resin-paper tubes and boards to prevent tracking is very effective, provided the right varnish is selected and its application correct. Referring to page 445, I entirely agree with the authors that the percentage of mica in built-up insulation should be always definitely specified as a percentage by volume and not by weight. This percentage by weight is becoming very generally adopted, and it is entirely misleading as it gives no mental conception of the density of the material. Referring to page 448, I would draw the authors' attention to their omission to emphasize the necessity for pressing long armature and turbo-generator coils before insulating. Whether a solid or flexible type of insulation is to be applied, not only is this pressing necessary but some treatment should be applied to produce very close adhesion between turns; it is impossible to attempt to insulate a large coil if this is not done. The authors, dealing with the question of varnish treatment on page 449, boldly state that they advocate a hot dipping method of treatment instead of vacuum impregnation. I entirely agree with them that this method is certainly efficacious and in a great majority of cases superior to the vacuum method of treatment, and is much more economical in practice. It will no doubt sound to many a retrograde step, and yet there is absolutely no need whatever to attempt to vacuum-impregnate anything with varnish if the varnish has been properly designed for impregnating purposes and is kept in proper condition. The authors advocate baking temperatures of 100-120° C. I not only entirely support this, but consider that temperatures even exceeding this figure can be used with advantage. There is nothing to fear—in many cases nothing but benefit will accrue—from baking at these temperatures, provided a good class of varnish has been used. Indeed, temperatures of 200° C. can be used with benefit in the hands of skilled operatives; this is the whole crux of the matter and is dealt with on the last page of the paper, where the authors emphasize the necessity of having skilled operatives for

insulation work. It must be admitted that skilled operatives have not been trained in the past and it is only now becoming recognized how important this aspect of the question is. With skilled operatives, intelligent selection and use of materials, there is no question that the insulating materials of to-day have a life comparable with the rest of the machine, provided the same proper supervision be given to the insulation as to the rest of the machine.

Mr. W. J. John: At the top of page 446 the authors refer to porcelain. This reference contains statements which are misleading, and I trust that the authors will adopt the suggestion made by a previous speaker and considerably modify it. British porcelain manufacturers are said to be lagging behind American and Continental manufacturers in the attention they are giving to research. Also they are said to be conservative. In the course of my work I have been brought into intimate contact with one of the largest firms of porcelain manufacturers in this country, and this particular firm has a staff of chemists and engineers who are engaged in investigating the various problems associated with the production of high-grade porcelain. Moreover, the research work is not hampered by lack of the necessary testing apparatus, in spite of the fact that the high-voltage testing equipment for this class of work is very expensive. This particular firm has spent during the last 2 or 3 years over £20 000 in providing high-voltage and high-frequency testing apparatus. The above facts, I think, refute the suggestion that all British porcelain manufacturers are not paying sufficient attention to research in their particular industry. Secondly, they are charged with being conservative, but I have found absolutely no signs of conservatism in my dealings with them. On more than one occasion, in fact, they have made radical alterations in long-established methods just to suit what must to them have appeared to be a whim on the part of the designer of the insulator. One thing which particularly impressed me was the way in which they tackled a new and difficult problem concerning the machining of fired high-tension porcelain. They tackled it with great enthusiasm and made a great success of it. In my considered opinion the charges of neglect of research and of conservatism made against the porcelain manufacturers of this country are unfounded. The authors express a fear that the British porcelain manufacturer will be excluded from the high-grade electrical porcelain market of the future, but my own opinion is that he will hold a very high place there.

Mr. P. Dunsheath: In Table 1 are given the ageing characteristics of two fibres extensively used in cable manufacture, and rather striking results are obtained. Five fibres are mentioned, viz. cotton, sulphate wood pulp, hydrated chemical wood, manilla and jutes, and they are placed in the order of merit as they appear on the test after heating. I shall confine my remarks to chemical wood and manilla. After 40° C. these two remain in the same order—the chemical wood superior in every case. This confirms some tests which I made a few months ago on the dielectric power factor and mechanical properties of these materials. Some engineers still consider that manilla is the only insulating paper that can be used on a cable, but in the cable industry itself there is no unanimity on this subject. Only quite recently I saw some curves which seemed to prove that manilla was better than wood pulp, quite as conclusively as the authors' figures prove the opposite —figures which my results support. In view of this conflicting evidence it occurs to me that there may be some other factor which has been overlooked: are we in these figures comparing fibres or are we comparing something else? I am wondering whether the order in Table 1 indicates the ease with which the fibres become impregnated rather than the electrical characteristics of the fibres themselves. The authors do not say what method of impregnation they used, and it would be interesting to have their views on that aspect. On page 440 they deal with lignification and suggest that the more highly lignified fibres deteriorate more rapidly. This hardly seems to confirm the comparison made in Table 1 as I do not think that manilla can claim to be more highly lignified than wood pulp. In Table 3 the insulation resistance of cotton is only given for samples after they have been subjected to air of 70 per cent humidity, but it is very unusual, I think, for cotton to be used under those conditions. In order to show the merits of the system and to show whether the dielectric resistance is improved by treatment, either by caustic soda or by ordinary bleaching, the samples should be dried before the test is taken, or possibly varnished if that is more convenient. It is interesting to note that the improvement in the electric strength is not nearly so great as that in the insulation resistance; the latter jumps from 34 to 1 000, but the electric strength varies from 95 to 94 on washing in water and up to 109 with the 0·5 per cent solution. It would be of great assistance if the authors were to state what kind of variations were obtained between the breakdown strengths of the different samples under identical conditions. My experience with breakdown tests is that with exactly similar conditions one would get very much greater variations than are used here to claim an advantage for the method. It is to be regretted that the authors dismiss the theory of dielectrics so summarily. It is obvious to anyone who has worked on the subject of dielectrics that any investigator who has collected the amount of information contained in the paper has certainly at the same time formed some views on the theory which might perhaps benefit other workers.

Mr. H. S. Holbrook (*communicated*): As a transformer engineer, I was particularly interested in the specimen specification for the varnish treatment of coils given in Appendix 7. It is about 20 years since the British Thomson-Houston Co., Ltd., found such specifications desirable. This specification is very similar but we find it worth while to measure the temperature when taking the specific gravity and to give the operators a table showing how the specific gravity should vary with the temperature. To keep the temperature of the treating rooms practically constant, summer and winter and all day, would involve an impracticable expense for ventilating and heating plant. During the war, considerable difficulties were experienced with supplies of spirit thinners, and we came to the conclusion that measurements on varnish baths of viscosity instead of

density would help matters, but before we had finished the development of a suitable viscosimeter for workshop use the spirit situation improved. The authors give some viscosity figures in **Appendix 4**; have they ever considered making routine measurements of viscosity? The specimen treatment specification uses the term "second drying" where we find it preferable to refer to "baking" of the varnish. As a matter of fact our more modern equipments use two separate ovens for the "drying" before the coils are dipped, and for the "baking" of the varnish after dipping. The drying ovens are complete with vacuum pumps and moisture condensers, and whilst we specify a minimum drying time, with alternative periods of free air and vacuum, we also specify that the drying is to be continued until no more moisture is given off by the charge of coils, and as shown by the condenser gauges. Some years ago the development of automatic recording hygrometers for transformer drying ovens was considered, but this was stopped by the war and since then we have not had time to return to the problems. The Western Electric Co., U.S.A., have developed an instrument for average humidities (see *Bell System Technical Journal*, April, 1924). Our transformer baking ovens are equipped with large fans for forced ventilation, the removal of varnish fumes and the supply of fresh oxygen, and we heartily agree with the authors regarding the futility of "stewing" coils in varnish fumes. One important point in connection with pressboards is the linear shrinkage which may occur during their manufacture. Another is the "coil shrinkage" which may occur when the coils are continuously immersed in hot transformer oil and exposed to fluctuating mechanical forces due to short-circuits, overloads, etc. Some pressboards have excellent machining properties; others mould well but none seem very satisfactory in riveted constructions. The industry needs an insulating cement which can be applied cold, sets quickly and is proof against hot oil. Perhaps the best test for indicating the propensity of an oil to sludge in service is the Synder life test given in A.S.T.M. documents, but it takes weeks, sometimes months. Mr. Nuttall's surface-tension test has the great advantage of being quickly carried out, but it remains to be seen if it will give consistent results when applied by different physicists in different laboratories, and whether it will always grade oils in the same order as the Michie test does. An important feature of bituminous materials used for "filling" apparatus—not mentioned by the authors—is the "free flowing point" or minimum temperature at which they can be poured. Unless comparatively expensive electrically heated and stirred melting pots are used, there is a great risk of these materials being overheated to an extent sufficient to ruin their disruptive-strength properties. Another class of bituminous material on which research is required is the "solid" fillers for fine-wire coils of oil-immersed apparatus. We agree with the authors that insulating processes, to be successful, need machines especially designed for the purpose, and that it does not pay to try to use up scrapped machine tools. Particularly is this the case in the manufacture of varnished-paper products, which, as the authors rightly state, call for the closest possible scientific control and technical supervision. It is a matter for regret that we in this country are so far behind the Swiss and Americans in the manufacture of these materials. This is one of the cases where the facility of thermostatic control with electric heating makes that method profitable. We cannot too strongly support the authors in their statement that the complete prevention of dirt is essential, even to the provision of double doors, linoleum-covered floors, and dust-screens over windows, etc. This was very forcibly brought to our notice during the winding of some aeroplane coils with 2-mil wire by hand on semi-automatic machines. The operators had a perfect record for freedom from breakdowns while the dust-screens were in position, the floor oiled, etc., but, if these precautions were relaxed, trouble at once occurred on test. A material not mentioned by the authors on which there has been some discussion as to whether it should be included in classes B or C of the International Electrotechnical Commission, is cured concrete. We find it a very successful material for fireproof current-limiting reactors.

Mr. H. Warren (*communicated*): The authors refer to the work of Moureu and Dufraisse, and I am able to confirm that the work of these two investigators may possibly have a useful effect in the arresting of certain changes that take place in insulating materials. Hydroquinone has, I believe, already been used as an anti-oxygene in the case of transformer oil, and the possibility of minimizing tracking in synthetic materials by the same agency has been investigated in the laboratories of the British Thomson-Houston Co. This property of tracking, possessed to such a pronounced degree by phenol-formaldehyde resins, together with their inflexibility, calls for the exercise of great caution and discretion in applying these resins to the general run of electrical insulation. Promising work has been done by Albert in the development of flexible phenol-formaldehyde resins, but up to the present no great application has been made of these. I can substantiate what the authors say in regard to the difficulties of manufacturing uniform synthetic bonded-paper tubes, and the difficulties in the control of the manufacture of the resins themselves are responsible for considerable variations in the varnishes used by the electrical manufacturer for this purpose. Phenol-formaldehyde resin, as a bonding medium, has received a great deal of support on account of its mechanical dependability at high temperatures, and in such cases as transformer work this is unquestionably an important consideration. It is, however, quite possible to make shellac-bonded cylinders, etc., for transformers, which have mechanical and electrical properties at least equivalent to those of synthetic bonded structures at the highest temperatures met with in service, and, bearing in mind the drawbacks of the synthetic resin, it is often preferable to retain shellac. I have had no successful experience of blending synthetic resin with shellac varnish, but several useful composite insulations, such as those for turbo-alternator slip-ring leads and controller shafts, have been prepared, using separate superimposed layers of shellac-bonded micanite or paper, and synthetic bonded paper or cotton fabric. Where mechanical robustness and resistance to abrasion are essentials, an outer coating

of synthetic bonded fabric or fibre is used, but where there is danger of surface leakage the outer layers are shellac-bonded. Both arrangements are given a finishing coat of oil baking varnish. The authors mention the applications of synthetic bonded asbestos, and there is no question that synthetic bonded asbestos fibre and fabric for packing blocks and distance pieces is of use where mechanical reliability at high temperatures is to be ensured. The common but erroneous idea that these particular asbestos compounds are non-inflammable must, however, be deprecated. The insulation of slip-ring sleeves can be very satisfactorily carried out with carefully selected asbestos paper bonded with suitable synthetic varnish, this compound being particularly immune from mechanical damage in the shops and flaking in operation at high speeds. These disadvantages are commonly encountered in the use of micanite. Synthetic bonded cotton fabric made from the right resin produces very satisfactory contactor spools and slot wedges, and this compound is generally useful where mechanical rigidity is essential. The most successful application of synthetic resin has undoubtedly been in the production of moulded insulations, and there is no question that the synthetic moulding is of unique service to the electrical engineer. Wherever the design can be so arranged that the danger of "tracking" is eliminated, the moulding of intricate shapes to a high degree of accuracy and finish, and the inertness of the material to reagents and high temperatures, are features of which considerable advantage can often be taken. The development of phthallic anhydride-glycerine synthetic resins, which do not track and have superior adhesive qualities, is being followed up, and the more recently devised urea-formaldehyde resins might possibly be utilized in the electrical industry.

Percentage of mica in wrappings.—The authors' comments in connection with the percentage of mica in mica wrappings are very interesting, and whilst I agree that 35 to 40 per cent of mica by volume undoubtedly yields good results, I would express the opinion that it is a distinct commercial possibility to obtain figures of the order of 50 per cent. The expression of the percentage by volume is certainly preferable to the rather misleading practice of stating the percentage by weight. There are, however, very considerable experimental difficulties in determining the percentage by volume directly, and a good, quick method of carrying out this test is greatly needed. As bearing on the authors' comments upon this point, I would mention that a certain mica tape recently investigated contained 70 per cent of mica by weight, and only 32 per cent by volume.

E.R.A. fuse-wire test.—We have made an investigation of the value of the E.R.A. standard fuse-wire test for arc resistance and tracking, as described in their publication A/S9 and referred to in the paper, and are of the opinion that this test forms a very useful indication of the properties under consideration.

Asbestos products.—The practical efficacy of asbestos tape in coil insulation is rather doubtful, not only because of the difficulty noted by the authors in securing thin tape, but because of the absorbent nature of the material. The predominant advantage of asbestos is its resistance to the action of flames, but any really efficacious water-resisting treatment of which I have knowledge seriously impairs this property. The whole question of rendering windings fireproof is one in which there is room for considerable advancement. Asbestos is, of course, of considerable use as a filler in moulded insulations, where resistance to high temperatures, and the additional mechanical strength arising from the length of fibre, are required.

Rubber latex.—The authors mention that the improvement of papers and pressboard by the agency of rubber latex does not (owing to the ageing propensities of this substance at 80° C.) present any features of great interest to the electrical engineer. There is, however, possibly a future for latex as a bond in moulded compositions.

Varnish treatment.—Under the heading of "Varnish Treatment" the authors refer to the falling into disuse of vacuum impregnation, but I should not have thought that the substitution of hot dipping had become so generally complete.

Wood.—The authors do not appear to make any reference to wood in the paper, and I would mention that although synthetic bonded paper and fabric rods and tubes have, to some extent, displaced wood for such purposes as tension rods and cross-arms in switchgear, there has been some advance in the treatment of wood for such purposes during the past few years. Properly selected and treated wood is still widely used for a variety of purposes, and it is often difficult to provide an equally practicable substitute.

Fibre.—In Appendix 1 fibre tubes and cylinders are specified for mechanical use only, but it may be well to bear in mind that the fuse-wire test reflects very favourably upon fibre, which actually in practice makes a satisfactory fuse tube or carrier.

Recommended standard names.—In connection with Appendix 3, in which certain useful suggestions are made as to standard names, it would appear preferable to avoid the use of such specialized semi-proprietary names as Empire silk, "Gilling's" twine, Bakelite kraft paper, Lacwatt No. 49, and Formite (bakelite) varnishes.

Messrs. K. G. Maxwell and **A. Monkhouse** (*in reply*). Mr. Wedmore criticizes the paper on account of the fact that the tests which we included in it were very empirical tests; that is to say, works tests. All of us on the manufacturing side are looking forward to the assistance that we hope to get from the Electrical Research Association, in order to make those tests more scientific and, at the same time, no more difficult to carry out in the works laboratory. If short tests and quick tests can be made which are at the same time scientific and which give us the figures we want, naturally we should prefer to use such tests rather than empirical tests; and that is one of the things we are looking forward to in the future.

Mr. Dunsheath has referred to the absence of anything more than a short paragraph dealing with the theory of dielectrics. We very much wish that we had had space and more time to discuss that subject, because it is extraordinarily interesting, but in our opinion it is a subject for at least a whole evening's discussion and probably then finality would not be reached. What

we hope to see is a comprehensive paper dealing with the subject in itself. This paper is more on the practical side, involving the application of materials and processes.

Mr. Digby has referred to the tracking down of defects in machinery, and made a plea in favour of high-pressure tests instead of the method which has been suggested here; but in our opinion the defects due to faulty windings or careless workmanship should be, and could be, found out, possibly by introducing the high-pressure test with the machine in a cold condition, even before it was put on to its first temperature run. After the first preliminary run all large machines are generally recognized to be in their most dangerous state, and a high-voltage test under these conditions should be regarded as exceptionally severe.

With regard to the question of standardization of terminology, Mr. Digby and other speakers have commented upon the unsuitability, from the standard point of view, of some of the names suggested in Appendix 3. We quite agree with that. As pointed out in the paper itself, these names are only intended to be suggestions. The Appendix is exactly as it was drawn up three or four years ago for use in the factory, where names which had been in use for 20 years were already in existence and where very much confusion was being caused by the use of other names. In choosing the names, therefore, we are afraid that the question of British standardization was not taken into consideration.

In dealing with the question of standardization, Mr. Symons also suggests that it might be more suitable to classify the materials and to grade them under numbers. His remarks particularly refer to papers. This is a subject which all those who have had anything to do with the preparation of specifications for works or for individual needs have very seriously considered and we are afraid that on the whole we do not agree with Mr. Symons's proposal. What is really very much more suitable, in our opinion, consists of standardized names, which must be carefully chosen to avoid anything in the nature of trade names, examples of which are recorded under Mr. Warren's remarks. As far as papers are concerned, we think that we are right in saying that the Electrical Research Association have already given standardized names to the majority of papers used in modern insulation practice.

In regard to the tests showing the electric strength of different papers, Mr. Silver and Mr. Dunsheath have both referred to the figures in Table 1. These tests were made in oil advisedly, because such papers are almost invariably used in a treated condition, not in either hot or cold air, but in some other medium. For this reason a standard transformer oil was chosen, because it was the medium about which we knew a certain amount. With regard to the time of immersion in oil before a test is made, when we began this investigation it was quite obvious to us that this time element would have an effect upon the result, as Mr. Dunsheath suggests, so that all the samples were soaked for a period of 24 hours before the tests at the temperatures indicated. With regard to the point of lignification, raised by Mr. Dunsheath, his opinion is that the sulphate wood pulp would be more highly lignified than manilla, but that is open to argument and is largely a question of the purity of the wood-pulp paper.

Coming to Table 2, referring to pressboards, Mr. Dunton in his remarks criticized us for not making the tests in oil. We agree, and if these tests had been made in oil we should have got very much higher electrical test-figures. Concerning the application of paper, we think Mr. Dunton's remark that paper-insulated conductors represent a new use would be best emphasized by noting its adoption as far as the heavy machine industry is concerned. Paper insulation of cables has been a standard thing for many years.

Mr. Rosen deplores the lack of research on high-grade insulating papers and pressboards, but in our opinion his remarks should be confined to the past, as there is at present a considerable amount of activity in this direction and really good work is being enthusiastically done by some of the leading manufacturers of this class of material; the presence of Table 2 should confirm this. We would endorse Mr. Silver's remarks concerning the care which should be exercised in the manufacture of paper and the stress which he lays on the fact that electrical papers should be regarded as a material altogether apart from ordinary paper.

In a communication from Mr. Holbrook reference is made to the linear shrinkage of pressboard, but this can be overcome by suitable curing before use.

Mr. Symons refers to the figures given in Table 3, and suggests that boiling water would have given results equally as good as caustic soda. That is very largely true, but the point we would emphasize is that although the cloths mentioned by Mr. Symons are treated and scoured before they are made up into varnish cloth, this is not true of cotton used as the insulation on wires. In the case of ordinary double-cotton wire the cotton is absolutely untreated from the time it leaves the cotton plant until it goes on the wire; and we were more concerned with this cotton insulation when making the investigation. It is particularly important in the case of cotton used on telephone flexible cords and similar wires where it is not impregnated and where a very high insulation resistance is essential.

Mr. Dunton, in his remarks with regard to varnished-paper products of a bakelite class, points out that various classes of bakelite are available and are generally recognized. That is one of the things which the Electrical Research Association have done for us. They have clearly defined three grades of bakelite products—varnished paper and varnished fabric products—and also two grades of varnished-paper and varnished-fabric products made with natural gums and resins. With regard to the production of varnished-paper products using a highly non-porous paper of the grease-proof variety, as suggested by Mr. Dunton, that of course requires special precautions, and the success of this is dependent to some extent upon the purities of the gums used.

Mr. Collins and other speakers refer to the question of tracking. He asks what particular kind of bakelite was used in making the test mentioned at the top of the illustration showing specimens after the fuse-wire test. During the course of these tests, we tested nearly

every bakelite on the market, and with one exception they all broke down on either the first or second exposure, whereas vulcanized fibre and some of the more despised insulating materials stood up to 20 tests. With regard to the pressure test being a cause of tracking, the ordinary pressure test, made with about 10 kW, to which Mr. Collins refers, will, of course, not have any effect. A flash can be produced across the surface and there will be no ill-effects, but for power work we think that pressure tests using a greater amount of power are desirable. When one applies something like 400–500 kV with 500 kW behind it, serious damage is likely to result if anything goes wrong.

Mr. Collins also suggests that insulating materials of the bakelite class should not be used in positions where they are exposed to power arcs or heavy discharges. We cannot always cater for that. If we take, for instance, the case of a high-tension bushing on a 110 000-volt transformer which is connected more or less directly to the overhead lines, and as with such high voltages it is often common practice not to employ lightning arresters, it will be agreed that we are liable to get a discharge across the terminal. This may possibly be caused by surges due to lightning.

As pointed out by Mr. Symons, the tracking effect can be minimized by suitable protective varnishes, or, as mentioned in a communication from Mr. Warren, by the use of superimposed layers of shellac-bonded material on a synthetic bonded interior. Experimental work to eliminate tracking is also being done, but the use of hydroquinone and other methods have not up to the present made sufficient advance to warrant adoption.

In a communication from Mr. Holbrook, it is suggested that British-manufactured synthetic materials are not up to the standard of those manufactured in Switzerland or America. Fortunately, we have been engaged on the testing of a large number of synthetic boards and tubes and can definitely state that material is being manufactured in this country giving test-results actually superior to those obtained on materials from the sources mentioned.

Both Mr. Rosen and Mr. Collins have touched on the subject of mica. We sympathize with them concerning the variation that exists in mica splittings and we hope that a definite grading of this material will soon be finally achieved. Mr. Rosen also refers to the expansion and contraction of the conductor in mica-insulated machines. He is there touching on what is a very real trouble, particularly in the high-speed machine with long cores. We think that modern methods of manufacture and the control of processes are largely getting over that trouble. We appreciate Mr. Symons's remark concerning the necessity for steam pressing of turbo bars—this of course is always done and very materially helps in raising the percentage by volume of the mica content, which has been mentioned by several of the speakers.

On the subject of porcelain, Mr. John and other speakers have referred to the remark in the paper taxing British porcelain manufacturers with not being so energetically engaged on research work as some of those in other countries. We are afraid that in the past there has been a tendency for British manufacturers to neglect research, and it is therefore very encouraging to note that active steps are now being taken to remedy this. All of those present at this meeting will realize what British brains and British scientists have done for the whole industry, and that we have led and still lead in insulating materials. The paper was not intended to belittle what has been done and what is being done, but rather to urge that the effort must be kept up. Much research needs to be done if we are going to keep the place we have hitherto held.

Several speakers have mentioned the omission of various subjects, such as the treatment of wood for insulation purposes, the use of asbestos, etc., but each of these subjects would provide matter for full discussion in detail and the paper has had to be confined to a more general consideration of the improvements effected in insulation practice of recent years.

North-Eastern Centre, at Newcastle, 14 December, 1925.

Mr. J. Rosen: In my opinion the authors do not give British producers of insulating material the credit they deserve; a good deal of research has been carried out here during past years, and is still being carried out, though perhaps it has not been so much advertised as elsewhere. Engineers responsible for the operation of electrical machinery are naturally the most severe critics and undoubtedly they have done a great deal from their experience to help the manufacturer; after all, the best place for research is in plant under operating conditions. Although much of the matter published may be considered to be only of academic interest, it undoubtedly forms a basis for practical investigation and, by increasing our understanding of the problems, will lead to practical improvements which will enable the known insulation to be used for even higher voltages than at present. Naturally, it is the one weak spot in the insulation that limits the stress to which the remainder of the plant is subject. If we could be assured of the complete uniformity in our insulating materials, we should be able to turn out more efficient plant at lower cost. There are three papers * which might with advantage be added to the authors' already fairly complete list; they give a simple conception of the mechanism of breakdown. The authors refer to the practical conditions of testing before putting electrical plant on load for the first time. For the largest machines it is to be recommended that the windings should be dried either on short-circuit or otherwise before pressure-testing. By this means the volatile matter or moisture is driven off and the windings are better able to withstand the test. These precautions are essential where plants are wound on site. Wherever possible, alternator stators should be

Steinmetz: "High-Voltage Insulation," *ibid.*, 1924, vol. 43, p. 36.

wound completely in the works to enable the windings to be thoroughly dried. It is worth a little thought and expense to overcome transportation difficulties to attain this result. On the question of mica products, mica has the inherent disadvantage of its poor mechanical properties, and steps have always to be taken to ensure that under all conditions of temperature the mica insulation is so prepared that it will not flake. In most designs it is very necessary to provide some form of mechanical support. I agree that there should be a limit in the amount of class A allowed in class B material, and should be interested to hear if the percentage of mica of 35–40 which is recommended for class B insulation is the percentage in the micafolium only, and does not take into account the possibility of using other material on the outside of the insulating tube for protection. If the authors do not include the latter, the figure appears to be low; I should expect it to exceed 50 per cent in a reasonable design. The authors refer to the use of casein as a binding base for a group of moulded materials. Have they had experience in the use of such material? I understand that it is inflammable, but I have not been able to find out under what conditions it failed. Another subject for investigation, which no doubt has been carried out by individual firms, is the comparative advantage of hard moulding insulation, and an insulation containing oil which enables the insulation to retain its properties of flexibility. There are advantages perhaps to be claimed for both. I have found that where long conductor bars have to be insulated for high voltages it is advisable to have some form of flexible varnish between the insulating tube and the conductor, or to use a flexible insulation to enable it to allow for the unequal expansion of copper, iron and the insulation at different temperatures. Otherwise there is the danger of the insulation cracking under load conditions.

Mr. F. H. Williams: One of the most interesting post-war developments of the big electrical and other manufacturing concerns of this country is that of the research department, which has now become an integral part of the manufacturing machine, with the result, for example, that many manufacturing processes are now controlled or supervised by technical men specially trained for the job. A day spent in a research department such as that with which the authors are connected is most interesting. Although the paper contains a considerable amount of valuable data, particularly from the point of view of the manufacturers, I am rather disappointed that the paper does not contain more information regarding recent improvements in insulation for extra-high-tension work. The only reference to this subject appears to be on page 444, where rough figures are given for the diameter and overall length of a condenser bushing for 220 kV. I am also disappointed that the authors have not given some information regarding recent improvements in testing methods. This is a natural corollary to improvements in insulating material and, whilst it could well form the subject of a paper itself, I think that the value of the paper would have been enhanced if the authors had given a résumé of the more recent improvements in testing methods. I had hoped to hear something about dielectric-loss measurements as applied to condenser bushings and also something about high-frequency tests. It is most important in connection with insulation for super-tension work that we should be able to determine by tests not only whether the material is likely to break down in service but also what is the actual factor of safety. For e.h.t. condenser bushings such as those referred to by the authors, the usual over-potential test is, I consider, practically useless as a test to determine whether the bushing will be satisfactory in service. In my opinion the only satisfactory method of testing such bushings is that involving an actual dielectric-loss measurement, and I believe that this will become a standard test for such apparatus in the near future. With regard to the testing of insulating oils referred to on page 447, I should like to ask the authors whether the test referred to has been approved by the B.E.S.A. Sub-Committee on Insulating Oils. There have been many attempts to find a substitute for the Michie sludge test, and some of these appeared at first sight to be very attractive but were subsequently found to give misleading results. Such a test was one which aimed at reducing the lengths of the test by substituting oxygen for air. This, it has been found, is not a test for sludge but for acid-forming properties. It is therefore of primary importance that any test put forward as a substitute for the present sludge test should be examined exhaustively before being adopted as a substitute for the present standard sludge test. I should also like to ask whether the vertical oil test-gap has been approved by the B.E.S.A. Sub-Committee. I looked into this matter some time ago and was informed that the vertical gap does not always give the same results as the horizontal gap. With regard to fibre, it would be very helpful if the authors could say how one could always ensure that a satisfactory variety was used, as many of the fibres at present on the market have practically no insulating properties and are liable to lead to trouble due to shrinkage.

Mr. T. Carter: The authors have covered the ground so thoroughly that little is possible by way of discussion except comment on details. What they say in Section 3 of the paper about the danger of the flash test is most valuable as a reminder of a too-often forgotten risk run in the application of the test, and I should like to emphasize the importance of keeping it in mind. Enamel insulation, mentioned in Section 4 (*a*), Sub-Section (3), under the heading of "Coverings for Wires," has been, in my experience, of doubtful value for anything but windings of purely cylindrical form. Anything approaching a sharp corner in a former is more or less fatal, and leads too often to breakage of the enamel. The effectiveness of the insulation is probably greatly increased by adding a single cotton covering to the enamel covering. Towards the end of Sub-Section (5) of Section 4 (*a*), leatheroid is mentioned as an excellent material for slot linings. It should be made quite clear that this is not a recommendation of leatheroid for slot insulation, and that it is referred to merely as providing a lining with a smooth and slippery surface, so that, when used in addition to the real slot insulation, it prevents damage when the coil is slid into the slot. Leatheroid alone has been used for the slot insulation of very small

machines, where the room is very limited, but except in such special circumstances it would obviously be bad practice to depend on it as the sole insulator. Coil-winding machines are mentioned in Section 5 [(*a*) and (*b*)], under the heading of "Coil Insulation"; they are admirable for their purpose, no doubt, but it may be pointed out that their full advantage is secured only when a large amount of repetition work can be done on them, and that if, on the other hand, an attempt is made to use them for single coils or only a few coils of one winding, the time spent in rearranging the setting of the machines when the winding is changed may seriously diminish their economy. Later in Section 5 [(*a*) and (*b*)], under the heading of "Assembling, Taping, etc.," reference is made to micanite for use between commutator segments. It appears to be growing more and more difficult to get even built-up micanite, at a reasonable price, that will wear evenly with the copper, and undercutting of the micanite, with its attendant disadvantages, is more and more frequently resorted to. As a mechanical process, it seems quite wrong to run an inflexible carbon brush, however good the spring behind it, on a cylindrical surface full of gaps; but presumably the exhaustion of supplies of the material that would make it unnecessary may have to be regarded as an indication that the second-best practice must be adopted. The value of the process specifications referred to in Section 5 (*c*) cannot be overestimated. Even with them something is left on which to exercise skill and judgment in supervision; but without them too much hangs on the presence of some particular person whose going away would so interrupt things that an entirely fresh start might have to be made. They are like family recipes, or even heirlooms, passing from one generation to another, and not to have them would be to head straight for failure in essential processes, and would result in constant lack of certainty in manufacture. Finally, I commend to users of electrical plant the plea in Section 5 (*d*) for their close co-operation with the manufacturers, to the end that both of them may profit from the experience of each. The user sees the plant in practical operation, and he looks at it thus from an angle entirely different from that of the designer or manufacturer. He may see things that could obviously be improved, and it is a real kindness on his partto point them out, so that under the scrutiny of all who are interested, and with the collective thought of many different persons applied to it, that which is bad may disappear, and that which is good may become still better than it was.

Mr. J. W. Jackson: Although the paper is of very great value from the point of view of the choice of materials for insulating apparatus, I am unable to agree with the remarks made under the heading "Standardization of Methods of Testing Insulation." The method usually obtaining is that of drying out and testing for insulation values at definite intervals. After the megger indicates infinity for a length of time the contractor is usually prepared to agree to a power voltage test to be applied while the machine is still hot. The particular value of this method of testing is that the apparatus is tested under conditions more nearly analogous to those that will obtain in service, as all apparatus is more or less hot in service. The method suggested by Mr. Hartshorn, viz. the bridge method of measuring leakage losses, is one that savours too much of the laboratory. What is the authors' opinion as to the value of bakelized insulation when subjected to service conditions where employed on the insulation of, say, switchgear which is occasionally called upon to function even with water in the oil? It is often a difficult matter to prevent water finding its way into the oil, and, so far as can be seen at present, the small amount of water with which oil will combine appears to be sufficient to cause the more or less complete deterioration of insulation where applied directly on conductors charged at over 3 000 volts. This has been observed on insulators made during the past 12 years. The disintegration allows the flat sheet and also cylindrical type of insulation to become separated into its component layers and in addition very much enlarged and at the same time softened, mechanically weak, and of a low electrical insulation value, allowing leakage to occur between layers. These remarks apply to insulation manufactured more than 4 years ago. It is at the same time realized that, provided frequent inspection is made and any doubtful pieces are immediately replaced, this type of insulation is still the most satisfactory from most points of view, in that it is very much more robust than porcelain, and, if it fails, does so at a comparatively low rate of speed, thus allowing sufficient time for replacements before serious risk is being run.

Messrs. K. G. Maxwell and **A. Monkhouse** (*in reply*): Mr. Rosen's statement that in our paper we have given insufficient credit to British producers of insulating materials, must be contrasted with his addition to our bibliography of three American works. We are, however, obliged to him for drawing our attention to these. Mr. Rosen and Mr. Jackson criticize our remarks upon the danger of the flash test immediately following the initial temperature run; Mr. Carter, however, agrees with us. Our point is that, even after sufficient drying-out to permit that initial temperature run, the immediate imposition of an overpotential test on complex insulation, from which certain volatile matter cannot have been completely freed but merely displaced from the hotter portions (only determined by actual running conditions) and therefore not yet "dried out" from the cooler end-windings, is an unnecessarily severe test condition. In giving the figure of 45 per cent mica by volume in wraps on, say, alternator bars, this includes the whole of the insulation on the bar as passed into the slot, and the volumetric measurement is taken on the finished bar ready for insertion. We agree with Mr. Rosen's experience of allowing for flexibility between copper and iron with the long slot-length of the modern machine. He refers to the inflammability of casein-bonded materials, but "Galolith" (mentioned in the paper) and "Erinoid" are two superior forms of such products which are practically non-inflammable. We have no experience of their extensive use yet, but as their true properties become recognized they will undoubtedly find a place amongst moulded parts.

Mr. Williams is right in suggesting that details of improved methods of testing would form the subject

of a separate paper, and we only make a plea for the standardization of the method of testing insulating materials at any stage in their production or use, as well as for standard nomenclature.

On the question of "factors of safety" for electrical tests, we do not consider that the various methods of making tests are to-day sufficiently defined to enable us to use such a term. The Nuttall test on insulating oils has not been approved by the B.E.S.A. Sub-Committee on Insulating Oils, probably because it has not been extensively developed, and we agree with Mr. Williams that it is of the utmost importance to establish clearly the relation between such a test and the life conditions of insulating oils in modern plant. The B.E.S.A. Sub-Committee have expressed the opinion that with good average quality of insulating oil it is immaterial whether the vertical or horizontal gap be used, and a suitable test gap of the vertical type has already appeared on the market. With regard to fibre and the necessary tests to ensure quality, B.E.S.A. Specification No. 216 has just been issued covering vulcanized fibre, but we readily agree with Mr. Williams that many of the fibres at present on the market have extremely indifferent properties viewed from the point of view of a stable product suitable for insulating purposes. As in the case of several other similar materials which have had trade uses quite apart from those of the electrical engineer, the only satisfactory method of ensuring reliable material is to develop a source the consistency of which has been established by a series of tests and observed ageing conditions, and to endeavour to keep the supplier tied to an established source and so to control the manufacture, transport and storage of the material that rejections from the consumer's point of view are kept down to reasonable figures. It can be said that makers are now appreciating this condition of supply, and considerable improvement has been effected through such channels. Freedom from shrinkage depends almost entirely upon this procedure and upon keeping the material, up to the actual time of treatment, to a known moisture content bearing an agreed relation to the natural absorption percentage (which may vary from 4 per cent to 20 per cent and even higher) for that particular density of material.

Mr. Carter is right in assuming that in referring to slot "linings" we mention leatheroid as a mechanical protection and not as an insulator. He speaks of the difficulty of getting uniform wear between segmental micanite on commutators and the copper, but modern practice confirms the use of undercut micanite segments on commutators and permits the employment of a harder micantite of lower bond content, giving easier assembly to permanent dimensions of the commutator and reducing the cost of "seasoning."

Mr. Jackson raises an interesting point in connection with the deterioration and ultimate failure at low voltage of bakelite products due to moisture absorption and disintegration. It is our opinion that this class of material, namely a synthetic resin varnish-paper product, has, since its development some 18 years ago, up to recent years certainly given trouble in the manner described by Mr. Jackson. Present-day high-grade bakelite products, however, where the raw materials have been closely watched and complete bakelization has taken place, may be considered to be unaffected by moisture under service conditions, although with severe exposure to moisture they are hygroscopic to between 3 and 4 per cent. Even under these latter conditions, however, the material will not separate along the laminæ and will retain its electrical properties with age. This requires the closest supervision and control in the whole of the manufacturing stages, both of the gum itself and of the composite material, and only the highest-grade products can be considered in this category. The mechanical advantages, however, of using such a material have not been unduly stressed by Mr. Jackson.

We are glad to hear that both Mr. Rosen and Mr. Carter advocate the linking up of the operating engineer's experience with that of the designer, and we should like to commend to the notice of the members the wide possibilities of using the Institution's discussions throughout the country as a channel whereby valuable exchange of experiences of electrical machinery can be debated with mutual advantage.

THE EFFECT PRODUCED ON THE PERMEANCE OF A LAMINATED POLE-CORE BY THE INSERTION OF A SOLID STEEL FIXING-PIECE.*

By B. HAGUE, M.Sc., Associate Member.

(*Paper first received* 18*th September, and in final form* 18*th November,* 1925.)

SUMMARY.

The object of the paper is to discuss the effect produced on the permeance of a laminated pole-core which has been perforated with an axial circular hole into which a solid steel fixing-piece or plug is inserted to receive the bolts which attach the core to the yoke. The theory of a core in which the plug fits perfectly in the hole is first examined, and curves for the permeance calculation are prepared. The theory is then extended to apply to a plug which fits loosely in the hole, the influence of imperfect fit being shown by a numerical example.

The application of the theory in practical cases is shown, in general, to be satisfactory. In the extreme example of pole-cores used in water-wheel generators, where numerous secondary matters have to be considered, the discrepancy between theory and practice is explained. The utility of the theory in calculating the permeance of transformer limbs consisting of laminæ clamped together by insulated bolts is shown, and uses in certain problems of current conduction, e.g. in a perforated busbar, are suggested.

(1) INTRODUCTION.

The object of this paper is to describe some solutions of certain problems in magnetic design which have a practical interest in connection with particular forms of construction used in dynamo-electric machinery and related apparatus.

It is the practice of some manufacturers to construct salient poles, especially for small dynamos, in the way shown in Fig. 1 (*a*). The pole-core and shoe is made up of a pile of stampings riveted or bolted together. The assembled pole is attached to the yoke by inserting through the laminæ a solid bar or pin of steel of square or circular cross-section and passing the fixing screws through the yoke into this steel piece, which is tapped to receive them. A better construction is thus obtained than would be the case if an attempt were made to drill and tap the pole to take the fixing screws directly. The problem presented by this construction is a troublesome one for the designer, since the insertion of the steel piece through the laminæ introduces considerable uncertainty into the calculation of the permeance of the path of the main flux through the pole-core. The complication of the problem is such that a rigorous mathematical solution is out of the question, but the author has frequently been asked by designers if it would not be possible to obtain even an approximate solution which would indicate the magnitude and general nature of the effect to be expected. It is the purpose of this paper to give such an approximation and to discuss its practical value.

Electrical design contains a number of problems of a similar character. For example, the laminated limbs of a transformer core are held together by insulated steel bolts as shown in a simple instance by Fig. 1 (*b*). It is of practical interest to inquire what will be the influence of the perforation of the laminæ and the partial filling of the hole by magnetic material upon the permeance of the limb, or of the section thereof associated with one bolt and comprised between the chain-dotted lines.

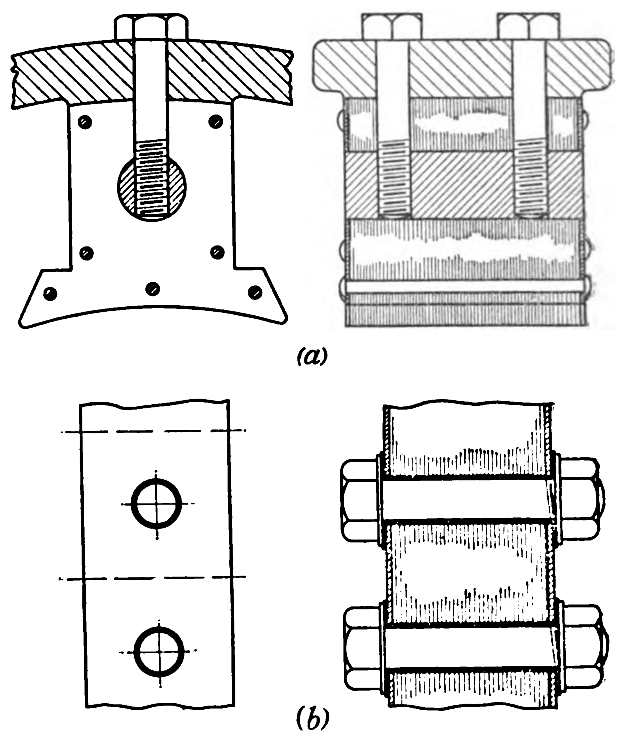

FIG. 1.—Diagram showing arrangement of steel fixing-piece in a pole-core, and of insulated bolts in a transformer limb.

In either of these problems an exact solution cannot be found, for two important mathematical reasons. The first is the extreme analytical difficulty of satisfying exactly the conditions imposed by the *geometry* of the magnetic masses. The second is the practical impossibility of dealing mathematically with the properties of

* The Papers Committee invite written communications (with a view to publication in the *Journal* if approved by the Committee) on papers published in the *Journal* without being read at a meeting. Communications should reach the Secretary of the Institution not later than one month after publication of the paper to which they relate.

ferromagnetic materials. It becomes necessary, therefore, to lay down three definite assumptions in order to bring the problem within the scope of mathematical analysis. These assumptions are as follow :—

(i) The perforated material is supposed to extend to infinity in all directions.

(ii) The pin or plug is assumed to have infinite axial length and is supposed to be situated centrally within the hole, which it may partially or completely fill.

Solutions restricted by these geometrical assumptions will closely apply to a pole-core which is of large peripheral width and radial length in comparison with the diameter of the steel pin, or to a transformer leg in which the width of the plates and the spacing of the bolts are large compared with the diameter of bolt. The flow of flux will, moreover, be two-dimensional, and will not be seriously different from that actually occurring. The precise effect of these assumptions in limiting the application of the solutions to practical instances will be discussed at a later stage.

The third and most serious assumption is of a physical nature and is as follows :—

(iii) The permeable materials of which both perforated mass and plug are composed are assumed each to have constant permeability and to be magnetically isotropic.

Actual magnetic materials are ferromagnetics, in which the relation of magnetizing force to magnetic induction is extremely complex, following the law of the magnetic hysteresis loop; this relation is not expressible in mathematical notation. The assumption means that the materials are supposed to be paramagnetics in which, throughout the region of each material, the permeability is constant and independent from point to point of the magnetic induction, i.e. the magnetization characteristics of the materials are linear. Such magnetic isotropy is approximately found in ferromagnetic materials when worked at very high or very low inductions, since the permeability is then not much influenced by the actual value of the induction. The solutions found under the paramagnetic assumption, however, fortunately enable limits to be assigned between which all practical ferromagnetic cases must lie.

In the following Sections solutions are worked out for two cases, (*a*) where the plug fits tightly within the perforated mass, so that only two media are involved, and (*b*) where the plug is separated from the mass by an annular space of air or other magnetically indifferent medium, involving three media.

(2) Perforated Mass with Close-Fitting Plug.

In Fig. 2 take the origin at the centre of the circular cross-section of the plug and use polar co-ordinates r, θ in the plane of the paper. The cylindrical plug has a uniform permeability μ_1 and cuts the paper normally; it is of infinite axial length. Outside the plug, and magnetically contiguous with it on the cylindrical surface, is the medium of permeability μ_2 extending to infinity in all directions both in and perpendicular to the plane of the paper. This represents the material which has been perforated with a circular hole of radius a and infinite axial length, the hole being filled with material of permeability μ_1.

At a considerable distance from the origin a uniform magnetizing force H_0 is supposed to be impressed in the medium μ_2 from right to left. Thus at a very great distance from the plug there exists in the perforated mass a uniform field of induction density $B_0 = \mu_2 H_0$ directed parallel to XO.

In virtue of the presence of the magnetic field, the distribution of which in the neighbourhood of the plug is to be investigated, magnetic potentials Ω_1, Ω_2 must exist in the two media. These potentials must be such as will satisfy Laplace's equation of continuity in their respective regions, viz.

$$r\frac{\partial}{\partial r}\left(r\frac{\partial \Omega}{\partial r}\right) + \frac{\partial^2 \Omega}{\partial \theta^2} = 0 \quad . \quad . \quad . \quad . \quad (1)$$

where $\Omega = \Omega_1$ within the plug and $\Omega = \Omega_2$ outside it. Moreover, at the interface $r = a$ between the two

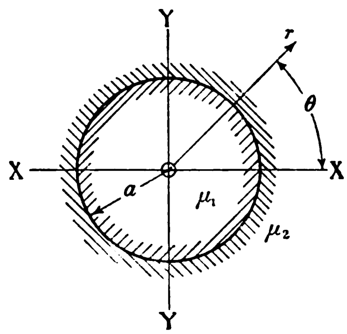

Fig. 2.—Co-ordinates for the field in a perforated mass with a close-fitting circular cylindrical plug.

media the potentials must ensure (*a*) equal tangential magnetic forces in the media,

$$-\left(\frac{1}{r}\cdot\frac{\partial \Omega_1}{\partial \theta}\right)_{r=a} = -\left(\frac{1}{r}\cdot\frac{\partial \Omega_2}{\partial \theta}\right)_{r=a} \quad . \quad . \quad (2)$$

and (*b*) equal radial magnetic inductions in the two materials,

$$-\mu_1\left(\frac{\partial \Omega_1}{\partial r}\right)_{r=a} = -\mu_2\left(\frac{\partial \Omega_2}{\partial r}\right)_{r=a} \quad . \quad . \quad (3)$$

Experience suggests that in a problem which has the central symmetry just postulated the solution must be sought in terms of two-dimensional cylindrical harmonics, the most general expression for a potential being

$$\Omega = \sum_1^\infty r^n(P_n \cos n\theta + Q_n \sin n\theta) + \sum_1^\infty r^{-n}(R_n \cos n\theta + S_n \sin n\theta)$$

where n takes integral values and the coefficients P_n, Q_n, R_n and S_n are independent of r and θ and are to be determined. It is clear from the physical conditions of the problem that the magnetic force in either medium

must be finite, i.e. $-\partial\Omega/\partial r$ and $-\partial\Omega/r\partial\theta$, the components of H, must remain finite, Ω being interpreted as Ω_1 inside and as Ω_2 outside the plug. Again, since the flux passes from right to left it is also clear that the axis YOY is a line of symmetry for the magnetic potential, the latter being zero thereon. To the right of YOY, whether above or below the axis of X, the potential is positive and increasing; to the left it is negative and increasing. It is obvious, therefore, that both Ω_1 and Ω_2 have symmetry in the four quadrants determined by a cosine law; hence sine terms are inadmissible and the general expression becomes

$$\Omega = \sum_1^\infty [P_n r^n + R_n r^{-n}] \cos n\theta$$

Inside the plug r has values lying between 0 and a; hence for the magnetic force to remain finite, terms involving r^{-n} must vanish, so that

$$\Omega_1 = \sum_1^\infty A_n r^n \cos n\theta \quad . \quad . \quad . \quad . \quad (4)$$

where A_n is written in place of P_n of the general form. Again, in the material outside the plug r lies between a and infinity; hence the magnetic force will only be finite if all the terms involving r^n vanish except that for which $n = 1$, hence

$$\Omega_2 = P_1 r \cos\theta + \sum_1^\infty \frac{R_n}{r^n} \cos n\theta \quad . \quad . \quad (5)$$

The coefficients A_n, P_1 and R_n can now be easily found from the boundary conditions.

The radial and tangential components of magnetic force at an infinite distance, where the field has the uniform value H_0 from right to left, are, from equation (5)

$$-H_0 \cos\theta = -\left(\frac{\partial\Omega_2}{\partial r}\right)_{r=\infty} = -P_1 \cos\theta,$$

$$H_0 \sin\theta = -\left(\frac{\partial\Omega_2}{r\partial\theta}\right)_{r=\infty} = P_1 \sin\theta;$$

whence $$P_1 = H_0$$

Substituting equations (4) and (5) in equations (2) and (3) gives

$$\sum_1^\infty n A_n a^{n-1} \sin n\theta = H_0 \sin\theta + \sum_1^\infty n \frac{R_n}{a^{n+1}} \sin n\theta$$

$$\mu_1 \sum_1^\infty n A_n a^{n-1} \cos n\theta = \mu_2 H_0 \cos\theta - \mu_2 \sum_1^\infty n \frac{R_n}{a^{n+1}} \cos n\theta$$

Comparing coefficients we get:—

$$\left.\begin{aligned} A_n a^{n-1} &= R_n/a^{n+1} \\ \mu_1 A_n a^{n-1} &= -\mu_2 (R_n/a^{n+1}) \end{aligned}\right\} \text{when } n > 1$$

$$\left.\begin{aligned} A_1 - (R_1/a^2) &= H_0 \\ \mu_1 A_1 + \mu_2 (R_1/a^2) &= \mu_2 H_0 \end{aligned}\right\} \text{when } n = 1$$

Solving these equations makes

$$A_n = R_n = 0; \quad A_1 = \frac{2\mu_2 H_0}{\mu_2 + \mu_1}; \quad R_1 = H_0 a^2 \left(\frac{\mu_2 - \mu_1}{\mu_2 + \mu_1}\right)$$

which, on substitution in equations (4) and (5), gives

$$\Omega_1 = \frac{2\mu_2}{\mu_2 + \mu_1} H_0 r \cos\theta \quad . \quad . \quad . \quad . \quad (6)$$

$$\Omega_2 = H_0 \left[r + \frac{a^2}{r} \left(\frac{\mu_2 - \mu_1}{\mu_2 + \mu_1}\right) \right] \cos\theta \quad . \quad . \quad (7)$$

Now the magnetic potential of a uniform field H_0 parallel to XO is clearly given by $H_0 r \cos\theta$; hence the field within the plug is also uniform and due to a potential $2\mu_2/(\mu_2 + \mu_1)$ times as great. The field inside the plug is therefore uniform, parallel to XO, and has a magnetic force $2\mu_2 H_0/(\mu_2 + \mu_1)$; the induction density in the plug is therefore $2\mu_1\mu_2 H_0/(\mu_2 + \mu_1)$, or $2\mu_1/(\mu_2 + \mu_1)$ times as great as the induction in the external mass at a great distance from the plug. In other words, the magnetic force in the plug is μ_2/μ times the value in the mass at a distance from the hole; whilst the induction therein is μ_1/μ times as great as the induction imposed on the mass at infinity, where μ is written for the average of the permeabilities of the plug and external mass.

Distribution of the field.—The magnetic equipotentials can be traced from equations (6) and (7) by writing $\Omega_1 =$ constant and $\Omega_2 =$ constant in the two media, successive equipotentials being characterized by equal increments in the appropriate potential. Greater interest applies to the lines of magnetic force (or to the lines of induction, which in paramagnetic materials are related to the former by a mere numerical factor) which cut the lines of constant magnetic potential at right angles. By the theory of orthogonal trajectories, the value of $d\theta/dr$ on an equipotential passing through any given point must be equal to the value of $-dr/(r^2 d\theta)$ on the line of force or induction intersecting the equipotential normally at the same point. Applying this within the plug, from equation (6) we get

$$\frac{d\theta}{dr} = \frac{1}{r} \cdot \frac{\cos\theta}{\sin\theta}$$

on the equipotential, so that on the orthogonal

$$-\frac{1}{r^2} \cdot \frac{dr}{d\theta} = \frac{1}{r} \cdot \frac{\cos\theta}{\sin\theta}$$

which on integration gives as the equation to the lines of induction in the plug,

$$r \sin\theta = \text{constant} \quad . \quad . \quad . \quad . \quad (8)$$

which is a uniform field parallel to XO.

Similarly, in the perforated mass from equation (7) we have

$$\frac{d\theta}{dr} = \frac{1 - (a^2/r^2)[(\mu_2 - \mu_1)/(\mu_2 + \mu_1)]}{r + (a^2/r)[(\mu_2 - \mu_1)/(\mu_2 + \mu_1)]} \cdot \frac{\cos\theta}{\sin\theta}$$

Putting this equal to $-dr/r^2 d\theta$ and integrating, gives as the equation to the lines of induction outside the plug

$$\left[r - \frac{a^2}{r} \left(\frac{\mu_2 - \mu_1}{\mu_2 + \mu_1}\right) \right] \sin\theta = \text{constant} \quad . \quad (9)$$

The lines of induction derived from equations (8)

and (9) have been plotted in Fig. 3 in some typical instances. Fig. 3 (*a*) shows the concentration of the field into the plug when the material thereof is twice as permeable as the surrounding perforated mass; Fig. 3 (*b*) shows the dispersal of the field from the plug when its material is only half as permeable as that of the mass. Fig. 3 (*c*) is the ultimate limiting case of a highly permeable mass perforated by a hole unfilled by permeable material. In all cases it is to be noted that the configuration of the field depends only on the ratio μ_1/μ_2 and not on the absolute values of μ_1 or μ_2; also that the least value of μ_1 or μ_2 is unity.

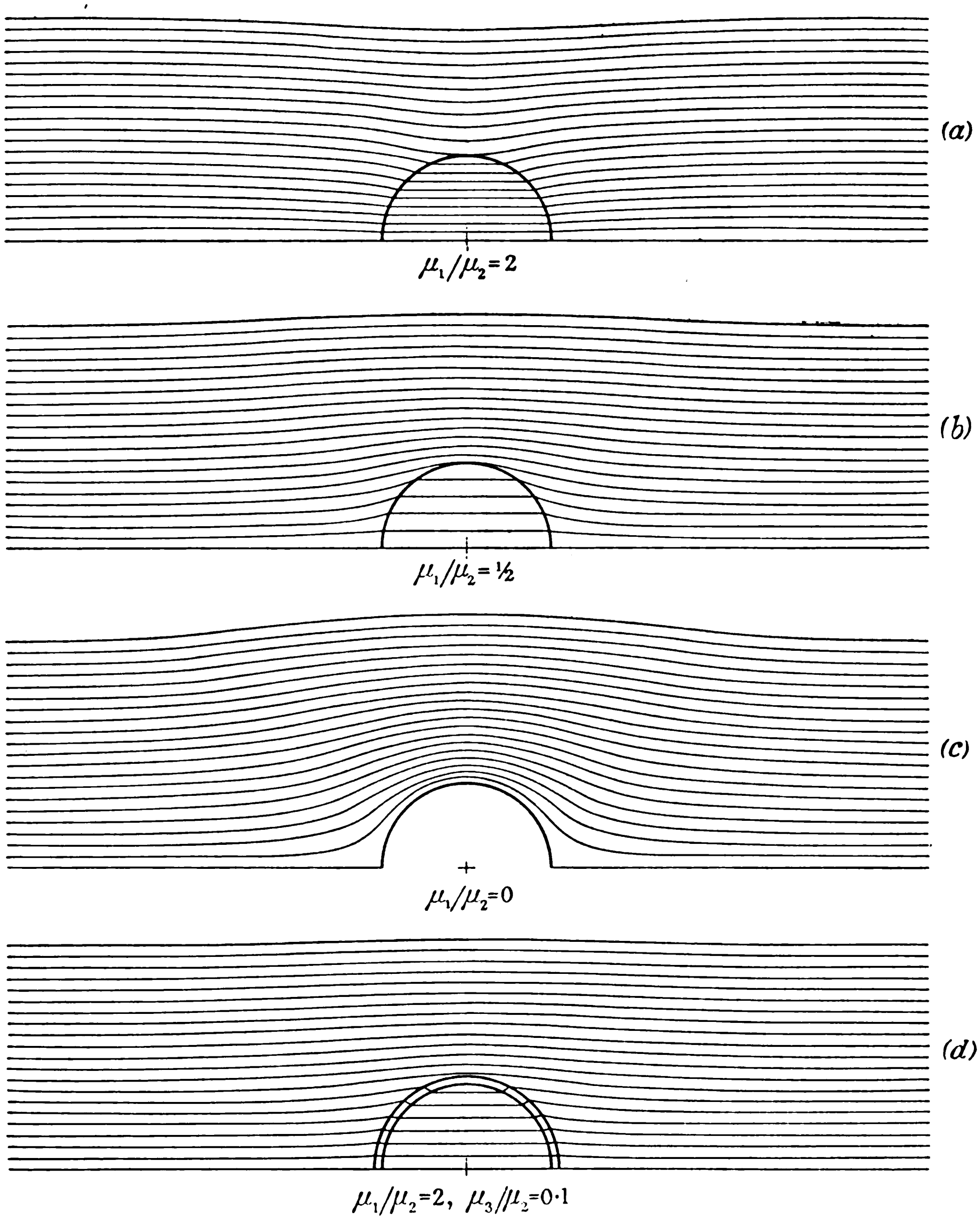

Fig. 3.—Diagrams showing the effect of a plug of circular cross-section on a uniform magnetic field in an iron mass.

Permeance of the field.—Consider a portion of the field bounded by lines of induction which pass through the points $(R, \pi/2)$, $(R, 3\pi/2)$ and by the equipotentials through the points $(l, 0)$, (l, π). Fig. 3 shows that these lines of induction and equipotentials are practically straight lines parallel to OX and OY respectively, provided that R and l each exceed about $3a$. They therefore bound a plate of closely rectangular shape $2R$ cm broad and $2l$ cm long of permeability μ_2; the plate is perforated with a hole of diameter $2a$ completely filled with material of permeability μ_1, as in Fig. 4. It is required to find the permeance of such a plate per cm of thickness parallel to the axis of the hole when a flux flows from right to left in response to the difference of magnetic potential impressed between the ends of the length of the plate.

For brevity write $k = \mu_1/\mu_2$ in equations (6) and (7), then

$$\Omega_1 = \frac{2H_0}{1+k} r \cos\theta$$

$$\Omega_2 = H_0\left[r + \frac{a^2}{r}\left(\frac{1-k}{1+k}\right)\right]\cos\theta$$

In the plug, the magnetic force across the Y axis is

$$-\left(\frac{\partial\Omega_1}{r\partial\theta}\right)_{\theta=\pi/2} = \frac{2H_0}{1+k}$$

showing that the field is uniform between $r = 0$ and $r = a$. The magnetic force across the Y axis in the perforated plate is

$$-\left(\frac{\partial\Omega_2}{r\partial\theta}\right)_{\theta=\pi/2} = H_0\left[1 + \frac{a^2}{r^2}\left(\frac{1-k}{1+k}\right)\right]$$

between $r = a$ and $r = R$.

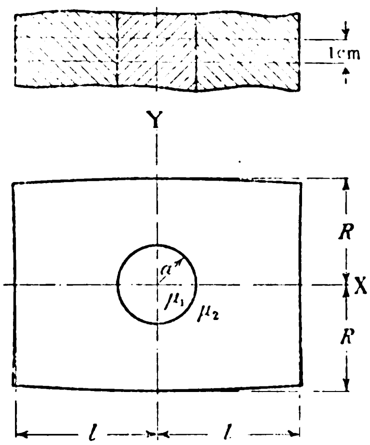

FIG. 4.—Diagram giving the dimensions of an approximately rectangular plate of iron with a permeable plug of circular cross-section.

The magnetic induction across the Y axis is, inside the plug,

$$B_1 = \frac{2H_0}{1+k}\mu_1 = 2H_0\mu_2\frac{k}{1+k}$$

and outside the plug

$$B_2 = H_0\mu_2\left[1 + \frac{a^2}{r^2}\left(\frac{1-k}{1+k}\right)\right]$$

The total flux of induction crossing the Y axis is

$$\Phi = 2\int_0^a B_1 dr + 2\int_a^R B_2 dr = 2H_0\mu_2\left[R - \frac{a^2}{R}\left(\frac{1-k}{1+k}\right)\right]$$

From equation (7) the difference of magnetic potential between l and $-l$ is

$$\Omega = 2H_0\left[l + \frac{a^2}{l}\left(\frac{1-k}{1+k}\right)\right]$$

Hence the permeance per cm axial length is

$$\mathbf{P} = \frac{\Phi}{\Omega} = \mu_2\frac{R - (a^2/R)[(1-k)/(1+k)]}{l + (a^2/l)[(1-k)/(1+k)]} = \mu_2\mathbf{P}' \quad (10)$$

The quantity $\mathbf{P}'$ may be termed the "geometric permeance" of the strip, since it depends merely on the relative dimensions of the plug and the perforated mass and on their relative permeabilities. Now let

$$\alpha = \frac{\text{Central width of plate}}{\text{Diameter of plug}} = \frac{2R}{2a} \quad . \quad . \quad (11a)$$

$$\beta = \frac{\text{Length of plate in direction of flux}}{\text{Diameter of plug}} = \frac{2l}{2a} \quad (11b)$$

$$\gamma = \frac{1-k}{1+k} = \frac{\mu_2 - \mu_1}{\mu_2 + \mu_1} \quad . \quad . \quad . \quad (11c)$$

Then

$$\mathbf{P}' = \frac{\alpha - (\gamma/\alpha)}{\beta + (\gamma/\beta)} \quad . \quad . \quad . \quad . \quad (12)$$

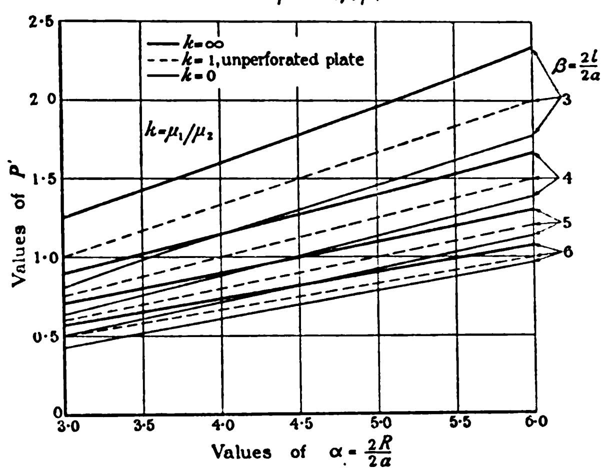

FIG. 5.—Geometric permeance curves for rectangular iron plate with close-fitting permeable plug of circular cross-section. The ordinates give the geometric permeance $\mathbf{P}'$ per cm axial length of the plate shown in Fig. 4.

μ_1 = permeability of plug.
μ_2 = permeability of plate.
$2l$ = length of plate in direction of flux.
$2R$ = central width of plate.
$2a$ = diameter of cylindrical plug.

All possible practical cases must be comprised between the following limits: (i) $k = \mu_1/\mu_2 = 0$, i.e. an infinitely permeable perforated mass with the hole filled by air or other magnetically indifferent medium for which $\mu_1 = 1$; and (ii) $k = \mu_1/\mu_2 = \infty$, i.e. a perforated mass of magnetically indifferent material plugged with infinitely permeable material. All other values of k lie between these limits, and a particular numerical example will be worked out later. For the present, Fig. 5 gives a series of curves showing $\mathbf{P}'$ as a function of α for various values of β with the limiting values of k just mentioned; the range of α and β is not extended below 3 as the validity of assuming the plate to be approximately rectangular then ceases to hold.

If a rectangular plate of breadth $2R$ and length $2l$ were unperforated the geometric permeance would be R/l, i.e. in terms of the hole in the perforated plate, α/β. Straight lines representing the permeance of the unplugged plate are shown in Fig. 5, whence it can be seen that the curves for $k = \infty$ and $k = 0$ lie above and below, respectively, the line for the unperforated plate, as would be expected. The influence of the plug on

the permeance becomes less as the perforated mass becomes larger, since, as is physically obvious, the local influence of the plug on the distribution of the field is then of much less importance, no matter what the relative permeabilities of mass and plug may be.

The effect of the plug is even more clearly shown by plotting the ratio of the permeance of the plugged mass to that of the unplugged plate, as has been done in

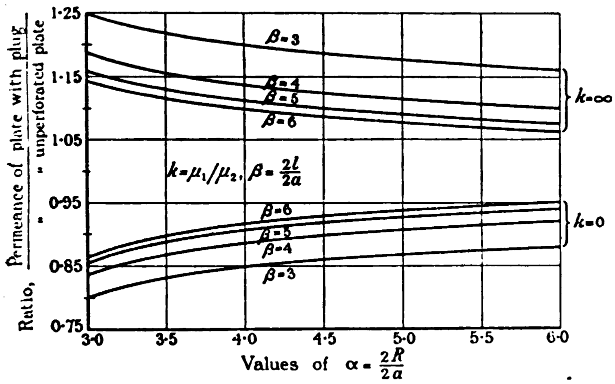

FIG. 6.—Curves showing the ratio of the permeance of a rectangular iron plate with a close-fitting plug to the permeance of the plate when unperforated.

μ_1 = permeability of plug.
μ_2 = permeability of plate.
$2l$ = length of plate in direction of flux.
$2R$ = central width of plate.
$2a$ = diameter of cylindrical plug.

Fig. 6. These curves show the proportion in which the permeance of a nearly rectangular plate is increased or diminished by plugging, plotted for the cases of $k = \infty$ and $k = 0$; all practical cases lie between these curves, probably nearer to the lower curves than to the upper.

(3) Perforated Mass with Loose-Fitting Plug.

The preceding solution differs in one particular from the conditions imposed by practical methods of con-

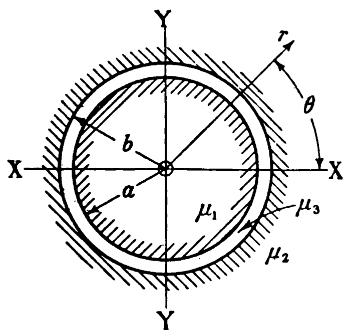

FIG. 7.—Co-ordinates for the field in a perforated mass with a loose-fitting circular cylindrical plug.

struction, in that the plug is assumed to fill completely the hole into which it is inserted. In the construction of a pole-core the steel piece is not necessarily a good machined fit in the hole; in the assembly of a transformer core the bolt is insulated from the laminæ by a tube or liner of paper interposed between bolt and laminated plates. An attempt will now be made to introduce some correction for the incomplete filling of the hole by the plug.

Consider an infinite mass of material of permeability μ_2 through which a hole of radius b has been drilled, a plug of radius a and permeability μ_1 being inserted concentrically therein, as in Fig. 7. The annular space between plug and walls of hole is supposed to contain material of permeability μ_3, usually magnetically inferior both to μ_1 and to μ_2. All other conditions of the problem are identical with those laid down in connection with Fig. 2. By arguments similar to those given in Section (2) appropriate general forms for the magnetic potentials in the three media will be

$$\Omega_1 = \sum_1^\infty A_n r^n \cos n\theta \quad . \quad . \quad . \quad . \quad (13)$$

$$\Omega_2 = H_0 r \cos\theta + \sum_1^\infty \frac{R_n}{r^n} \cos n\theta \quad . \quad . \quad (14)$$

$$\Omega_3 = \sum_1^\infty \left(C_n r^n + \frac{D_n}{r^n}\right) \cos n\theta \quad . \quad . \quad (15)$$

The coefficients can be found by noting that at the walls of the hole the tangential magnetic forces in the μ_2 and μ_3 media must be equal, and likewise the radial components of magnetic induction, i.e.

$$-\left(\frac{\partial\Omega_2}{r\partial\theta}\right)_{r=b} = -\left(\frac{\partial\Omega_3}{r\partial\theta}\right)_{r=b} \quad . \quad . \quad (16a)$$

$$-\mu_2\left(\frac{\partial\Omega_2}{\partial r}\right)_{r=b} = -\mu_3\left(\frac{\partial\Omega_3}{\partial r}\right)_{r=b} \quad . \quad . \quad (16b)$$

Again, at the surface of the plug similar relations for the tangential magnetic forces and radial magnetic inductions in the μ_1 and μ_3 media must hold, viz.

$$-\left(\frac{\partial\Omega_1}{r\partial\theta}\right)_{r=a} = -\left(\frac{\partial\Omega_3}{r\partial\theta}\right)_{r=a} \quad . \quad . \quad (16c)$$

$$-\mu_1\left(\frac{\partial\Omega_1}{\partial r}\right)_{r=a} = -\mu_3\left(\frac{\partial\Omega_3}{\partial r}\right)_{r=a} \quad . \quad (16d)$$

Substituting from equations (13), (14) and (15) in these boundary conditions gives the equations

$$H_0 \sin\theta + \sum_1^\infty n\frac{R_n}{b^{n+1}} \sin n\theta = \sum_1^\infty n\left(C_n b^{n-1} + \frac{D_n}{b^{n+1}}\right) \sin n\theta$$

$$\mu_2 H_0 \cos\theta - \mu_2 \sum_1^\infty n\frac{R_n}{b^{n+1}} \cos n\theta = \mu_3 \sum_1^\infty n\left(C_n b^{n-1} - \frac{D_n}{b^{n+1}}\right) \cos n\theta$$

$$\sum_1^\infty n A_n a^{n-1} \sin n\theta = \sum_1^\infty n\left(C_n a^{n-1} + \frac{D_n}{a^{n+1}}\right) \sin n\theta$$

$$\mu_1 \sum_1^\infty n A_n a^{n-1} \cos n\theta = \mu_3 \sum_1^\infty n\left(C_n a^{n-1} - \frac{D_n}{a^{n+1}}\right) \cos n\theta$$

Comparing coefficients we get:—

$$\left.\begin{aligned} R_n/b^{2n} &= C_n + (D_n/b^{2n}) \\ -\mu_2(R_n/b^{2n}) &= \mu_3 C_n - \mu_3(D_n/b^{2n}) \\ A_n &= C_n + (D_n/a^{2n}) \\ \mu_1 A_n &= \mu_3 C_n - \mu_3(D_n/a^{2n}). \end{aligned}\right\} \text{when } n > 1$$

$$\left.\begin{aligned} H_0 + (R_1/b^2) &= C_1 + (D_1/b^2) \\ \mu_2 H_0 - \mu_2(R_1/b^2) &= \mu_3 C_1 - \mu_3(D_1/b^2) \\ A_1 &= C_1 + (D_1/a^2) \\ \mu_1 A_1 &= \mu_3 C_1 - \mu_3(D_1/a^2) \end{aligned}\right\} \text{when } n = 1$$

It is not difficult to show that the first set of equations is satisfied by

$$A_n = C_n = D_n = R_n = 0.$$

Solving the second set of equations, if

$$c = \frac{2\mu_2 b^2}{a^2(\mu_2 - \mu_3)(\mu_1 - \mu_3) - b^2(\mu_2 + \mu_3)(\mu_1 + \mu_3)} \quad . \quad (17)$$

we have

$$A_1 = -2\mu_3 c H_0$$

$$R_1 = \frac{a^2(\mu_1 - \mu_3)(\mu_2 + \mu_3) - b^2(\mu_1 + \mu_3)(\mu_2 - \mu_3)}{2\mu_2} c H_0$$

$$C_1 = -(\mu_1 + \mu_3) c H_0$$

$$D_1 = a^2(\mu_1 - \mu_3) c H_0$$

Substituting these values in equations (13), (14) and (15) we get finally:—

$$\Omega_1 = -2\mu_3 c H_0 r \cos\theta \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (18)$$

$$\Omega_2 = H_0\left[r + \frac{a^2(\mu_1-\mu_3)(\mu_2+\mu_3) - b^2(\mu_1+\mu_3)(\mu_2-\mu_3)}{2\mu_2} \cdot \frac{c}{r}\right]\cos\theta \quad (19)$$

$$\Omega_3 = -cH_0[(\mu_1+\mu_3)r - (a^2/r)(\mu_1-\mu_3)]\cos\theta \quad . \quad . \quad (20)$$

Distribution of the field.—As in the preceding Section, applying the theory of orthogonal trajectories gives for the equations to the lines of induction

$$r\sin\theta = \text{constant} \quad . \quad . \quad . \quad . \quad (21)$$

in the plug;

$$\left[r - \frac{a^2(\mu_1-\mu_3)(\mu_2+\mu_3) - b^2(\mu_1+\mu_3)(\mu_2-\mu_3)}{2\mu_2} \cdot \frac{c}{r}\right]\sin\theta = \text{constant} \quad . \quad (22)$$

in the perforated mass; and

$$\left[(\mu_1 + \mu_3)r + \frac{a^2}{r}(\mu_1 - \mu_3)\right]\sin\theta = \text{constant} \quad . \quad (23)$$

in the annular space.*

The field has been plotted in Fig. 3 (*d*) for the case where $b = 1 \cdot 1a$, $\mu_1/\mu_2 = 2$, $\mu_3/\mu_2 = 0 \cdot 1$; that is to say, taking the annular space to be of air, for which $\mu_3 = 1$, this means that $\mu_2 = 10$ and $\mu_1 = 20$. It will be seen that the presence of the air space makes the concentration of the field unto the plug much less than when the space is absent, as in Fig. 3 (*a*). These values of μ_1 and μ_2 are much smaller than those which occur in a practical case; consequently the proportion of magnetic flux entering the plug is greater than would be found in practice where μ_1 and μ_2 are considerably larger in comparison with μ_3. For example, if no change be made other than that of taking $\mu_3/\mu_2 = 0 \cdot 01$, corresponding to $\mu_1 = 200$, $\mu_2 = 100$ for $\mu_3 = 1$, the field within the air space and plug becomes far too weak to enable it to be shown by tubes of induction of the strength used in drawing the diagrams in Fig. 3. In these more practical circumstances, and still more so as μ_3/μ_2 becomes smaller, i.e. as the iron parts increase in permeability relatively to that of the air space, the field in the main perforated mass becomes almost indistinguishable from that which is found by supposing the permeable plug completely removed. It follows, therefore, that when b/a is not too small, i.e. when there is a fairly considerable space of air or paper between pin and hole, as in the case of an insulated bolt passing through a transformer plate, the field can hardly differ appreciably from that treated in the preceding Section when $\mu_1/\mu_2 = 0$, i.e. an infinitely permeable plate with a hole of radius b in it. Thus in a highly permeable transformer plate the influence of bolt-holes can be allowed for by neglecting the presence of the bolt and calculating the permeance from the curves of Fig. 5 for $k = 0$.

In the case of a pole-core the pin or plug is not insulated from the main mass and the air space is therefore much smaller, being of the nature of a mechanical clearance. It is difficult to lay down any general principle governing this case since the permeance depends on so many factors. A particular numerical example will, however, enable important practical conclusions to be drawn.

Permeance of the field.—As in the preceding Section, the permeance of an approximately rectangular strip of breadth $2R$, length $2l$ and thickness 1 cm can be readily calculated from equations (18), (19) and (20). Calculating the magnetic induction across the Y axis in the plug, in the space, and in the main mass respectively, and determining therefrom the total flux Φ flowing in the plate, gives

$$\Phi = 2H_0\mu_2\left[R - \frac{a^2(\mu_1-\mu_3)(\mu_2+\mu_3) - b^2(\mu_1+\mu_3)(\mu_2-\mu_3)}{2\mu_2} \cdot \frac{c}{R}\right]$$

The difference of magnetic potential across the strip is, from equation (19),

$$\Omega = 2H_0\left[l + \frac{a^2(\mu_1-\mu_3)(\mu_2+\mu_3) - b^2(\mu_1+\mu_3)(\mu_2-\mu_3)}{2\mu_2} \cdot \frac{c}{l}\right]$$

Making use of equation (17), write

$$\frac{a^2(\mu_1 - \mu_3)(\mu_2 + \mu_3) - b^2(\mu_1 + \mu_3)(\mu_2 - \mu_3)}{a^2(\mu_1 - \mu_3)(\mu_2 - \mu_3) - b^2(\mu_1 + \mu_3)(\mu_2 + \mu_3)} = \gamma' \quad (24)$$

Then the permeance per cm axial length is

$$\mathbf{P}_1 = \frac{\Phi}{\Omega} = \mu_2 \frac{R - (b^2\gamma'/R)}{l + (b^2\gamma'/l)} = \mu_2 \mathbf{P}_1' \quad . \quad . \quad (25)$$

* The theory so far given, unrestricted as to the values of μ_1, μ_2 and μ_3, is precisely similar to the theory of a cylindrical magnetic screen. In the present problem μ_3 is small in comparison with μ_1 and μ_2 since the annular space contains air, paper or similar magnetically indifferent material, whilst the remainder of the field is occupied by permeable iron. In the screening problem the precise converse holds; μ_3 is large in comparison with μ_1 and μ_2, these being constants for air. The annular space of the present problem then becomes the wall of a permeable tube. For details of the screening problem see H. du Bois: "On Magnetic Screening," *Electrician*, 1898, vol. 40, pp. 218, 316, 511, 652 and 841, and vol. 41, p. 108.

Now write

$$\alpha' = \frac{\text{Central width of plate}}{\text{Diameter of hole}} = \frac{2R}{2b} \quad . \quad . \quad . \quad . \quad (26a)$$

$$\beta' = \frac{\text{Length of plate in direction of flux}}{\text{Diameter of hole}} = \frac{2l}{2b} \quad (26b)$$

Then
$$\mathbf{P}_1' = \frac{\alpha' - (\gamma'/\alpha')}{\beta' + (\gamma'/\beta')} \quad . \quad . \quad . \quad . \quad (27)$$

which is identical in form with equation (12). It is not possible to show the variation of $\mathbf{P}_1'$ in so simple a way as for $\mathbf{P}'$, since the quantity γ' contains the relative values of b/a, μ_1/μ_2 and μ_3/μ_2, i.e. three parameters. It is necessary therefore to take a specific numerical example to demonstrate the practical application of the results.

(4) Numerical Example.

Take the case of a rectangular plate pierced centrally by a hole, the length of the plate in the direction of the flux being four times the diameter of the hole. Take the breadth of the plate as four times the diameter of the hole and its thickness as 1 cm. These will represent fair practical proportions for a pole-core arranged for the insertion of a steel piece, or for the section of a transformer limb to be associated with one clamping bolt.

the hole, its radius a being given different values relatively to the radius b of the hole. Taking various values of b/a, γ' can be calculated from equation (24)

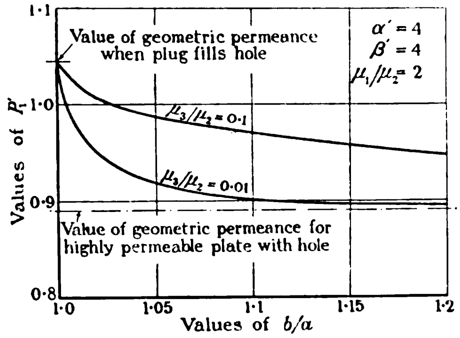

Fig. 8.—Geometric permeance of a rectangular iron plate with a loose-fitting circular cylindrical plug of permeable material.

μ_1 = permeability of plug.
μ_2 = permeability of plate.
μ_3 = permeability of space between plug and plate.
b = radius of hole.
a = radius of plug.
α' = (central width of plate)/(diameter of hole).
β' = (length of plate in direction of flux)/(diameter of hole).

for a given value of μ_3/μ_2. This has been done in the cases of $\mu_3/\mu_2 = 0{\cdot}1$ and $0{\cdot}01$, the resulting values of γ' for $b/a = 1{\cdot}01$, $1{\cdot}05$, $1{\cdot}1$ and $1{\cdot}2$ being calculated

Table 1.

μ_1/μ_2	∞	2	1	0·5	0·1	0·01	0
$\mathbf{P}'$	1·1334	1·0425	1·0000	0·9591	0·9027	0·8846	0·8823

Suppose first that the hole is completely filled with a permeable plug of permeability μ_1, that of the plate being μ_2. Then in equation (12), inserting $\alpha = \beta = 4$ gives for the geometric permeance of the plugged plate

$$\mathbf{P}' = \frac{4 - (\gamma/4)}{4 + (\gamma/4)}$$

Taking values of $k = \mu_1/\mu_2$ between ∞ and 0, calculating γ from equation (11c) and inserting the values in the above expression for $\mathbf{P}'$ enables the latter to be found. Table 1 shows some of the results.

This table shows at once that where the perforated plate is more than 10 times as permeable as the plug, i.e. when μ_1/μ_2 is less than $0{\cdot}1$, the permeance differs by less than 2 per cent from the value obtained on the assumption that no flux enters the plug at all, i.e. for $\mu_1/\mu_2 = 0$. A similar result can be shown to hold for other proportions of length and width of plate to size of plug than that chosen, the statement being more nearly true the wider and longer the plate becomes in comparison with the diameter of the plug.

Turning now to the case of a loose-fitting plug, take a plate of the same proportions as above, i.e. in equations (26a) and (26b) take $\alpha' = \beta' = 4$. Suppose a plug for which $\mu_1/\mu_2 = 2$ to be situated centrally in

and inserted in equation (27). The results are given in Table 2 and are plotted in Fig. 8.

Practical interest centres on two cases, (i) where the ratio b/a is nearly 1, the annular space being of the

Table 2.

b/a	$\mu_3/\mu_2 = 0{\cdot}1$	$\mu_3/\mu_2 = 0{\cdot}01$
	$\mathbf{P}_1'$	$\mathbf{P}_1'$
1·000	1·0425	1·0425
1·01	1·0160	0·9753
1·05	0·9891	0·9177
1·10	0·9686	0·9028
1·20	0·9465	0·8938
∞	0·9027	0·8846

nature of a mechanical clearance; and (ii) where the ratio b/a is of the order of $1{\cdot}2$ or so, where a definite liner is inserted as in the case of an insulated bolt passing through a transformer limb. In the former instance it is sufficiently accurate for design purposes

to suppose the clearance to be negligible and the hole to be totally filled by the plug, provided the clearance is less than 1 per cent of the hole radius. The permeance is then calculable from equation (12) with $a = b$, and the given value of μ_1/μ_2. In the second instance, if the plate has a high permeability exceeding, say, 100 times that of the annular air space, the permeance does not differ appreciably from the value obtained by assuming that no flux enters the hole at all whatever the permeability of the plug may be, taking $a = b$, $\mu_1/\mu_2 = \mu_3/\mu_2 = 0$, and using the curves of Fig. 5 for $k = 0$.

(5) Conclusion.

Experience shows that the modification of permeance given by the above theory for transformer limbs and pole-cores where the diameter of the hole is not greater than about one-third of the width of the perforated plate, agrees fairly well with what is found to occur in practice. There is one practical case of considerable importance in which the reduction of permeance predicted by the theory is much less than is actually found. This occurs with the pole-cores used in water-wheel generators, the plug having a diameter which may exceed three-quarters of the core width. Since the mere fact of perforating the core and filling the hole with a pin is insufficient to account for the reduced permeance it is well to point out the other facts, not included in the theory, which may contribute to the difference between theory and practice. (i) The plug is a large proportion of the width of the core and the theory is not, therefore, strictly applicable to perforations of such a large ratio. (ii) The plug is not concentric with the hole but is pulled down to the bottom thereof. (iii) The magnetic character of the core material in the narrow region left after punching the hole for the reception of the plug may be greatly impaired by the effect of local hardening due to the punching stresses. (iv) The permeability of the steel, especially in the narrow portion on either side of the hole, may be greatly reduced under the influence of the high tensile stress to which the pole-core laminations are subjected when the machine is running at the high peripheral speeds common in water-wheel generators. (v) The theory takes no account of the influence of the bolts which pass longitudinally down the core into the plug; as these bolts may be nearly as large as the plug itself their influence may be considerable. It would thus appear that such an extreme case as this, where the conditions of the theory are not fulfilled and the matter is complicated by numerous practical difficulties, can only be satisfactorily dealt with by exhaustive experimental investigation.

The results given in the paper have been worked out visualizing a magnetic problem. They apply, however, to the flow of electric current in a rectangular strip of metal perforated and plugged with a conducting pin, a conducting liner being interposed in the general case between the pin and strip. The permeabilities μ_1, μ_2, μ_3 are then to be taken as the conductivities of the media, $\mathbf{P}'$ and $\mathbf{P}_1'$ being the geometric conductances. In particular, the results of Section (2) for $k = 0$ enable the conductance of a strip with a hole through it to be found directly from the curves of Fig. 5.

In conclusion the author desires to thank Mr. S. Neville for valuable criticism and advice, and Professor S. Parker Smith for numerous practical suggestions.

POWER STATIONS AND THEIR EQUIPMENT.*

By W. M. SELVEY, Member.

The progress in power station design and equipment, much hindered by the war years, and by the following unsettled time, has now fairly resumed its former rate of rapid advancement. Progressing as it has in the past by waves, of which the crests represent departures towards increasing efficiency, and the troughs periods of consolidation, that is of increasing reliability, we are at the moment confronted with a steeply rising wave-front which may be termed the " High Steam Pressure " wave.

This departure, viewed in a detached attitude or, as our old English writers would have put it, viewed by the curious observer, is one of intense interest. The crests of the waves are always accompanied by increased capital costs—the cost of experimenting. The periods of consolidation show decreasing capital cost, the liquidation of experience. But the troughs are not quiescent, they have strong harmonic ripples.

Since to make a new departure involves increasing costs in one direction, it must be accompanied by some factor which diminishes cost. In power station plant this factor has hitherto been readily available; it may be termed the increase in the economic utilization of material. This obtains with increase in size and higher running speeds. But the harmonics are too important to be ignored. The advance once achieved on the larger scale, the benefits filter down almost proportionately to plant on the smaller scale. This done, during a period of consolidation, a fresh effort is necessary for advance.

Previous to the period under review the former steps of high superheat, low exhaust pressure, and increased ratio of blade speed to steam speed, which commenced with what were formerly large sets, had been very well digested in the smaller sizes. What had hung fire, so to speak, was steam-raising, and hence the protagonists of the " saurian " type of power station soon turned their attention to a development of boilers of a much larger size, and, almost incidentally, at first may it be said, to higher pressures. It will be realized that these simultaneous urges involved conflicting considerations. Thanks, however, to the special conditions and enterprise of the United States companies, every assistance was readily given to the development of size.

Simultaneously with size came the question of handling large quantities of fuel and increasing the temperature of combustion. Mechanical stokers were a little slow to respond to the new demands, and, moreover, engineers were instinctively feeling for a new outlook. The achievements of gas- and oil-firing were before them. For years they had dreamed of handling coal under similar combustion conditions. Diesel had dreamed of doing this direct in his earliest engine. Much good work had been done in cement processes. Fine grinding as applied to the manufacture of pigments was highly developed.

And then suddenly it came, and already the first ripple of the harmonic, the application of the " unit " system of coal pulverization to small-size boilers, is a " burning " question.

Moreover, stoker designers have felt the impetus and they have in large, and later in small, sizes considerably advanced. Another ripple arising out of the same matter bids fair to attain considerable amplitude. The smallest boilers, generally of the shell type, have given rise to Blake's now familiar expression, " Those black satanic mills." Power stations, with their partially brick-lined furnaces, showed how to solve the smoke problem. Alas, in this country the great majority are still of the old type. The advent of the large boiler, and its combustion chamber of rational size, has minimized the importance of the brickwork function. This is being effected naturally by the almost perfect mixing of " combustible " and " supporter," by the conserving effect of a large mass of flame, and by the space factor allowing time for the completion of the chemical action.

Hence we are now advancing to either a minimum amount of brickwork or partially cooled brickwork. The carrying out of the change is taking very interesting forms, both of tube walls and brick-covered tubes. Both old devices, coupled with the names of Yarrow and Bettington, are being resurrected for these purposes. Finally on this point a reaction on the boiler from the turbine has brought into prominence air heating.

The idea is very old both as regards producing better combustion and as regards recovering waste heat, but it has now a new aspect, that of the " regenerative " cycle. The heat in the gases leaving the boiler proper, i.e. the actual steam-raising surface, must now be kept in circulation by regeneration as it is rapidly becoming useless for feed-heating. This signifies really hot air. Even with stokers, boilers are now running with air at 400° to 500° F., but pulverized fuel provides a field for air much hotter than this in conjunction with very high-pressure boilers.

Fortunately, interchange of low-grade heat at atmospheric pressure between gases is much cheaper commercially and even easier than between gases and water under high pressure, and hence perhaps we foresee, in developments which are almost ripe, the disappearance of the mechanical stoker, the furnace brickwork, and the economizer all in one step. The boiler of the future will have small heating surface (the expensive high-pressure part), large superheaters, a large regenerator, powerful fans, and pulverizers.

It was perhaps fortunate, therefore, that this question of size came first, because if pressure had come first there would have been much hindrance due to installing a multiplicity of little boilers at high pressures which would have much delayed combustion progress. The

* A review of progress (see page 160). Reprints, in pamphlet form, price 1s. 6d. each, can be obtained from the Secretary of the Institution.

problem of size, however, was soon and ably solved, and this left the field free for a gradual increase in pressure, which at the present time is making rapid progress. This, however, is not quite all the story. The increase in pressure for an increase in efficiency would seem naturally to require as a corollary an increase in temperature. There, however, the work of previous pioneers, notably Ferranti, had called a halt. The providers of engineering materials were not yet prepared to supply steels which were equally strong, ductile, and permanent when rod-hot as when only warm. Now that the question has been raised much good work is being done. Hence, temporarily at any rate, this road of advance was diverted.

It has long been known that the Rankine cycle differed adversely from the Carnot cycle. Fortunate, indeed, has it been for mankind that the disadvantages hidden under this terse label were accompanied by much greater advantages to people with primitive raw materials. Nevertheless, the early engineering philosophers, many years ago, in inquiring into such matters, divulged a way of getting around the difference by employing a regenerative cycle. Again, by the process known as "reheating," it is possible more nearly to approach the Carnot fundamental. This, it is well to reapprehend from time to time, is to take in all the heat at the highest possible temperature, and effect the discard (probably a more correct expression than "losses") at the lowest possible temperature. Hence the "saurian" type of plant will hungrily appropriate into its constitution devices for reheating and bleeding, and find these the more to its liking the higher the initial steam pressure. This type has permanently appeared in France and the United States for ordinary and adequate commercial reasons. It is being fostered by political pressure in Germany and Great Britain, and consequently in both countries other considerations intervene. While 30 000-kW to 60 000-kW sets are becoming quite common in the States, and in France are being freely adopted, in England and elsewhere on the Continent the same impetus which commenced with 10 000-kW sets for capital stations is now expending itself in developing the largest output which at present can safely be given from a single alternator running at 3 000 r.p.m. At the moment this is 20 000 kW, but no difficulty is anticipated in increasing this to 25 000 kW. In fact the A.E.G. have constructed units for 32 000 kVA, and a British manufacturer has offered 35 000 kVA. It is too early to predict what the harmonics of this new departure will be. These will take several years yet to discover. One of them, which is applicable to all sizes of units, say, above 6 000 kW, is that of the slightly increased efficiency due to lower steam speeds. A previous ripple, that of the use of gearing, is still, however, progressing below this limit of 6 000 kW, and may, on the score of cheapness, come more prominently forward. A 10 000-kW unit has been constructed, and a 8 000-kW unit is under construction on the Continent.

A third, which is yet in its infancy but holds out some promise, is to add to the life of old stations by installing, for the steady part of the load, high-pressure (probably 600-800 lb.) boilers and discharge their output through back-pressure turbines to the main range.

As the conclusion of this essay, and before giving a brief résumé of plant particulars, it is necessary to point out the voluminous literature available on the subject. First there are the papers of the World Power Conference; then there has been an excellent series of articles in the principal English mechanical engineering journals. *World Power*, the organ of the B.E.A.M.A., has given a series of articles on typical power stations. The electrical Press has kept its readers well informed as to development. On the Continent the High-Pressure Steam Conference was held in the beginning of 1924; the discussions and the subsequent comments of the A.E.G. engineers are very instructive.

Finally, we may pay a well-earned tribute to the documents produced in the States and familiarly known in this country as the "Prime Movers Committee Reports" (National Electric Light Association).

Power Station Design.

This is a subject on which very little literature exists, and it was somehow reserved for Klingenberg to make it a substantive subject. Our early English writers have had their activities diverted into other channels. For some reason or other in this country anything "synthetic" is second-class matter; all the kudos is reserved for "analytic" work. It is a trait of the national character and is reflected in our policy, literature, and journals.

In most power stations in this country there can be no evidence of complete design, as their present state is the result of long accretion and alteration. New capital stations, however, are being built. Very fortunately their sites are being chosen for water facilities, as this generally carries with it ample land. After a generation of cramped extensions, more ample designs are possible.

The right-angled boiler-house design is still being developed in few but the more important cases, and this admits of much auxiliary gear and facilities being pleasingly housed in the space between two otherwise adjacent boiler houses. This design is, however, particularly adapted to small boiler units, and with the larger type of units coming into use the parallel design is necessary. Two boilers, and perhaps ultimately only one boiler, per turbine will be required. At present it involves placing special reheater boilers as close up to the engine room as possible.

When the implications of reheating and pulverized fuel have been fully absorbed, it seems possible that entirely new designs will emerge. It may then be that the buildings will be in three sections. A fuel-preparation section will contain the coal-handling and treatment plant. A power section may contain a number of turbo-boiler units, and a third section will be necessary for the switchgear.

Pulverizing plant at present runs to height and in the States it would almost seem that the mentality enforced by the sky-scraper of New York had been imported into power station designs, even when situated in lonely surroundings. It is suggested that

the condensation of plant achieved by plant manufacturers with generating machinery will later be supplemented by the power station designers who deal with steel work, buildings, and general civil work. This will result in less lofty buildings occupying a little more ground space and will lower prime cost.

The coal-handling plant for large stations is assuming a certain phase of standardization. The coal store is spanned by a travelling conveyor which can pick up at each end and deliver to any part of the store. Grab recovery from the store is also arranged. Wherever water-borne coal is available in addition to railway coal the apparatus must deal with barge or ship at one end and the coal unloaded by the usual truck tipplers at the other. On the larger sizes the old endless bucket conveyor is gradually being superseded by horizontal or inclined belts for traversing and grabs or automatic skips for hoisting. Over the bunkers either belt or travelling grab is employed. Many of such schemes embody automatic weighing apparatus.

The other big bulk "raw material," condensing water, has also received much attention. Tidal rivers present awkward problems. Travelling gravel and silt may seriously interfere with good conditions. However, the problem is still more acute in river water power schemes and valuable work is being done in overcoming these problems. Prolonged investigations have proved that merely muddy water is quite good water for condensing purposes, and a large station is now projected using Bristol Channel water, two smaller stations having used it for some time. Pumps are now generally installed of the vertical spindle type and with drowned suctions at minimum water level. Single pumps can deliver up to 1½ million gallons per hour. The design of a system using impure water calls for the elimination of settling pockets wherever occurring. What is required is to maintain the velocity uniformly throughout, and it is perhaps a coincidence that a reasonable velocity through condenser tubes for general efficiency is also a reasonable velocity for large conveying pipes.

Much progress has been made in screening plant. It has been realized that the earlier type of a travelling band in which the water went through both sides in series was not well conceived, because any detritus which escaped the water jets on the advance side was washed off on the trailing side into the system. Hence appeared the revolving-plate design, afterwards condensed into a hollow drum, and also the design where the travelling belt was still used, but the water was passed from both sides inwards and taken off laterally, or vice versa. In all of these later cases the foul side is always away from the screened water.

In busy rivers where much foul floating and water-logged detritus is caught on the screens, it has become quite a problem to dispose of the refuse. For a really large station an automatic transfer to a small destructor cell would seem to be indicated, with possibly a return of the ashes to the outgoing circulating water conveyed by the screen-cleansing water. These cleansing problems are absent where cooling towers are in use, and a fresh impetus to efficiency has been received by the use of these in an inland capital station, and by taking off the shackles as regards height. As in other phases, increase in size and ample land makes new departures profitable. Care has been necessary in providing for the expansion of the piping systems.

The movement of capital stations to river-side sites has brought out the fact that many of these are on uncertain alluvial deposit often water-logged, and extensive piling is required. This feature is international. In the States, with river-level rises greater than even the Severn tidal rises, this has given rise to difficult and expensive designs. If no question of coal unloading is a determining feature it is a matter for consideration as to whether a cheaper construction on the whole could not be maintained by bringing the water in open cuts or tunnels to some distance inland.

Very great progress has been made in civil engineering of late years in the use of powerful machinery for removing bulk material, and excavation is becoming only of relative importance compared with heavy piling and concrete rafting.

With larger stations the amount of railway sidings desirable is steadily increasing, and is a feature which is receiving growing attention. In the opinion of some engineers this is a main feature in going from 100 000-kW to 200 000-kW grouping in this country, having regard to railway and colliery conditions. Fortunately *pro tanto* the consumption of coal per unit is steadily decreasing, but against this there is the consideration that such stations must ultimately run as high-load-factor stations. The question may arise as to equipping such stations with trains of 20-ton trucks, especially if there is need to remove much ash from the site by rail.

Where adjacent land is available for ashes, telpher plant is proving very useful. Parallel development in coal-washing at the collieries will to some extent minimize this problem. The water-conveying system from ash-hoppers in town stations is incidentally providing a product which is finding increasing use in industry, and in some cases stations can actually sell all such material. In older stations, and especially in the States, the ashes contain such a high quantity of carbon that they could be rehandled in a modern destructor plant, entirely removing the carbon, and if in any quantity could be worked up into commercial material on the spot by a slab plant.

More than ever it can be realized that the future capital station should be surrounded by subsidiary industries and, although the time is not quite ripe, with the chemical refining works attached to a "low-temperature carbonization" process. It would seem that future legislation might well define some 300 to 600 acres around such a station as an "industrial area" relieved from the ordinary law of nuisance. It may, however, seem "Utopian" to look to legislation (new) for relief from legislation (old).

Boiler Plant.

While dealing later with the question of the utility of high pressure under the heading of turbines, a brief study of recent boilers may be of interest. So far plates of ordinary thickness with riveted joints have been found sufficient up to pressures of 300 lb. to

450 lb. (20 to 30 atmospheres). As the pressure rises the volume decreases and, with a constant steam volume per unit of disengaging surface, extra size does not seem to have involved priming. Perhaps, however, this is assisted by the adoption of the closed-circuit feed system which has resulted in a make-up almost negligible, in some cases as low as $\frac{1}{4}$ per cent. Such a small amount can easily be provided by a system of evaporation by live steam. Apparently also the simple system of expanding tubes into plates and headers has been equally successful.

With superheaters, however, the tendency in the States is to make this a speciality supplied by a separate company to the boiler maker, and there is a growing use of the ball-and-cone metal-to-metal joint as adopted in the Schmidt type. With the headers, bolts and nuts left unlagged or lightly lagged, the tube may be adapted to much higher temperatures, especially with new materials, which are gradually becoming available. The use of a material to stand strain and temperature at the same time is, as a general principle, to be avoided wherever possible. This will be referred to later in connection with turbines.

For reasons which have already been touched on, overhead heating surface is now in large boilers being supplemented with furnace side wall and bottom heating surface. The initial arrangements were a little casual, but the principle is now finding acceptance of making such heating surface into a proper circulating system in parallel rather than in series with the remainder of the heating surface. This principle had already received some acceptance in the double-circulation type of horizontal-tube boiler, wherein the two bottom rows of tubes had their own headers and discharged straight to the main drum. Considerable developments are expected in this connection, and although the outward resemblance may be superficial there will be underlying the design of future boilers much that will remind the engineer of the pioneer work of Bettington. There will, however, be important differences.

Out of the much higher pressures there will also arise demands for solid forged drums of large diameter. At present, forge-masters, both in Britain and in Germany, are seriously tackling this problem, where it has the added interest of being associated with the problem of catalysis under high pressure and temperature for the synthetic production of mineral oil direct from coal, and for other endothermic reactions such as cracking for the production of petrol from crude oil. One British boiler manufacturer has done excellent work in this direction, producing drums 40 feet long, 42 inches internal diameter, and 4 inches thick. The 1 200-lb. pressure boiler at the new Boston station has a solid forged drum 34 ft. long, 4 ft. internal diameter and walls $4\frac{1}{2}$ in. thick (Patchell). The whole problem of large forgings is calling generally for a fresh step forward in this country, and in this should be included not only boiler drums but also turbo-alternator rotors and discs and piping for larger diameters. While on the question of materials this addition to the use of solid drawn piping should lead to the abolition of all pipe flanges for high pressure, the ends of the pipes being socketed and the whole welded up after erection. Good progress is being made in the States in this direction, and for the small amount of large-diameter piping foreshadowed in the "one turbine—one boiler with reheating" unit it may become standard.

At the present time much interest is displayed in cellular brickwork furnace construction. With the intermediate size of boiler, some brickwork must remain for a long while. The drawing of combustion air through such cells by unit fans and using it directly through forced-draught stokers, combined with the use of newer refractory materials of clay, bauxite, magnesite, or electric furnace products, may be a first harmonic applicable to existing boilers which already have ample economizers installed.

With larger boilers, and especially with boilers using pulverized fuel with hot air, the brickwork problem will gradually become secondary compared with the ash-disposal problem.

The progress made with clinker grinders, and at the same time with various water-trough systems, should ultimately lead to an abolition entirely of the boiler basement and at one stroke reduce the height of the boiler house some 16 ft. to 20 ft., with consequent reduction of what is really overhead cost. At the moment no use seems to be found for the dust from pulverized-fuel combustion which is collectable from all passes in the boiler, and also from the latest and highly desirable development of centrifugal dust extractors at the stack. Considerable progress has been made in the use of machine soot-blowers, and published curves of back-end temperature give a clear idea of their value. All is tending to eliminate rough labour in quantity and replace it by skilled attendance and repair. This will doubtless be followed up in a period of consolidation by close scrutiny of repairs, which are at present a considerable item in the economic balance sheet.

If we are to treat the pulverizing plant as part of the boiler plant, it is advisable here to comment on British coal conditions. The British customer, with his majority of shell-type boilers, has been utterly spoilt, and it was a serious embarrassment to this country during the war years to find that many boiler plants could only be kept going by the use of washed treble nuts. It was also an almost equal embarrassment to find so many consumers fully persuaded that they were in like case, which illusion had to be exploded. It is remarkable to find, however, that in many cases it was only suppressed and has recrudesced even in some large power stations. Great pressure is to-day being put on collieries to increase their supplies of washed and graded fuel. Many American stations are adapted to take "run of mine" coal, and for pulverizing work this may be a positive advantage as it gives a product with lower average moisture content. British products for a long time will, however, be divided into best large, nuts, and good and poor slacks, washed and unwashed but often very damp. Hence predrying is going to be a much more serious matter in this country, where the introduction of this new method must be based on these tail-end coals. No doubt, with the unit system and small boilers, apparatus will be found to deal satisfactorily within

certain limits as to coal sources and moisture contents, but for the general problem predrying is still in the development stage. It can be done satisfactorily, but the apparatus is expensive and large.

It is interesting to note that in the new station at Rummelsburg for Berlin, the drying of fuel is to be effected by bled steam from a "feed water heater turbine" of 10 000 kW.

Grinding plant is in a much more satisfactory position and the period of time for replacement of wearing parts is increasing. Greater attention to detail has made the plants more dust-proof, but perhaps it is too much at present to ask the designers to make them noiseless, although promises as to this can even now be obtained.

There is nothing to hand at the present on the subject of burners discharging upwards, whilst information as to burners discharging downwards and horizontally is not new. With the abolition of much furnace brickwork positive supply of secondary air is increasing, and this will lead to flame-shortening and greater liberation of heat per cubic foot of combustion space. Progress in this direction is likely to be rapid.

The progress in stoker plants is also worthy of mention. Compartment-type forced-draught stokers are replacing totally-enclosed chain grates, and with these hotter air can safely be passed now only through the upper coal-carrying side of the belt. This leaves the grate on its return journey open to any form of cooling which may be devised, such as water cooling. With some types of British coal this will result in burning out the volatile too early in the grate, whilst with other types of gassy coal excessive temperatures will be developed, and forced cooling of the metal in some way will be essential.

The suspended type of arch now admits of very wide single stokers which, considering their duty, are worthy of a great tribute to stoker designers.

In the attempt to save the last trace of heat losses, boiler forced-draught fans are now sometimes arranged to draw hot air from the boiler room, thus recovering some of the heat losses lumped under the term "radiation." The system of drawing in the alternator cooling air for the same purpose is now obsolete owing to the advent of alternator closed-circuit coolers. Traversing shutes for mixing the coal in the stoker hoppers have been adopted as good practice.

Turbines.

As a preliminary to the turbine question it is proposed to quote a considered opinion by the A.E.G. engineers as a summing up of the discussion at the High Pressure Steam Conference of 1924.

"While theoretically the heat consumption for condensing machines shows a decreasing tendency up to 100 atmospheres (1 500 lb., taking atmosphere = 15 lb. instead of 14·7 lb.) any increase of the pressure over 60 atmospheres (750 lb.) has no practical advantages in ordinary condenser power stations from a thermo-technical point of view.

"The most economic steam pressure for condenser power stations is generally below 60 atmospheres because the thermal gains are counteracted by the greater capital costs at the higher pressures, principally on account of the increased cost of boiler equipment. The present state of boiler construction indicates that, as shown by calculation, the most economical boiler pressure for a condenser station is about 30 to 35 atmospheres (450 lb. to 525 lb.).

"The use of high steam pressure in large power stations has become possible because the high-pressure part of the turbine has been successfully arranged to work at least as economically as the low-pressure part. Until a short time ago the high-pressure part worked at a lower economy. This was permissible because with pressures of about 12 to 15 atmospheres (180 to 225 lb.) only a small part of the heat drop took place in the high-pressure part. . . .

"Turbine manufacturers are now in a position to build turbines for the highest pressures whose efficiency approaches that of the best machines that work with normal pressures (180 to 225 lb.). . . .

"With pressures over 35 atmospheres (525 lb.) an intermediate superheating of the steam in the middle stages is necessary to reduce moisture in the low-pressure stages.

"Tests are being undertaken at 60 atmospheres (900 lb.) in Germany and Sweden, at 84 atmospheres (1 260 lb.) in the United States."

We might add "at 1 500 and 3 000 lb. in England," referring to the Benson boiler, further experiments with which it is understood are to be transferred to Germany. Also that there are Babcock boilers working in Belgium at 800 lb. per sq. in. supplying a high-pressure turbine which exhausts at a pressure of 350 lb. into an existing steam main serving other turbines at this pressure.

We might also mention the 1 200-lb.-pressure boiler at the Boston new station, which supplies steam at 1 000 lb. pressure and 700° F. total temperature to a 2 500-kW turbine, which discharges for reheating at 375 lb. back pressure (Patchell).

There is also the curious system of Löffler in which the heating surface is entirely tubular and the steam generated is circulated through an external drum and superheater by a pump. This system is being installed on a small scale in Vienna for 1 500 to 1 700 lb. pressure and 750° F. to 900° F. total temperature. A 18 000-kW plant is stated to be under construction for collieries in Moravia.

In this condensed statement there is much matter for discussion by experts, but it is on the whole a fair résumé of the facts as they appear at the moment.

First as to the theoretical side, it is a matter for congratulation that British turbine manufacturers have been able to arrange for Prof. Callendar to extend his well-known steam tables to meet these higher conditions, and that they are in touch with our American

friends in the same matter. A theoretical essay on the same subject has appeared in the *Journal*.*

It has been generally noted that the gains yet to be made were, compared with previous advances, rather on the small side. Since that time more attention has been paid to the fact that the practical value of superheat is nearly double that of the diagram value, but on the other hand closer attention has emphasized that the reheating must be done without appreciable pressure drop. Because of this the second turbine taking the reheated steam cannot have its own governor, and the volume of steam entrained in the re-superheater is enough to cause a turbine to run up beyond emergency speed if tripped when fully loaded. The present solution is rapid vacuum breaking, but we think others will emerge. The reheating pressure is too low for this system, and already a scheme is being constructed whereby a small back-pressure turbine operates direct on the boiler and governing is done past the reheat at a high pressure still sufficient to give 80 per cent of the output. The alternators being solidly interlocked, the small turbine cannot run away, and in any case it can still be under the operation of a full-way emergency trip valve.

The conditions of high efficiency referred to no doubt signify the abolition of the "Curtis" wheel, but we should like to point out that the high-pressure end of a large reaction machine has always been of high efficiency, especially since the introduction of "end-tightening." The new Chicago machine for 525 lb. pressure is a case in point. With the advent of rustless steel blades for this work, as now used at Heaton, combined with their method of manufacture, it is quite safe to assume that English manufacturers are also in a like position. We also recall Ferranti's pioneer work with nickel-coated welded-on blades which were used in a successful turbine at Sheffield several years before the war. Moreover, an important large machine of the impulse type using forged stainless-steel blades is under construction for a municipal power station.

A Continental firm claims, after an investigation by Stodola, to have still further improved the efficiency of reaction blading, and it would seem that a prediction made in the *Journal* so long ago as 1904 † as to turbines having an efficiency of 85 per cent is likely to be realized shortly. We are reminded by this that in certain other of Ferranti's early experimental work a small non-condensing reaction element was run at varying speed to discover the optimum of efficiency, and a result of 90 per cent was believed to have been obtained.

The question of casing, however, does require some consideration, as the small high-pressure turbine casing has to carry pressure and temperature and the intermediate-pressure casing has also full temperature in the newest proposals. (Also in emergency, if on a separate shaft, a direct steam supply.) Proposals are being made to investigate any possible growth of casing steels under these high temperatures.

The question of providing a material to stand both stress and high temperature at the same time has long been considered. At last as a result of research by French engineers a material is available which, according to Hadfield, is "not only non-scaling at temperatures up to or even exceeding 1 050° C., but is also resistant to the action of the sulphurous products of combustion, and further this steel also possesses remarkably high strength and tenacity at even up to about 900° C. at which, as is well known, the strength of ordinary steel is practically negligible."

Thus a new door is opened to increasing total temperature.

In Ferranti's pioneer work, which was with very hot steam, the high-pressure casing was double, and English manufacturers are now considering the application of a lower-pressure jacketed casing, particulars of which cannot yet be published. In fact, many of the most interesting proposals both for boilers and turbines must remain confidential at present.

The introduction of one bleeder heater is now becoming standard even in moderate sizes of units, and where re-superheating is employed one interheat is at present all that is proposed.

Reference may be made to the theoretical essay already mentioned. No clear-cut figure can be given for the value of one or more interheats as the selection of the data is arbitrary. It may be considered as being around the value of 6 per cent. With regard to successive bleedings the matter is also complicated by boiler conditions.

Thielsch (A.E.G.), however, in a very able paper elaborating the general conclusions already given, states as follows :—

Values applicable to a 16 000-kW turbine or larger.

No. of bleeding points	1	2	3	4	5	6	8	10
Heat saving, per cent	4·9	6·4	7·1	7·7	8·1	8·4	8·8	9·1

His comment is that there is no considerable advantage in using more than three stages.

The matter is further complicated in British and American practice by apparatus for taking up steam from feed pumps, air pumps, glands, etc., in series with the turbine bleeders proper, and probably one bleeder heater is nearly enough for most moderate-size plants in this country.

In the States, however, in what are there termed "heat balance" stations where no flue-gas economizers are employed, this system is pushed to its limits, and results of 13 000 to 14 000 B.Th.U. per kilowatt-hour are claimed over a month's run.

It is very interesting to note Dr. Thielsch's conclusion as to what can be accomplished as a whole, using to the fullest advantage the schemes which have been outlined. Perhaps his comment on the table which is reproduced on page 491 provides a pointer. It is: "This proves that in modern power stations which are built in accordance with the principles stated above, a thermal utilization very nearly equal to that possible with Diesel engines can be realized in practice." However that may be, there are other considerations, and the results of Barton and Carville B, published in

* W. M. Selvey: *Journal I.E.E.*, 1920, vol. 58, p. 31.
† C. H. Merz and W. McLellan: *ibid.*, 1904, vol. 33, p. 696.

Steam pressure	15 225	35 525	100 atmospheres 1 500 lb. per sq. in.
Heat consumption	3 400 13 500	3 050 12 100	2 800 kg cals. per kWh 11 100 B.Th.U. per kWh
Thermal efficiency	25·2 %	28·2 %	30·6 %

the Electricity Commissioners' returns and the recently published results from Hell Gate, show that these figures are being approached without fully adopting all that is now open in the way of thermodynamic advance. The results of the new Chicago station at 525 lb. and with 50 000–60 000-kW units are keenly awaited.

In many cases the older stations, which were constructed at times of lower prices, can well hold their own when it comes to total generating costs, including capital charges, but since high prices are now becoming stabilized, this cannot be used as an argument for hesitating to adopt the more elaborate efficiency cycles in complete new stations.

The impulse type of turbine has now taken a fresh step forward by adopting features of many wheels, low steam velocity, high velocity ratio, and complete peripheral admission. As far as the high-pressure end is concerned, coupling efficiencies of over 80 per cent are credibly claimed. This had been due, in this country at any rate, to the results published by the Steam Nozzles Research Committee of the Institution of Mechanical Engineers. These showed conclusively that the best results could be obtained by a moderate pressure-drop per stage. The name of "Erste-Brunner" is popularly associated with this many-stage design, but hardly with justice, as a reaction from extremely high peripheral velocities had set in previous to this phase, and most English and American manufacturers were already moving in this direction when the Committee's results gave added impetus to the movement by providing additional good reasons for the reaction.

Hybrid designs with low velocities at the high-pressure end and high velocities at the low-pressure end are still being prepared for single-cylinder machines, with calculated efficiencies but little lower than the best.

Some Continental designs are very similar in appearance to Rateau's first two-casing turbine made by Sutter-Harlé so many years ago. This design, though arrived at for other reasons, lends itself well to the increased pressure, temperature, reheating, and bleeding cycles.

When pushed to its logical conclusion, one Continental design shows 4 casings and extends 100 ft. There are no engine-rooms in this country as wide as this. The solution which has long been in vogue in the American Westinghouse designs, and which will probably increasingly be adopted in large units, is that of using more than one shaft line with electrically interlocked alternators as at Barking.

The double-revolution turbine continues to progress and a 10 000-kW unit is under construction. This size of plant is similar to the 5 000-kW size, in that the last stage has single-revolution radial blading, giving double flow of steam for the last expansion.

Coming to the exhaust end, while impulse turbines have for a time adhered to one casing with multiple exhaust wheels, including the Baumann exhaust, the advent of the multiple-wheel design calls for two casings, and in Continental designs a plain double-flow low-pressure design is employed. The advent of 3 000-r.p.m. machines has led to the abandonment of the $D/5$ rule, and an important development is that of tapering, shouldering and even twisting blades.

This latter development makes a blade similar in principle to a propeller blade. Shrouding has also received attention and is being specially lightened between blades, and in some cases chrome steel is employed for strength. The vibration trouble of blades has also resulted in special lacing and stiffening. Disc vibration, which appeared suddenly during the war, has now become both a theoretical (Stodola, Lamb and Southwell) and practical (Chittenden and the late Wilfred Campbell) subject, the synchronous period of transverse vibration being tested out before assembling. Discs are also overspeeded in a wheel-pit before mounting. As before mentioned, the question of large forgings has been reinvestigated because of a phenomenal flaw, which wrecked a well-known machine and which could not have been previously discovered by methods then in vogue.

The multiple-casing design has one important feature, that of limitation of the size of forging. Almost everywhere at the present time there is a certain unrest on the question of large forgings for high revolution work, especially where temperature gradients are present simultaneously. Hence makers of prime movers are devising elaborate methods of scrutinizing forgings, and it is not by any means a foregone conclusion that a forging will be passed. Sometimes flaws are not discovered until the final machining has been done.

A notable 20 000-kW machine which has just been set to work has been designed to take advantage of the "low velocity—many-wheels" scheme. The high-pressure rotor has been turned out of the solid forging, only the blades having to be added. By this method, combined with trepanning, only a few inches of metal in a large forging remain unexamined. The above machine is also of special interest in that it has a low-pressure double-flow reaction bladed end in tandem. We may also refer to another slightly smaller tandem-cylinder machine which has recently been put into service. This embodies an impulse high-pressure cylinder with the "many-stage" low-velocity impulse wheels followed by a few rows of reaction blading and a double-flow reaction low-pressure cylinder. The actual rotor forgings in this instance are also of small diameter, all discs in the high-pressure cylinder being shrunk on to the rotor, and in the low-pressure cylinder where the reaction blading is

fitted a disc construction is similarly used. In this particular machine a novel method has been devised allowing free expansion, whilst preserving alignment. Most manufacturers have adopted exploring apparatus to sight any flaw which crosses the bore of the trepanned portion, and one firm is developing electrical methods for completely exploring the whole forging, particulars of which are not yet available. These methods are of equal assistance in dealing with alternator rotors.

To present fairly both sides of the question the following remarks are offered by one of the prominent forge-masters :—

> "Some designs of turbine forgings, however, are causing considerable uneasiness in the minds of British forge-masters who appreciate the dangers of internal stresses due to rapid variations in diameter, combined with the segregation which is bound to exist in all ingots. The present tendency is to increase the size of turbine forgings, and designers generally appear to be ignoring the fact that the greater the mass of liquid steel in the ingot mould, the longer it takes for the ingot to cool down, with a consequent increase of segregation, crystalline structure, and internal stresses. Further, from the anxiety in the minds of the designers to have a reasonable margin of safety, specifications are stiffened up so much that the figures asked for cannot be given without hardening and tempering. This operation in a solid mass with quick changes in diameter presents a very real danger. In heating and cooling during treatment operations it is impossible, whatever precautions are taken, for the whole shaft to be kept at a uniform temperature, with the result that internal stresses must inevitably be left in the forging. It should always be in the designer's mind, therefore, to avoid sudden changes of section, and, wherever practicable, to design heavily stressed turbine forgings with as large a hole as possible along the axis."

From what has been said in the previous paragraph on two-cylinder machines, it would appear, however, that designers are not by any means ignoring the facts.

Condensers.

Although condensers are not subjected to high pressures and temperatures, the physics and economics of their functions are equally fascinating to the narrower circle interested. Progress in this direction is still very rapid. With the advent of the steam ejector air-pump, now almost universal, the condenser as then constructed completely outran the turbine.

Designers began then to fit smaller condensers made, so to speak, to the same drawings. This has been seen to be a mistake as the most important economic factor, pressure-drop on the steam side, was misapprehended. Now these steps are being retraced and it is being realized that there is a certain consideration which takes the form of an optimum value of the percentage volume occupied by tubes in a given condenser shell, counting this from the turbine flange.

The effect of increased water velocity has been explored and discounted by pumping loss settling down to between 6 and 8 ft. per sec. through the tubes. If anything, the tendency is at present to keep down the velocity. Theoretically the ideal condenser has its tubes arranged only two or three deep with very large width. This is discounted by the abnormal shell necessary and the latest design, passing through the boat-shaped stage, is towards either an accordion type, or squirrel-cage-type arrangement of tubes. Both designs are directed to short steam paths, but the accordion type lends itself to the preservation of steam velocities, and the small recovery of pressure from velocity seems from experiments on a small scale greatly to increase the condensation rate. On a larger scale a remodelling of one of the Genevilliers condensers on these lines has produced remarkable improvement (Rauber). It is easy to see that a shallow condenser is less affected by tube fouling than a deep one.

Most engineers are now familiar with this station and yet in its short life there has already been opportunity to make three separate advances. Both the accordion and squirrel-cage types are being developed in England in conjunction with the American and French originators. From the outside engineer's point of view, the advance will be summed up by viewing it as condensers with somewhat smaller shells and very many fewer tubes.

Twin condensers for the largest sizes are becoming increasingly common, and have the advantage of lesser depth than one large one as well as some slight advantage of sectional cleaning. We believe, however, that modern methods will generally be developed of cleaning without the labour of brushing tubes by hand labour.

Condensation rates to-day can confidently be taken on a 450 B.Th.U. per sq. ft. per hour per 1 deg. F. logarithmic mean difference between water temperature and "inlet" steam temperature. Half as much again can be ensured if special methods are adopted, and it would seem possible to look forward to double this rate in the future. Combining modern air-tightness with ample air-pump capacity, condensate temperatures with the new designs will only be a degree or so below steam inlet temperatures.

The demands of closed-circuit and heat-balance systems have resulted in the adoption of two-stage air-pumps, with a combined surface intercooler and condensate heater, which replaces the system of a jet intercondenser. All the steam heat is recovered. It is realized that compression ratio is the determining factor in steam economy, and in one important station to meet a difficult specification three-stage pumps were fitted to 25 000-kW units. Since then, the system having proved economical, it has been supplied for still larger units.

Where the circulating water to the unit is supplied by its own isolated auxiliary, it is now practically standard practice to have two circulating pumps each having a capacity of 60–75 per cent of the total water required. Generally one of these pumps is steam-driven, and sometimes a pump is arranged to be either steam- or motor-driven alternatively. The busbar system of supply from the common pump-house is, however, generally preferred.

Alternators.

Much quiet progress has been made in alternator design. Rotors of 60 000 kW at 1 800 r.p.m. have been started up, and 25 per cent larger are offered. 25 000-kVA rotors are running very successfully at 3 000 r.p.m. in England, and offers have been made up to 35 000 kVA at the same speed. It is stated that units have been constructed on the Continent of 32 000 kVA at 3 000 r.p.m. and of 62 500 kVA at 1 500 r.p.m. In America a 80 000-kVA unit at 1 200 r.p.m. is under construction. To appreciate this, reference should be made to Baumann's papers.*

Only a few points can be touched on. Ventilation is one of the most interesting. The air is now specially guided over end-turns and also guided to all parts of the rotor gap. Some rotors are made up solid, depending entirely on peripheral cooling. The higher resulting temperature is permissible because of greatly improved shop methods of coil insulating by hot pressing. Other designs show great ingenuity in getting air along ducts in close proximity to rotor coils. Most designs are machined from the solid, that is with solid teeth closed after winding by partially magnetic wedges; others have laminated teeth riveted while under hydraulic pressure and carried in dovetail slots.

Whilst shrunk-on end-caps for rotors are still generally used, in one particular design great care is exercised, in this the most difficult part of the whole rotor (the end-turns), to wire-wrap them on to the shaft with known and recorded tension. It should be stated that considerable advance has been made by the steel-makers in producing material suitable for end-caps, combining high yield-points with good elastic and even non-magnetic properties.

Modern developments call for flexible cable or laminated copper for coil-turns, and this is now generally used, being pressed into shape and also transposed within the slots, all to minimize copper eddy-current losses.

Stator end-windings still persist in their three forms, and advocates of each type appear to have arrived at satisfactory bracing.

End-clamping stator plates are also devised to render through coupling bolts unnecessary.

An interesting development is the use of a non-magnetic cast iron with high specific resistance for these end frames.

The feature which has recently so rapidly become standard is that of closed-circuit air coolers, thus superseding both dry and wet air filters. Their advantages are too well known to need recapitulation in full; absence of dirt, moisture, limited supply of oxygen, shorter shaft when employed with external fan, and more efficient fan, are a few of these.

In all cases these must be fed in some part by the coolest convenient source of inexpensive water. It can, however, be arranged that the condensate shall participate in the first stage of cooling when the incident air is at its maximum temperature. With the various sources of heat available for feed-heating and with the practical disappearance of condenser loss this scheme is more applicable to river water than to cooling-tower stations.

* *Journal I.E.E.*, 1912, vol. 48, p. 768; also 1921, vol. 59, p. 565.

Buried temperature detectors have been slowly introduced for stator coils and iron, and are now recommended as a standard practice for machines above 5 000 kW. Records which enable rotor voltage to be divided by rotor current on an instrument which does this may shortly become a common means of watching rotor temperature by change of resistance.

In addition to the magnetically-closed slots, which are of importance with machines running on high-capacity systems, another feature is of considerable interest. Some designs provide for building what is really a squirrel-cage winding into the rotor slots. This acts as an additional damping winding, and protects the rotor in case of short-circuit, and with out-of-balance currents in the stator.

Designers are more than ever convinced of the value of inherent reactance in the alternator. They now incorporate between 15 and 20 per cent and they expect to be able to increase this in the larger sizes. We should recognize the merits of the automatic voltage regulators in making this possible. Whilst there is no difficulty in winding most machines to-day for 11 000 volts, the tendency where step-up transformers are employed is to revert to 6 600 volts. There appears to be no development yet along the lines pointed out by Welbourn * of winding for higher voltages.

Power Station Auxiliaries.

Whilst much discussion has taken place on this subject there is not much new matter. There is perhaps an increasing proportion of electrical auxiliaries supplied

(*a*) From low-tension house turbine alternator in parallel with and/or

(*b*) Unit transformers or unit winding on step-up transformers in parallel with and/or

(*c*) Transformer across main e.h.t. busbars.

A variation of the house-turbine or unit-transformer scheme is to add a low-tension alternator or d.c. generator for the auxiliary service in tandem with the main alternator, i.e. on a shaft extension.

Of these methods, two as far as possible independent sources are considered to be a minimum provision. It is now generally considered advisable to use storage batteries for stand-by emergency lighting and for operating the switchgear trip-coils.

Switchgear.

Switchgear in large sizes and for high tension contains so many unknowns that it is difficult to know whether four lines of development now going on are all simultaneously worthy of being called "progress." Research and experience are gradually eliminating certain of the unknowns and the importance of the switchroom is now being realized.

Schools of thought receiving almost equal support are:—

(1) The all-metal-clad compound-filled (and/or oil) system.

(2) The moulded stone cubicle system.

(3) The air-divided porcelain-insulated system.

(4) Cubicle "phase isolated" system.

* *I.M.E.A. Proceedings*, 1919, p. 78.

The largest metal-clad switches have developed duplicate busbars and separated phases into individual tanks, in some cases with duplicate switching.

The moulded-stone-cubicle advocates are beginning to coquette with mica or tape insulation over all live parts, and composite designs are also proposed.

The "phase-isolation" designers are going almost to extravagances in pursuing their ideals. In this country the first types can be seen in their developed stage at Dalmarnock, Nechells and Barking, and the second at Barton and Salford. The third is perhaps best seen at Gennevilliers, but for the latest development of the fourth type we must go to the States (Hell Gate, Calumet, etc.).

All types, without knowing definitely (if such a matter can ever be known) what their switches will stand up to, have steadily increased in size of units. Such is the state of the art that no one desires wantonly to produce a short-circuit providing an adequate test, and whilst tests are gradually being carried out on single generators, which are on the whole coming out well, yet the use of, first, busbar reactance, and later of feeder and interconnector reactance, is still is some quarters regarded as essential on large systems. The inherent reactance of a single machine protects the machine, but given a sufficient number of machines the switchgear is still unprotected, unless reactance is suitably diffused through the system for its own protection and the switchgear is sectionalized.

Much good work has been done to protect the operator and prevent accidental contact when cleaning, or during wrong operation. The engineering and workshop practice is getting highly developed. Larger single porcelain insulators are being satisfactorily obtained, as well as moulded insulation tubes. Condenser type and oil-filled terminals are all contributing their quota to satisfactory operating gear, but at present it would seem impossible to nail down any one specification and say "thus." The use of metal-clad gear for auxiliary switching is becoming general, and only in a few instances when the designer has some particular leaning to direct-current auxiliaries will be found the old elaborate polished slate and burnished copper type of board.

It is tacitly implied in the foregoing that wherever the amount of power to be dealt with is large the main switchgear will be dealing with the current from the step-up transformer, and that the transformer for this purpose may be practically considered to be an extension of the generator.

General.

A matter in which considerable progress is being made is that of station instruments. Electrical boiler-level remote indicators are now available and seem to afford a reliable indication at firing floor-level of the water in the drum. In view of the severe strain on gauge glasses at high pressures and temperatures, such an addition is welcome.

Temperature, draught, and CO_2 indicators are becoming of a more robust design suitable for engineering works. Instruments are now available for recording the presence of combustible gases in the flue gases. Steam meters with electrical indicators, and integrators with compensated voltage effect are finding gradual acceptance. A recent development of this, the combination of a steam meter with a water meter, enables steam consumption rates to be observed directly.

The principle of the "Dionic" water tester has now been applied for indicating and recording the conductivity of the condensate for watching condenser leakage. Chlorinating gear has been successfully applied for keeping down marine growth in water pipes. Closed-circuit systems for condensate have been more conveniently opened into surge tanks, steam-sealed, which device prevents the entrance of air, and incidentally still admits of "V" notch recording.

Where large make-up is required multi-effect evaporators are being installed. For smaller quantities a heat interchanger is incorporated in the general heater system. To keep the engine-room air sweet, in some cases a washed supply of air is arranged. Progress has been made in integrating the machine outputs of a station by means of delicate thermo-couples, and this, by means of some of the spare cores of the pilot protection cables, has been extended to more than one generating station of an interconnected system.

Clever devices of the fire-alarm pattern have been installed at static substations, by which can be ascertained from a tape machine what switches have tripped when a disturbance occurs. It is suggested that an extension of this system, coupled with high-frequency, multi-frequency supplies, may yet result in all important switches being operable from the control room. Precision watt-hour meters of a high degree of accuracy are now gradually becoming available. There is a growing practice of installing special condensate mains, and permanent weigh tanks, so that with the aid of these and precision meters accurate routine tests are possible.

It is a growing practice to insert in parallel with the oil circulation system of a prime mover a centrifugal type of oil purifier, by means of which a portion of the oil is for long periods being continuously freed from water and sludge. The machine has, however, to be shut down occasionally for removal of solid matter.

An important device by Piggott has been tried out on a large machine in the States. Atmospheric relief valves in large sizes are undesirable. This device provides a mercury column, which on loss of vacuum in the condenser is arranged through a relay to trip out the main emergency valve, thereby shutting down the set.

The mercury turbine of Emmot, i.e. a "binary fluid cycle," has attracted great interest, but further developments are awaited.

The use of brown coal with over 50 per cent moisture without previous separate drying, is gradually growing. Klingenberg's book on the Golpa station is of considerable interest.

Present attention is, however, rather focused on the Morwell station where gradually the problem is being solved on mechanical stokers with variations of "Welsh setting" for the brickwork. To get full output, however, some simultaneous preheating on a separate grate, by radiation and/or hot air, seems the natural line of progress.

Water-Power Stations.

It is not proposed to examine this question, and very good information will be found in the papers read before the World Power Conference. From these it will be realized that the reaction principle, i.e. the Francis turbine, is being applied to greater heads, and similar progress has been rapidly made corresponding to that on the steam side in going from 750 to 1 500 and now to 3 000 r.p.m. There is a similar cheapening due to more economic utilization of material.

Again, on the exhaust end, due to rational designs of exhaust chambers, leaving losses are being much reduced.

Considerable progress is also being made on high-speed propeller-type runners for low falls. It is very interesting to read of the electrical heating devices which, by slightly raising the temperature of the metal parts, prevent frazil ice from adhering to screen bars and casing and running parts of water turbines in cold climates.

Double operation governing has reached a high degree of efficiency. Brakes are being used to bring large high-speed units to rest as soon as desired after disconnection from the bars.

There is a considerable advance in the efficiency of turbines for small isolated schemes, whilst large turbines are approaching a value of 90 per cent efficiency at the coupling.

Oil-Engine Stations.

In spite of the fact that Great Britain is a coal-producing country, at the present time the total plant capacity of stations using heavy oil in this country is now 50 000 kW. Whilst most of the sets are of small capacity, there is a 750-kW Fullagar engine of English make running, and a Continental maker has supplied a 2 500-kW six-cylinder set to a Belfast firm. Great progress is being made both in the Diesel type (with air injection) and the solid injection type. One British firm is now offering a solid injection two-stroke engine which has been well tried out in the States. Another has recently constructed a number of 1 000-h.p. engines running at 300 r.p.m. Considering the progress made generally in all countries it would seem that the oil engine is passing through a phase corresponding to the development of the high-speed steam engine from the low-speed steam engine.

This will undoubtedly result in a considerable cheapening in price, and a wide use abroad for countries where the oil supply is reliable and at a competitive price. It will also speed up the movement to make a ship's power plant into a power station. It will also result in the increasing use of such engines as stand-by to water-power plants, and one such engine for starting up auxiliaries and essential services may find its place in capital stations as an insurance in the event of total shut-down.

STANDARDIZATION.*

By P. Good, Member.

Historical.

Industrial standardization in the electrical field in Great Britain carried out on a national basis may be said to have started with the proposals made by the late Sir William Preece, acting for the Council of the Institution about the end of the year 1901,† which resulted in the association of the Institution with the four other leading Engineering Institutions in the work of engineering standardization, and the appointment by the British Engineering Standards Association (then called the Engineering Standards Committee) of a Sub-Committee for Standardization of Electrical Plant.

At the meeting called to inaugurate this work, the then Chairman of the Main Committee of the Engineering Standards Committee, Mr. Mansergh, drew attention to the fact that standardization of electrical machinery was already receiving attention in America and Germany. He urged the necessity, not only of national but of international agreement, and it is interesting to note, in passing, that one of the first representatives nominated by the Institution to the Main Committee of the Engineering Standards Committee was Colonel R. E. Crompton, C.B., who founded the International Electrotechnical Commission in 1906, the Institution fathering for many years the British National Committee appointed to co-operate in this work. (The Sectional Electrical Committee of the B.E.S.A. is now the British National Committee of the I.E.C.)

In enumerating matters needing attention, Mr. Mansergh stated that considerable confusion prevailed as to how to define the rated output of an electric motor, also emphasizing the desirability of establishing, in addition to certain physical and mechanical details, the interchangeability of parts. Another important result to be achieved by standardization, as stated by Mr. Mansergh at that meeting, was to discourage the use of varying specifications by individual bodies and persons when one standard specification would serve the purpose. To achieve such a result, however, it was imperative that it should be given an official character, and this, he pointed out, the Engineering Standards Committee would do.

The work thus inaugurated went forward steadily and by the end of 1902, or early in 1903, Committees were hard at work considering the standardization of telegraph and telephone material and electrical machinery.

The necessity for a central organization to carry out standardization over the whole range of the engineering industry, thus early recognized, has not grown less, so

* A review of progress (see p. 150). Reprints, in pamphlet form, price 2s. 6d. each, can be obtained from the Secretary of the Institution.

† It is not suggested that this was the commencement of electrical standardization. The first edition of the I.E.E. Wiring Rules was issued in 1882. The standardization of electric cables was commenced by the Cable Makers' Association in 1899, and other instances could no doubt be cited.

that, at the present time, in all matters of electrical standardization, the Institution co-operates actively and gives very substantial financial support to the work of the B.E.S.A.

Development.

That electrical engineers quickly realized the far-reaching importance of co-operative standardization is well indicated by the large number of those now voluntarily taking part in the work. The British Engineering Standards Association (B.E.S.A.) has at the present time 70 Committees preparing electrical specifications, whilst the Electrical Research Association (E.R.A.) has a large number of Committees either preparing standard methods of test or carrying out researches which will in due course provide data to form the basis of standard specifications.

The Institution, through its Wiring Rules Committee, its Ship Electrical Equipment Committee and its Committee on Rules and Regulations for Electricity Supply, is itself directly engaged in important co-operative standardization.

Committees considering questions of electrical standardization (mostly for reference to the B.E.S.A.) exist in the following organizations :—

British Electrical and Allied Manufacturers' Association,
Cable Makers' Association,
Electric Lamp Manufacturers' Association,
Incorporated Municipal Electrical Association, and
Municipal Tramways Association ;

whilst practically every industrial and scientific body in the electrical industry lends its active support to the work.

In 1919, a Government Interdepartmental Committee was set up to co-ordinate the electrical requirements of the Government Departments, and this Committee works in close co-operation with the B.E.S.A., with the intention that, as far as possible, Government requirements shall be in accordance with general industrial practice. This Committee adopts, as far as possible, existing British Standard Specifications, but where Government requirements are special, the Interdepartmental Committee has prepared a number of specifications covering somewhat more detail than is considered appropriate for ordinary industrial Standard Specifications, and these Government Department specifications are published by the Stationery Office. This step, initiated in connection with electrical requirements, has resulted in a widespread application among Government Departments of the principle of standardization, so that there are now Interdepartmental Committees preparing specifications for a wide range of general stores.

An important development during 1925 has been the widening of the basis of membership of the B.E.S.A. whereby those associating themselves with the work will be kept in close touch with its progress and with standardization and simplification in other parts of the world. Members of the Committees of the B.E.S.A. will in future be known as Honorary Members, and ordinary membership will be available to all connected with the industry on payment of a small annual fee. In return for this, members will be in a position to secure direct representation of their interests on the Main Executive Committee through a duly elected Advisory Council, certain free copies of specifications and free advice on all matters of standardization, whilst they will have the additional satisfaction of knowing that they are assisting in a work of national importance.

Scope.

Whilst it is probable that, at this date, no better terms than "standardization" and "simplification" can be found to describe the scope of the work thus undertaken, this scope is not yet well understood, as the expression "standardization" has, to a great many people, only a limited meaning.

The B.E.S.A., in carrying out the task laid upon it, has endeavoured to set up standards of quality in order to limit the use of unnecessary and unsuitable materials and sizes, as well as to bring about a greater degree of equity in the purchase and sale of materials and electrical apparatus generally, not the least valuable result of the work being that the general use of agreed specifications has made a comparison of tenders more satisfactory. Because of this, the term "standardization" has grown to mean, in the minds of engineers, not only a simplification in the number of types and sizes and the securing of interchangeability, but also the laying down of performance rules or codes for all types of apparatus, including measuring instruments, prime movers, generators, transformers and motors. Thus broadly the term "standard," in addition to being a measure of quality or standard of comparison, means a common unified practice, method or dimension, which it is to the interest of industry and the community to adopt.

Useful standardization and simplification are not, however, confined to technical requirements, but are equally of value on the commercial side. An outstanding illustration of this form of standardization is to be seen in the I.E.E. Model Conditions of Contract. There are also a number of other standardized conditions of contract in operation, and whilst in most cases these have been agreed between definite groups of purchasers and makers, it is probable that they would be still more effective if carried out under an organization bringing into the deliberations interests other than those directly concerned in the making of the contract.

Conditions of employment have also been standardized to a certain extent in the electrical industry.

Progress in Great Britain.

Probably one of the most valuable pieces of work brought to completion during the past year is the British Standard Glossary of Terms used in Electrical Engineering. This Glossary, intended to cover the technical terms ordinarily used in electrical science and in its application to the electrical industry, comprises some 2 000 terms and will have the important effect of stabilizing the language of the industry. These terms and definitions have been prepared with the assistance of a large number of experts, and the Editing Committee, consisting of Mr. C. C. Wharton and Lt.-Col. K. Edgcumbe, has given untiring service for more than 3 years to co-ordinating and unifying the mass of material thus collected.

This Glossary has been adopted by the International Electrotechnical Commission as the basis for an International Glossary now in preparation, and completes the first stage of the work started by the Institution in 1908.

In the table on pages 498 and 499 an attempt has been made to illustrate the range of the work coming under the general term "standardization" as carried out by the electrical industry in this country (excluding that being done by individual firms), by sub-dividing the subject into a number of headings as follows :—

Nomenclature and Symbols.
Simplification of Types and Sizes.
Standardization of Tests.
Interchangeability of Parts.
Rules for Performance (Rating, etc.).
Quality of Material.
Conditions of Contract and Sale, and Schedules of Guarantee and Performance.

The table is believed to be complete in so far as technical standardization of electrical material is concerned, but it may not be so complete in regard to the conditions of contract. Standardized conditions of employment have not been shown, but could probably with advantage be included in future reports.

An examination of this table will show that a very substantial measure of progress has been made. Moreover, it has been found that, in the opinion of the industry, the specifications and other documents are of great value not only to the manufacturer and user but to the community in general. It is recognized that generally acceptable technical specifications and standard conditions of contract form very efficient machine tools for the rapid completion of a commercial transaction, saving an immense amount of detailed work and leaving the consulting engineer free to devote his attention to the broad questions which an engineering problem as a whole presents. Also the work of preparing these standards involves the pooling of a vast amount of technical knowledge, so that the Committee work of the B.E.S.A. and the E.R.A. is probably one of the finest continuation courses obtainable for senior engineers.

Future Work in Great Britain.

The growing recognition of the necessity for a standard of comparison for complex articles as well as the necessity for simplifying practice by the elimination of unnecessary sizes, is likely to be reflected in the production of an increasing number of new specifications in the near future.

The increase in the output and the rapid spread of the distribution of electric power on a large scale have created quite new problems, and the question of the rating of switchgear generally is one to which much attention is being given at the present time. The necessity for Standard Specifications for materials for overhead line construction, radio apparatus, insulating materials and tramway and railway equipment, is recognized and early progress in this direction is likely.

It is becoming clear that industrial motors of small and medium sizes are, like the electric lamp, being looked upon as ordinary articles of commerce, and attention is being directed to the possibility in the near future of having the speeds and some of the leading dimensions unified. The Government Interdepartmental Committee has already included recommendations on this question in its specifications for motors.

The following are a few of the specifications which the B.E.S.A. is likely to issue early in 1926 :—

Electrical Performance of Transformers, Rotary Converters and Fractional Horse-Power Motors

(being the remaining sections of the revision of the old Standardization Rules).

Tests for Flame-proof Enclosures for Electrical Apparatus.

Standardization in the British Dominions.

Fairly complete machinery now exists whereby the closest co-operation has been achieved between those preparing electrical specifications in this country and engineers in all branches of the British Empire. In Canada and Australia the Local Committees of the B.E.S.A. have formed independent Standardization Associations, and the Australian Association has obtained permission to reproduce the British Standard Specifications as Australian Standards when applicable to local conditions. The B.E.A.M.A. Overseas Committees also co-operate in the work.

Standardization in other Countries.

The recognition of the urgent necessity for national Standard Specifications is now practically universal, and the preparation of such specifications and the laying down of standard rules are being proceeded with in practically all countries. Generally speaking, the organization of the work follows closely that adopted in this country. A large amount of work has already been done in Germany and the United States.

International Electrotechnical Commission.

With the increasing industrial interdependence of the different countries of the world, the same necessity for an equitable basis of tender for exports and imports of electrical merchandise has led, as briefly referred to above, to the formation of the International Electrotechnical Commission. Thus the tendency is growing to have the standards in all countries developing, in so far as fundamentals are concerned, along certain agreed lines, based on international discussion and goodwill, and much valuable interchange of knowledge has thereby been promoted. Progress in this work has been marked. In addition to the international symbols and an agreed international standard for the resistance of commercial annealed copper, agreement has practically been reached for an international standard for the resistance of aluminium. International agreement has also been reached in regard to temperature-rises for electrical machines, and international ratings for prime movers, both steam and hydraulic, are in preparation.

STANDARDIZATION OF ELECTRICAL PLANT, APPARATUS

Where the document referred to in the table is a British Standard Publication issued by the B.E.S.A. a reference number only is given. In all other cases the organization responsible for the document referred to is indicated by the abbreviation given in brackets as follows :—

Institution of Electrical Engineers (I.E.E.) ; International Electrotechnical Commission (I.E.C.) ; Electrical Research Association (E.R.A.) ; Interdepartmental Government Committee (G.D.S.) ; British Electrical and Allied Manufacturers Association (B.E.A.M.A.) ; Municipal Tramways Association (M.T.A.) ; Incorporated Municipal Electrical Association (I.M.E.A.).

AND MATERIAL IN GREAT BRITAIN (1925).

The main reference to these documents is given in capitals under the heading which particularly applies. Cross references under other headings are given in small type.

NOTE.—In addition to the specifications for electrical material and apparatus there are a large number of B.E.S.A. specifications for iron, steel, copper and aluminium and their alloys, and other materials, as well as specifications for pipes, rolled steel joints, keys and keyways, limits and fits, fire extinguishers, etc., which are of use to electrical engineers but are not included in this report.

INSTITUTION NOTES.

Jubilee of the Telephone.

The Council are making arrangements for the celebration of the fiftieth anniversary of the first public use of the telephone (25th June, 1876). Particulars will be announced in due course.

Lending Library.

A new edition of the Lending Library Catalogue has been published. Copies can be obtained on application to the Secretary.

Associate Membership Examination Results.

OCTOBER 1925, SUPPLEMENTARY LIST.*

Passed.

Aschmann, G. D. (New Zealand).
Irvine, H. B. (New Zealand).
Mackersey, C. A. (New Zealand).
Paine, G. R. (Australia).

Passed Part II only.

Swift, L. A. (New Zealand).

The Late Mrs. Hertha Ayrton.

A biography of the late Mrs. Ayrton, by Evelyn Sharp, has recently been published. Mrs. Ayrton was a Member of the Institution from 1899 until her death in 1923, and was the widow of the late Professor W. E. Ayrton, F.R.S., who held the office of President in 1892.

Gas and Electricity Undertakings.

With the concurrence of the Council of the Institution and of the National Gas Council, a Joint Committee has been set up with the following reference: "To consider whether in the national interest an inquiry might advantageously be held into the possibility of closer co-operation between gas and electricity undertakings in promoting capital and fuel economy in the supply to the public of energy derived from coal," with the understanding that no Reports or Discussions of the Committee are to be published without the consent of both Councils.

The Committee is constituted as follows :—

Mr. R. A. Chattock Mr. J. S. Highfield Mr. G. W. Partridge Mr. C. P. Sparks, C.B.E. Mr. W. B. Woodhouse	Nominated by the Council I.E.E.
Mr. D. Milne Watson, D.L. Mr. W. Cash, F.C.A. Sir A. Duckham, K.C.B. Mr. A. W. Smith Mr. C. Wood, O.B.E., F.C.S.	Nominated by the National Gas Council.

The Science Museum, South Kensington.

The Annual Conversazione of the Institution will be held on Thursday, 24th June, at the Science Museum, South Kensington, instead of at the Natural History Museum. In this connection the following particulars of the collections of electrical apparatus now on view at the Science Museum have been supplied by the Director and Secretary of the Museum :—

"The collections at the Science Museum which illustrate the various branches of electrical engineering have now been placed on view in the galleries of the new Museum building in Exhibition-road, where they occupy more than 12 000 sq. ft. Electric power and lighting, as well as telegraphy, telephony and radio-telegraphy, are shown in Gallery XXVI on the first floor, while electrical instruments are arranged in Gallery XLIII on the second floor. Atmospheric electricity and lightning protection are included with the geophysical collection in Gallery XLIV.

"Advantage has been taken of the additional space now available to show many objects of great historical and technical interest which had previously been in store. The collection of historical objects which was lent by the Institution of Electrical Engineers to the National Collection in 1923 is now prominently exhibited in all these galleries, and of it Clarke's magneto-electric machine, an early Gramme alternator, an early Edison 10-kW two-pole dynamo, a Gramme dynamo from the Crystal Palace 1882, Ladd twin-armature dynamos, a coil of the 10 000-volt 1 000-kW Ferranti dynamo of 1889, a 10 000-volt Ferranti cable and fuse, and a 10 000/2 500-volt Ferranti transformer of 1890 are shown in Gallery XXVI.

"An extensive collection of historical switches and lampholders, many of which were presented to the Institution by Mr. Killingworth Hedges, and a collection of 86 early incandescent lamps are exhibited with the electric lighting collection.

"A valuable collection of early meters includes an Edison electrolytic meter, recording meters by Richard Frères, Kelvin and Walker and Laurence Scott, also Scheeffer and Forbes meters.

"Among the early arc lamps are the Holmes arc lamps from the South Foreland.

"The collections also include an original Pacinotti dynamo and the original dynamos of Ladd, Wheatstone, Wilde, Varley and Siemens; also original Gaulard and Gibbs transformers. In addition, there is a very extensive collection of electrical measuring instruments of much historical interest.

"In that part of the collection which illustrates electric lighting, Swan's carbon pencil lamp of 1879 and specimens of early Swan carbon and cellulose filaments, also the Edison bamboo filament lamp of 1879 are important.

"The collection illustrating electrical communication is now in the same gallery and includes an early siphon recorder (one of the first six made for the Eastern Telegraph Co.), a number of coils, condensers, etc., used by Marconi and his assistants in the early days of wireless telegraphy, an early manual telephone exchange, an early Strowger automatic telephone instrument (the system is still used, though greatly changed), the original Reis telephone and Sir William Cooke's original alarum,

* See pages 92 and 192.

as well as a large number of obsolete telephone receivers and transmitters and many submarine cable specimens, all of which form part of the Institution's collection.

"Other objects of historical importance which are on exhibition are:—In telegraphy, Sir Francis Ronalds's electrostatic telegraph; Cooke and Wheatstone's instruments; Hughes, Edison, Murray and Creed type-printing; Atlantic cable specimens and submarine cable apparatus. In telephony, early Bell telephones and original Hughes microphones. In radio-telegraphy, historical exhibits relating to the early work of Prof. D. E. Hughes, Sir Oliver Lodge, Senatore Marconi and others. The collection of thermionic valves includes the original Fleming diodes, together with many modern examples. Some broadcasting microphones are shown, and there are scale models of the aerial equipment of the new Government station at Rugby. There is also an important working model of the automatic telephone systems for London and the provinces, the former as described in a recent Institution paper. The model was exhibited in the Government Building at Wembley and has been installed by the Post Office. This will be demonstrated daily from the 1st April.

"On the second floor the collection of electrical instruments is in course of arrangement. It includes several which have been lent by the Institution, e.g. a Byrne cell made by Ladd, Kelvin's ampere balance No. 1, Baily's apparatus to show Arago's motion, and a series of early vacuum and X-ray tubes made by Sir William Crookes and Mr. A. A. Campbell Swinton.

"In the section illustrating Lightning Protection are a number of objects contributed by Mr. Killingworth Hedges."

The Benevolent Fund.

The following is a list of the Donations and Annual Subscriptions received during the period 26 February–25 March, 1926:—

NOTES ON THE TESTING OF STATIC TRANSFORMERS.

By J. LINDLEY THOMPSON, M.Sc., Member, and H. WALMSLEY.

(*Paper first received 7th November, and in final form 11th December,* 1925; *read before* THE INSTITUTION 21*st January, before the* WESTERN CENTRE 1*st February, before the* NORTH-EASTERN CENTRE 22*nd February, and before the* NORTH-WESTERN CENTRE 2*nd March,* 1926.)

SUMMARY.

The paper describes the usual methods adopted in the commercial testing of static transformers. Emphasis is laid on the need for accuracy, and methods are suggested whereby it can be obtained.

The drying-out of transformers, the determination of dryness, and the measurement of insulation resistance are discussed. The measurement of the iron loss and load loss is described, together with methods for obtaining greater accuracy.

The measurement of form factor and its effect on the loss measurements are dealt with; and methods for determining the ohmic resistance, also corrections for the same, are detailed.

The loading of transformers for a full-load test, and the temperature-rise readings obtained on this test, are discussed. Over-potential and pressure testing are described, and the methods of measuring high voltages are detailed.

In this paper the authors describe how transformers can be efficiently tested, and also some of the methods employed for determining and correcting any measurements taken.

Accurate results are essential in all the various tests. This tends to create confidence in the mind of the customer, and also gives the designer and manufacturer confidence in their product.

Testing serves as a check on workmanship, materials, design, and drafting, and should function as the most critical inspection of the product.

Apart from the visual inspection and the testing of mechanical attachments, the following general tests are required on all transformers, in order to ensure their satisfactory design and manufacture :—

(1) Ratio.
(2) Polarity.
(3) Iron loss and magnetizing current.
(4) Copper or load loss, and impedance.
(5) Resistance, cold and hot.
(6) Full-load temperature-run.
(7) Over-potential tests.
(8) Pressure tests.

ACCURATE TESTING.

To ensure accurate testing there are a few simple precautions that should always be taken.

It is essential first of all to study the requirements of the transformers under test as regards the instruments most suitable, in order to prevent overloading or subjecting them to a higher pressure than that for which they are designed. This precaution may seem obvious, but unless carried out it may easily involve the destruction of, or damage to, valuable instruments.

The method of carrying out the test should be studied so that the most accurate one may be employed. The means employed also require thought, so that the best and most favourable condition may be selected. A little thought in this direction may often save the overloading of a generator or auxiliary transformer, and so tends to lengthen the life of the test plant. Where a considerable amount of auxiliary apparatus and plant is required to carry out a particular test, it is wise to draw up a clear, full diagram of connections and also to set out the sequence of the operations to be performed, together with a table of all load currents, voltages, frequencies, oil flow, and water quantities, etc., that will be required. To ensure accurate testing, it is essential that all instruments should be well cared for, checked, and calibrated at regular intervals.

Preliminary tests should be carried out on all transformers during the process of manufacture, in order to ensure a satisfactory product and prevent, as far as possible, time and labour being spent on a defective unit. These tests being repeated in the final stage, the authors do not intend to describe them here.

DRYING-OUT AND INSULATION RESISTANCE.

Before final tests are carried out on a transformer, it is essential that it be in a safe condition for those tests. This condition is that it be thoroughly dry and free from moisture. The drying-out of transformers is in reality a test of insulation resistance. By this is meant not the actual insulation-resistance value obtained from any megger reading, but the insulation characteristic with time and constant temperature.

There are many well-known ways of drying out transformers, the most satisfactory being those carried out by the circulation of dry, heated air and by the vacuum process.

Drying-out by the circulation of dry, heated air should be confined, from the point of view both of efficient drying and of the necessary time taken to ensure dryness, to transformers wound for voltages not higher than 11 000. This method is carried out in an enclosed, heat-insulated chamber fitted with a steam pipe or heating element under the floor. Air inlets are provided underneath the heating elements, and outlets are provided in the roof, thus ensuring free circulation of air.

The temperature necessary in a drying-out chamber of this description is about 80° C., and the time required varies with the size and construction of the unit, i.e. it depends on the quantity of insulation embodied therein. The length of time can be gauged from the dielectric characteristic, as shown by the curve of megger readings taken during the process. It is not essential to

take the characteristic of the insulation for all transformers dried out by this method, though, if possible, it is advisable; for if we determine the necessary time and allow a safety margin similar units may be assumed to take the same time.

It is necessary, however, to "megger" each transformer finally before withdrawing it from the drying-out chamber, i.e. at its maximum temperature, in order to ensure it being in a safe condition for the tests it has to withstand. In the case of transformers, and especially high-voltage transformers which have a high electrostatic capacity and so require an appreciable charging current, in order to ensure that a reading as reliable as possible is obtained, the megger voltage should be applied for at least 60 seconds.

A high-voltage megger is essential, i.e. one wound for 1 000 or 2 000 volts. As a guide to megger readings, when a transformer is dry the following empirical formula, in which f is the frequency, will be useful:—

$$\text{Megohms at approx. } 75^\circ \text{ C.} = \frac{\text{Kilovolts} \times 20}{\sqrt{\dfrac{(\text{kilovolt-amperes})}{f}}}$$

When the transformer is immersed in oil, its megger reading for the same degree of dryness will be much lower than when in air. This is due to the fact that when immersed in oil the resistance is the resultant of an increased number of high-resistance paths in parallel, whereas when dry the resistance is confined to the insulation in contact with the windings and the core or earth. A new transformer that has never been dried may show a megger reading of "infinity" when cold, but, when heated, the moisture that has been absorbed and may be localized is dissipated throughout the windings and insulation, thus the insulation resistance will fall to the region of zero. With the continued application of heat the dissipated moisture becomes liberated and the megger reading will gradually rise to a safe or infinite value. In general a transformer may be said to be dry if the insulation resistance is at a high or infinite value when the transformer is heated up to a temperature of 80°–85° C. For transformers for higher service voltages than 11 000 the vacuum process of drying is recommended as being the surest and quickest way of obtaining the desired result. This method is really an extension of the method already described, the drying-out being accelerated by the application of a vacuum in order that the moisture may be more rapidly vaporized and liberated.

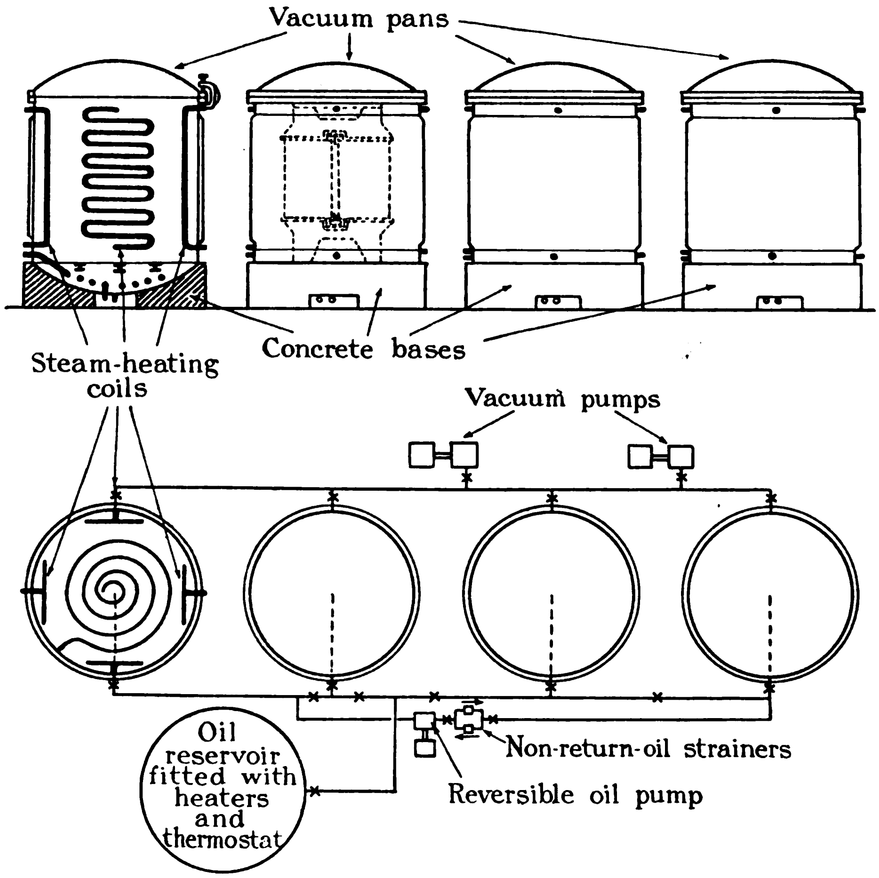

FIG. 1.—Group of vacuum pans.

Fig. 1 shows diagrammatically a system of heated vacuum chambers. The process of drying is briefly as follows:—

The transformer to be dried out is placed in the container and is connected to the insulation-resistance

terminal-board or plug. Distant-reading thermometers are fitted on or near the windings and insulation. The container is heated up to the required temperature at atmospheric pressure, and is allowed to remain in this condition until the transformer becomes uniformly heated and the insulation resistance has reached a low and constant value. This condition being reached points to the fact that the moisture has been distributed throughout the unit, as against the localized moisture in a cold unit. The cover is securely clamped down and the container and contents are subjected to a vacuum of approximately 28 inches. The vacuum type. There are two points of interest in these curves: first, the shutting down of the pump or the falling away of the vacuum is reflected in the temperature reading of the container and the flattening-out of the insulating characteristic; and, second, with the impregnation of oil the insulation resistance rapidly falls.

RATIO TESTING.

The checking of the voltage or winding ratio is the first test that should be applied to the transformer, for if it be found incorrect all other tests are of no value.

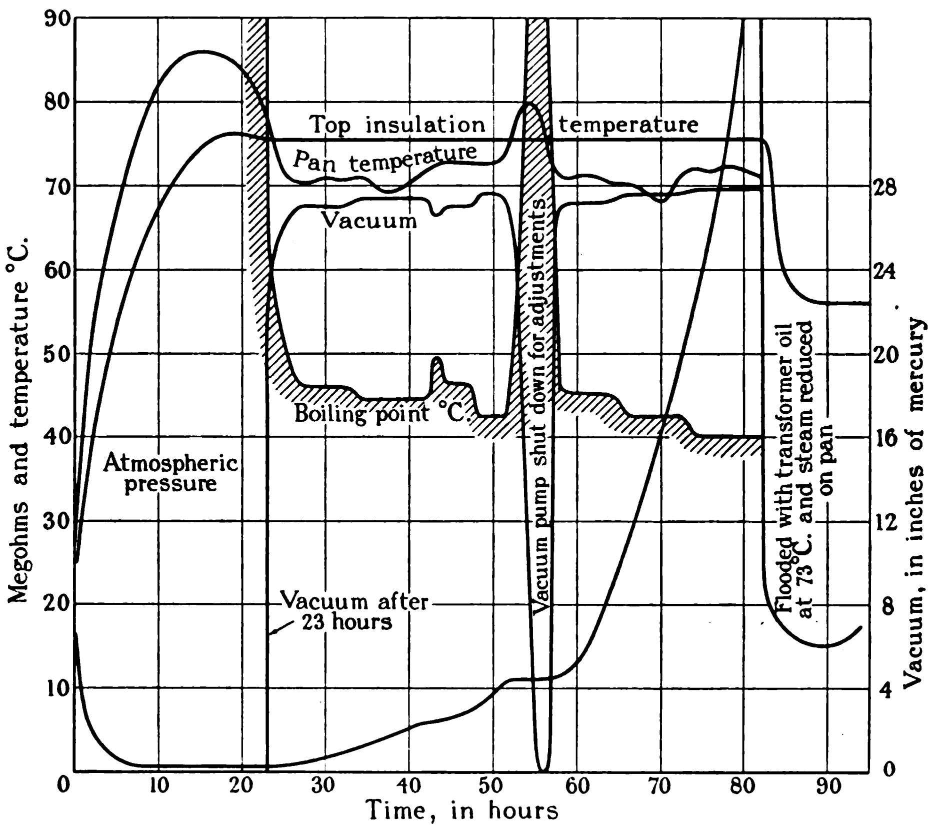

FIG. 2.—Drying-out characteristics for 125 000-volt 7 333-kVA single-phase shell-type transformer.

accelerates the drying by rapidly liberating the moisture, which is drawn off through the pump. The insulation resistance after a time begins to rise, slowly at first, and then at a gradual increasing rate until it reaches a safe or infinite value.

If oil impregnation is required it is done at this stage when dry, clean oil at a temperature approximately that of the transformer being allowed to enter under vacuum until the transformer is fully immersed. The plant is then allowed to stand in this condition until such time as full penetration of the insulation is complete. If oil impregnation is not required the vacuum must be released slowly through an air drier, to prevent moisture entering with the air.

Fig. 2 shows a typical insulation characteristic curve of a 125 000-volt 7 333-kVA transformer of the shell

There are several methods which can be employed, namely:—

(1) Voltmeter method.
(2) Standard transformer-ratio method.
(3) Resistance balance ratiometer.

The voltmeter method is self-explanatory, and is carried out by using two suitable, calibrated voltmeters, one on the primary and the other on the secondary side of the transformer under test. The accuracy of this method leaves much to be desired, on account of possible errors in reading two meters at the same instant, and also due to the fact that in many cases potential transformers have to be used, thus magnifying any error that may be present.

The standard-transformer method is carried out by

balancing the transformer under test against the standard transformer, having an adjustable ratio. This method is well known and needs no detailed description, and until the last year or two was the standard method employed by most manufacturers. The accuracy of this method varies according to the size of the transformer under test and the voltage for which it is designed. For instance, high-voltage transformers having a large capacity take an appreciable charging current, and hence, as this method is a null one, errors within limits are quite possible.

Resistance-balance ratiometers are now generally employed and give reliable results in all cases. Such instruments can be purchased as standard instruments.

Fig. 3 shows diagrammatically a typical resistance ratiometer which compares the ratio of the transformer under test with a resistance bridge. The high-tension winding of the transformer is connected across a resistance R, tapped to suitable dial switches arranged to give various resistance values. The low-tension winding is connected in opposition across a part of

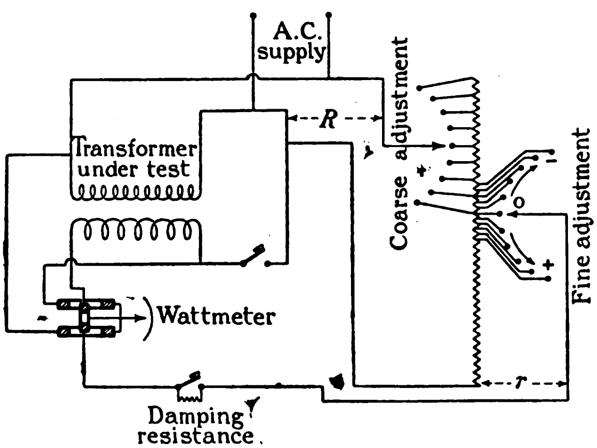

FIG. 3.—General arrangement of a resistance ratiometer.

this resistance R, also tapped through suitable dial switches to a sensitive wattmeter movement to show the balance of the two circuits the field coils of which are excited off the high-tension supply. By this arrangement any current flowing in the low-tension windings will be indicated by a wattmeter reading. The procedure is so to adjust the dial switches as to obtain a true balance and a zero reading on the meter. The ratio of the transformer is then R/r.

There are several modifications of this type of instrument, but all function on the same principle. In general, this type of ratiometer has superseded the other methods mentioned, as it is not subject to the same inherent errors, and accuracy can be obtained over a much wider range.

Polarity Testing.

The polarity test confirms the relation of the windings to one another, and is the only means of accurately determining the connection of transformers for parallel operation or connecting in banks.

Apart from a visual examination of the rotation of the windings, there are several ways of obtaining the required result. The polarity can be readily obtained by comparison with a transformer of known polarity, and can be carried out at the same time as the ratio test if the standard-ratio transformer be suitably marked.

Another method is that of employing a single-phase eddy-current wattmeter, the direction of rotation of the eddy-current disc indicating the polarity.

Still another method is that of using direct current. A direct current is passed through the high-tension winding and a voltmeter is connected across its terminals to give a positive deflection. The voltmeter leads are then transferred to the low-tension windings, the individual leads being changed over in a definite way according to the standard of polarity. A break in the current in the high-tension winding produces a kick on the voltmeter, now on the low-tension side, due to the momentary induced voltage, and the direction of the kick will denote the polarity.

Iron Loss and Magnetizing Current.

The accurate measurement of iron loss and magnetizing current is essential, as this loss is in most cases constant and, therefore, important to the customer, from the point of view of running costs. The iron loss and magnetizing current are measured by supplying the normal voltage at the correct frequency to one winding of the transformer, with the other open-circuited, as shown in Fig. 4. The voltage and fre-

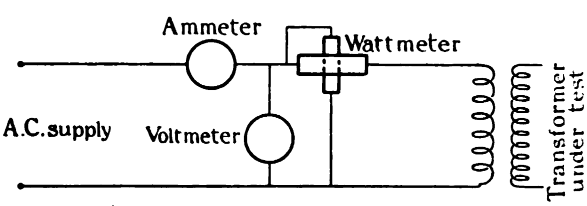

FIG. 4.—Simple single-phase iron-loss connections.

quency are adjusted to the correct values for the particular winding. The wattmeter reading then gives the iron loss and the ammeter reading the no-load current, often mistakenly termed the "magnetizing current." The no-load current is made up of a watt component due to the energy loss and a wattless component due to the magnetization, and, as the power factor can be obtained, the wattless or magnetizing current can be calculated.

With large transformers the magnetizing current is almost equal to the no-load current, but with small transformers there is an appreciable difference. The no-load power factor varies according to the size and frequency of the transformer under test, and comes within the range of 0·2 to 0·06 approximately. This necessarily results in small readings on the wattmeter and, therefore, the possibility of errors in reading.

To overcome these inaccuracies of reading, or to reduce them to a minimum, it is essential that a wattmeter be used suitably designed for low-power-factor work. Such meters are available and the authors have had them in constant use for some considerable

time with satisfactory results. One such instrument has its maximum capacity in volt-amperes equal to five times the maximum scale reading in watts, and this means that, compared with an ordinary wattmeter for unity power factor, the scale reading will be five times as great and, consequently, the error in scale reading only one-fifth.

Wattmeters are generally so connected in the circuit that the pressure coil of the instrument is on the supply side, or between the supply and the current coil, thus introducing small errors due to losses in leads, joints and instrument coils. The low-power-factor wattmeter is fitted with a compensating device to neutralize the effect of the current taken by the pressure coil passing through the current coil. This enables the pressure terminals of the wattmeter to be connected directly across the terminals of the transformer under test. For three-phase iron-loss measurements several instruments are necessary, unless some special change-over device is used for putting the same instruments in the different phases in turn. Two well-known methods of measurement are available, namely, the two-wattmeter and three-wattmeter methods, each of which gives accurate results provided suitable instruments are used.

Fig. 5 shows the instruments and connections necessary for the three-wattmeter method, and Fig. 6 those for the two-wattmeter method. Unity-power-factor wattmeters are permissible when using the two-wattmeter method, but low-power-factor meters are essential for the three-wattmeter method. To illustrate the above, Table 1 gives figures for a 200-kVA transformer tested by the two methods, and it can be clearly seen that the meter power-factors are much higher for the two-wattmeter than for the three-wattmeter method.

ment for the two-wattmeter method, and Fig. 8 an arrangement suitable for both methods of measurement. In all change-over switch arrangements the

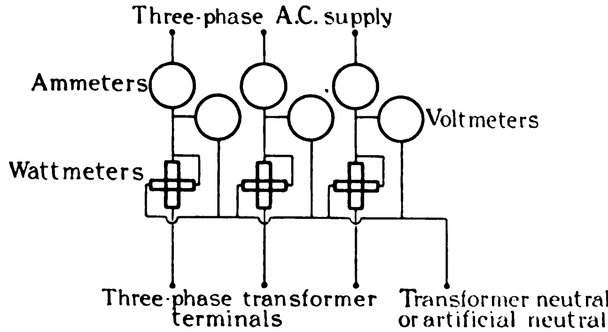

Fig. 5.—Three-wattmeter method of measuring three-phase iron loss.

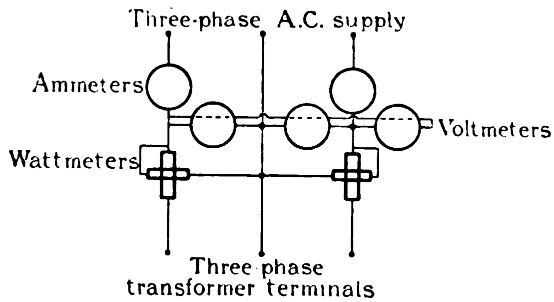

Fig. 6.—Two-wattmeter method of measuring three-phase iron loss.

inclusion of an additional voltmeter for checking and so maintaining the voltage of supply at a constant value during the test is advisable. The special arrangement for earthing the instruments automatically as the switches are changed over should be noted.

Table 1.

Iron-loss Tests on a 200-kVA 40-Period Three-Phase Transformer.

	Line volts	Amps.	Meter kW	Meter kVA	Meter power factor	Overall power factor
Two-wattmeter method	440	10	3·12	4·400	0·706	0·153
	440	8·5	—	—	—	
	440	10·2	−2·0	4·480	0·447	
	Phase volts					
Three-wattmeter method	$440/\sqrt{3}$	10·2	0·62	2·595	0·237	0·153
	$440/\sqrt{3}$	10·0	0·16	2·542	0·063	
	$440/\sqrt{3}$	8·5	0·34	2·16	0·1535	

In connection with the three-wattmeter method, if used for delta-connected transformers it is necessary to create an artificial neutral. This neutral may be the neutral point of the a.c. supply, the neutral point of another transformer across the same supply, or the neutral of a bank of three resistances or choke coils.

In order to reduce to a minimum the number of instruments in use, special change-over switches can be arranged suitable for both methods of measurement. Fig. 7 shows a change-over switch arrangement for the two-wattmeter method, and Fig. 8 …

For high-voltage iron-loss testing, provision has to be made for the insertion of potential transformers, but as the ammeter and current coil of the wattmeter are always earthed, no current transformers are necessary. This tends to more accurate results, due to the elimination of errors brought about by phase-angle displacements such as are present when they are used.

Temperature measurements are usually not necessary, though advisable. The corrections for temperature are

so small that they are generally neglected. This point is described in detail later.

Easy and accurate measurement of frequency is of vital importance in transformer testing, for more than 25 per cent of inaccurate results can be traced to insufficient care in obtaining a true reading.

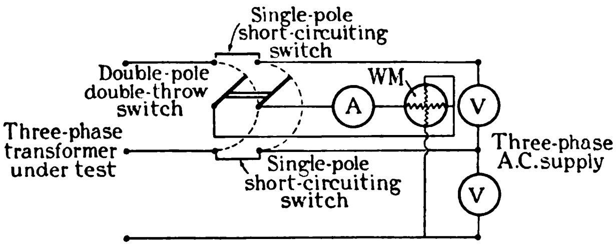

FIG. 7.—Change-over switching for 2-wattmeter method.

Several methods may be used, but the one recommended is a series of frequency meters of the electromagnetic type, connected to slip-rings off the armature of the d.c. driving motor. This is necessary, as the instrument is dependent on voltage and is accurate

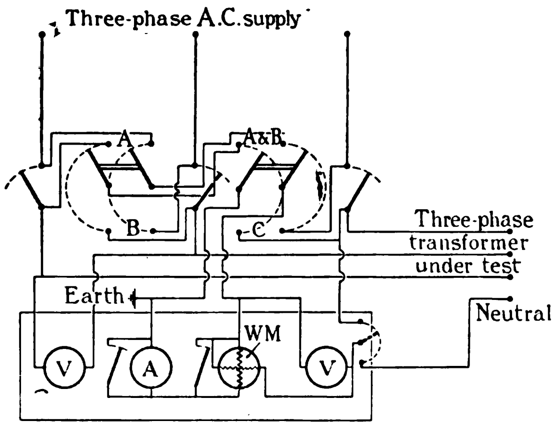

FIG. 8.—Change-over switching for 3-wattmeter method.

within certain voltage limits. If the frequency is measured by meters on the a.c. side of the motor-generator set, it would be necessary to include variable-resistance or multiple-ratio transformers to compensate for the varying voltages that the machine has to supply. The

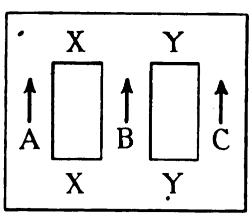

FIG. 9.—Flux diagram for core-type frame.

d.c. voltage for the driving motor is usually constant within limits, so that tappings from the armature windings to slip-rings provide the ideal conditions.

Several advantages can be claimed for this method. For instance, by using a relay the instrument can be easily connected to any measuring table; the instruments can be used for several machines, and the range of frequencies measured can be limited, a wide scale being provided for a small variation in frequency.

Belted or driven tachometers should be provided for each machine, for checking and for starting up the sets, but the final adjustment can be made on the various measuring tables.

THREE-PHASE CORE-TYPE TRANSFORMERS.

When measuring the iron loss of three-phase core-type transformers by the three-wattmeter method the losses measured in the three phases are never equal,

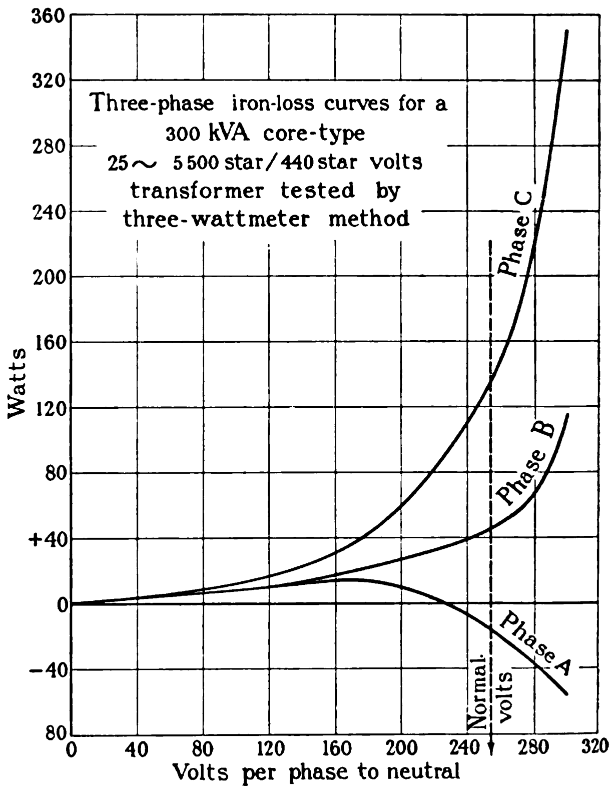

FIG. 10.

and in some instances a negative reading is obtained in one of the outer phases. This apparent anomaly is puzzling to many, but it can be accounted for by the unbalancing of the magnetic flux in the core, due to its shape. If we consider a transformer similar to Fig. 9, then by applying a symmetrical three-phase voltage to the three phases, we excite each limb to the same flux density. Half the flux in limb B returns through limb A, and half through limb C, because from the point of view of phase B the core is symmetrical. The flux in limb A returns part by limb B and part by limb C, but due to the fact that the reluctance of the return path through B is lower than that through C more flux will pass through B than through C. Similarly the flux in C will return in like manner through B and A. Supposing the reluctances of these paths are in the ratio of 60 to 40, then 60 per cent of the flux

from A will return through B and 40 per cent through C, and similarly 60 per cent of the flux from C will return through B and 40 per cent through A.

The reason for the unequal loss measurements is found in the unequal distribution of the return flux, and a concrete example will make it more clear.

Details of a test taken on a three-phase 300-kVA 25-period core-type transformer by the three-wattmeter method are given in Table 2.

between the no-load current and voltage in phase A must be greater than 90°.

Fig. 11 shows this relation graphically, and has been drawn up from the above test figures, with certain assumptions. The no-load currents have been taken as a measure of the reluctance, though this is not strictly true owing to their watt components. The reluctance of the return paths for flux B is proportional to 6·6 in A and 6·6 in C; the reluctance of the return paths for flux A is proportional to 6·6 in B and 11·8 in C; and the reluctance of the return paths for flux C is proportional to 6·6 in B and 11·8 in A. Whilst the above relation of reluctances is not strictly true, it is of the right order and gives the result required, which is that attaining to a phase angle greater than 90°, and thus a negative wattmeter reading.

TABLE 2.

Volts, per phase	No-load current, amperes			Kilowatts			Kilovolt-amperes			Phase power factor		
	C	B	A	C	B	A	C	B	A	C	B	A

* Normal volts.

Fig. 10 shows a characteristic curve of loss measurements in each phase, plotted against the applied voltage. The curve for phase C shows an increasing loss with voltage, and similarly phase B, but phase A shows an increase and then a decrease, and finally a negative reading for higher voltages. The extent of the negative value depends on the induction in the core at normal voltage, and also on the relation of the reluctances of the two magnetic paths for the flux in limbs A and C. This negative reading also means that the phase angle

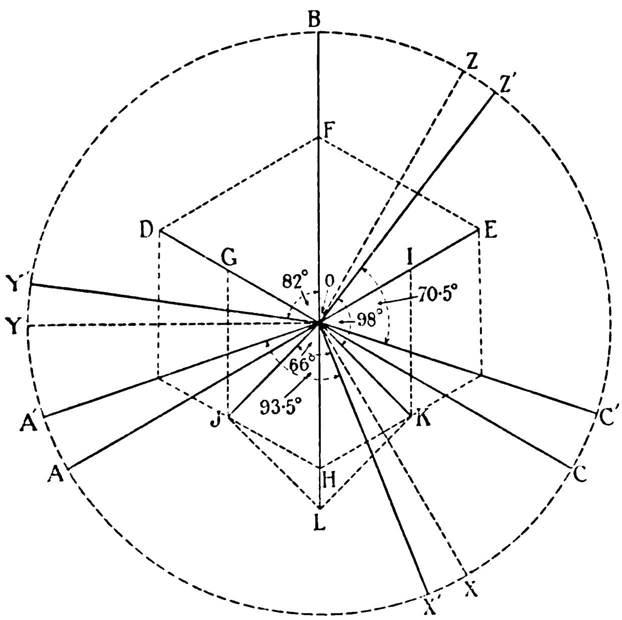

FIG. 11.—Vector diagram for three-phase core-type unbalanced magnetic circuit.

In the diagram,

- OA, OB and OC represent the main flux in limbs A, B and C.
- OD represents the return flux of C through limb B.
- OE represents the return flux of A through limb B.
- OF represents the resultant flux of C and A through limb B.
- OG represents the return flux of C through limb A.
- OH represents the return flux of B through limb A.
- OJ represents the resultant flux of C and B through limb A.
- OI represents the return flux of A through limb C.
- OH represents the return flux of B through limb C.
- OK represents the resultant flux of A and B through limb C.
- OL represents the resultant flux of OJ and OK and is equal and opposite to OF.

The main flux being 90° behind the applied voltage, OX, OY and OZ represent the applied voltage, and if there were no watt component in the no-load current the angles between OF, OJ, OK and the applied voltage would represent the phase angle of the return flux, but owing to the watt component the angle of 90° is reduced. From the test figures we know the phase angles and, taking the one for the symmetrical phase, which is 82°, OX′, OY′, OZ′ represent the applied voltage at an angular displacement of 8° from OX, OY and OZ.

The no-load current, though dependent on the return

flux, is not in phase with it, for the current is proportional to the reluctance of the magnetic circuits whilst the flux is inversely proportional to it. The resultant of OD and OH gives the phase position of no-load current OA′ in phase A, and the resultant of OE and OH gives the phase position of the no-load current OC′ in phase C. The phase angles of the no-load current relatively to the applied voltage are equal to 82°, 93·5° and 70·5°, and are approximately equal to those obtained from the test results and are in the same rotation. It will also be noticed that the sum of the angles from the diagram is 246° and from the test figures 247°. The slight variation in the values of the angles is due to the assumption already mentioned, but the result proves the possibility of a lag greater than 90°, and hence a negative reading on a wattmeter in one outer phase of a three-phase core-type transformer.

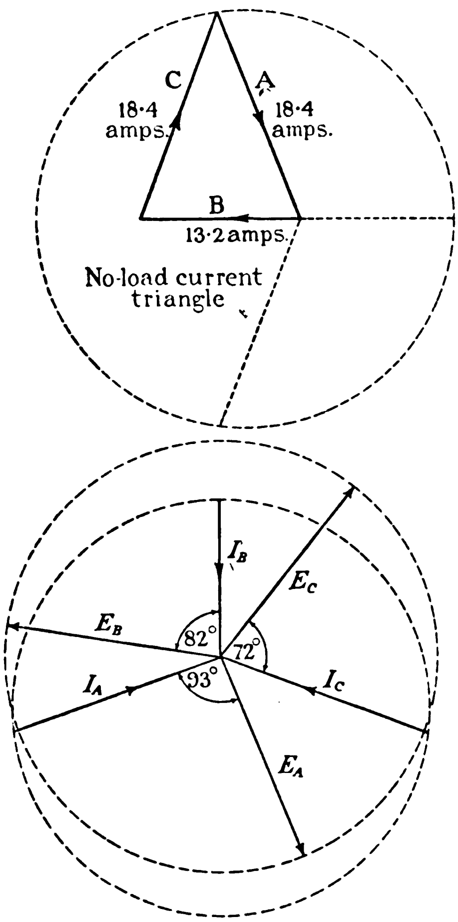

Fig. 11A.—No-load current and voltage vector diagram for three-phase core-type transformer.

Fig. 11A shows the vector diagram at normal voltage for the test example taken. The no-load currents form a closed triangle, and as the currents are unequal the angles between them must be unequal. As the reluctance of the return path for the magnetic flux of phases A and C increases, so will the negative value increase due to the increase of the angle between the currents in phases A and C. The shorter the length of the core, the greater will be the divergence of the current vectors. Although a negative reading is obtained it must not be assumed that there is no energy loss in that particular phase. The method of measurement and the result of the phase relation of the starred currents produce the effect obtained.

Iron Loss and Form Factor.

The iron loss of any particular transformer may be directly measured by the method already described, but unless the wave-form of the applied voltage be a sine wave the results will be greater or less than the estimated or correct loss. If the wave-form be peaked, having a form factor (R.M.S. volts divided by average volts) greater than 1·11, then the measured loss will be lower, whilst if the wave-form be flat with the form factor less than 1·11 the measured loss will be too high. In general the wave-form will be peaked, due to the nature of the load on the machine, and the measured losses will be of a low order. Since the form factor of the wave does not affect the eddy loss in the same manner as the hysteresis loss it is necessary, if a correction is to be made, to separate the loss into its two components and correct the hysteresis loss in line with the form factor.

Table 3 shows the effect of form factor on hysteresis loss, the effect at a form factor of 1·11 being taken as 100 per cent.

Table 3.

Form factor	Relative hysteresis loss
	per cent
1·0	118
1·05	109
1·11	100
1·15	94·5
1·2	88·2
1·3	77·6
1·4	69·3

When it is remembered that the hysteresis loss forms by far the greater proportion of the total loss, any increase in form factor will appreciably reduce the measured loss and so give erroneous results.

Before passing on to the ways and means of carrying out this correction, it would be well to point out that the iron loss in service will rarely be that for a pure sine wave, especially for large units, but for a basis of standard reference and comparison the loss as measured should be that obtained for a sine-wave voltage or should be corrected for such a wave.

The correction for form factor may be accomplished in two ways :—

(1) By obtaining the form factor of the applied voltage and correcting the hysteresis loss in line with the form factor.

(2) By applying an equivalent voltage to compensate for the form factor by means of an instrument termed an iron-loss voltmeter.

To carry out the correction for form factor by method (1), it is essential to obtain the correct wave-

form of the applied voltage, or its form factor. This can be done by means of the oscillograph, thus obtaining a true picture of the wave and then analysing it for the form factor. The form factor can also be obtained by fixing a commutator or mechanical rectifier to the machine giving the a.c. supply, or it may be obtained

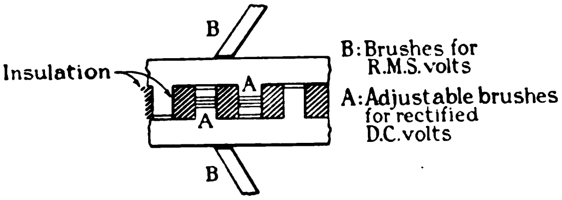

FIG. 12.—Plan of simple commutator rectifier.

by the authors' arrangement of thermionic valve rectification. The mechanical means of obtaining the form factor is by a special commutator, shown in Fig. 12, fitted on the alternator shaft.

This type of apparatus is not recommended as a commercial test instrument owing to the great care

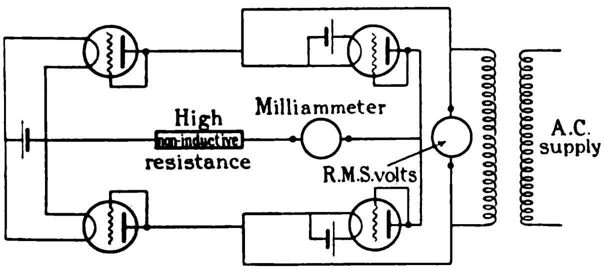

FIG. 13A.—Four-valve full-wave rectification.

that has to be exercised in setting it. Another disadvantage is that each alternator used has to be fitted with a special commutator, and, further, the method is quite impossible when the a.c. supply is taken from a.c. mains and not from a definite machine.

In considering the question of form factor and the

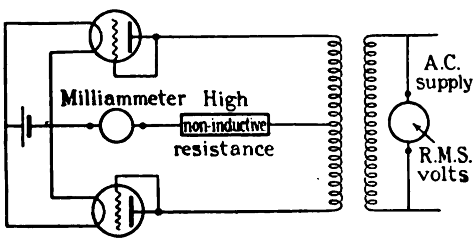

FIG. 13B.—Two-valve full-wave rectification.

method of obtaining it without having recourse to mechanical means, the authors have carried out many experiments and have obtained a scheme of apparatus which gives very reliable and consistent results. The methods employed cover the rectification of the complete a.c. voltage wave by means of either two or four three-electrode thermionic valves. Fig. 13A shows the connections of the four-valve full-wave rectification, and Fig. 13B that for the two-valve full-wave rectification. The valves are connected in bridge form, and across the bridge the rectified direct current is caused to flow through a standard, high, non-inductive resistance and a milliammeter, thus giving a means of obtaining the rectified voltage or the average a.c. voltage.

To obtain satisfactory results, a straight-line characteristic had to be aimed at for valve impedance plotted against circuit voltage. By maintaining the filaments at a constant, normal temperature and the external resistance at a high value relative to the internal resistance of the valves, the working part of the characteristic was approximately a straight line. It was found that the valves most suitable were those of low impedance, and to reduce still further their impedance the grid was connected to the plate. Using an external resistance of 104 310 ohms, it was found that as the voltage across the valve outers was increased, the valve impedance decreased rapidly and became constant or asymptotical at 160 volts, or approximately 5·6 volts (d.c.) across the valves. With four-valve rectification, two valves were used in series for each half-wave rectification, and, with the valves used, their impedance became constant at 4 000 ohms.

With two-valve full-wave rectification the mid-point of the transformer was used as the bridge point, and the results obtained were more accurate than those obtained by the four-valve method. The former is therefore recommended as the most suitable.

In this particular method with a grid connected to the plate, the valve impedance became constant, or asymptotical, at 3 000 ohms, with 150 volts across the valve outers, i.e. with 75 volts across the valve and resistance. The same resistance of 104 310 ohms was used and the d.c. voltage across the valves was 5·5 volts.

For these experiments two B.T.H. B4 valves were used, but any low-impedance receiving valve of the three-electrode type is suitable, provided the circuit voltage for constant valve impedance is ascertained and the voltage is maintained at not less than this value.

The original experiments were conducted with an ordinary potential transformer with a mid-point tapping, but it was found that the d.c. component affected the R.M.S. voltmeter so that the R.M.S. voltage was measured on the primary side as shown in the diagram.

On testing the apparatus on a machine specially designed to give a sine wave-form of voltage, the actual form factor was given correctly when allowance had been made for the valve impedance, which is constant for a particular valve.

Many tests were taken as checks on distorted waves, and the form factors obtained corresponded almost exactly to that obtained from the actual wave as recorded by an oscillograph.

The authors claim the tests to be accurate within 0·5 per cent by the method described. In addition to obtaining the form factor, the losses measured must be separated into the two components, hysteresis and eddy loss, because, since the form factor affects only the hysteresis loss, that component must be obtained.

Separation of Losses.

The separation of losses as given by the measured loss can be carried out by several methods :—

(*a*) Measure the loss at constant induction and varying frequency and draw the curve showing the relation between loss and frequency. The tangent to the curve gives the dividing line of the losses, i.e. the ordinate between the datum line and the tangent is the hysteresis loss, and that between the tangent and the curve is the eddy-current loss.

This method is not recommended, owing to the difficulty in drawing a true tangent and also in obtaining losses at low frequencies, which is essential if a true curve is to be plotted.

(*b*) Measure the loss at varying induction and constant frequency and draw a curve showing $W/E^{1\cdot 6}$ plotted against $E^{0\cdot 4}$, which should be a straight line. The ratio of the ordinate at the vertical axis to the ordinate at normal voltage gives the ratio of hysteresis loss to total measured loss.

(*c*) Measure the losses as in (*a*) and plot loss/frequency against frequency. This should be a straight line, and the ratio of the ordinate at the vertical axis to the ordinate at normal frequency gives the ratio of hysteresis loss to total measured loss.

(*d*) Measure the loss at constant voltage and varying frequency and plot it against $1/f^{0\cdot 6}$. This should be a straight line, and the point where it cuts the vertical axis gives the eddy-current loss in watts.

Methods (*c*) and (*d*) are recommended as being likely to give the most accurate results, and of these methods (*c*) is the simpler and quicker, which is a great asset to test-bed work.

Having obtained the hysteresis component and the form factor, the hysteresis loss should be multiplied by

$$\frac{(\text{Form factor})^{1\cdot 6}}{(1\cdot 11)^{1\cdot 6}}$$

Various opinions are still held as to the value of the index in the expression for hysteresis, especially at high inductions. Some authorities give it as 1·68, whilst others say that it is 2.

The test-bed not being a laboratory, the authors have retained the original constant in their calculations, and this is supported by the test results obtained from the analysis of test curves for samples of transformer iron taken at random. Results were obtained by the above loss-separation methods on a 7 500-kVA single-phase shell-type transformer for 25 frequency, and it will be noticed that from a commercial-test point of view there is little variation in the results obtained :—

	per cent	per cent
Method (*a*)	Hysteresis loss 81 ;	eddy loss 19
Method (*b*)	Hysteresis loss 80·7 ;	eddy loss 19·3
Method (*c*)	Hysteresis loss 80·9 ;	eddy loss 19·1
Method (*d*)	Hysteresis loss 81·6 ;	eddy loss 18·4

As examples of corrected measurements the following tests were taken on two large transformers, one designed for 25-period service and the other for 50-period service.

25-Period Example.

7 500-kVA single-phase shell-type 33 000/5 500-volt transformer.
Form factor of applied voltage = 1·4.
Estimated loss with normal voltage for sine wave = 24 000 watts.
Measured loss with normal voltage for a form factor of 1·4 = 17 850 watts.
Separation of measured loss gives 80·9 per cent hysteresis and 19·1 per cent eddy loss.
Hysteresis loss corrected for form factor = 116·31 per cent of measured loss.
Total corrected loss in watts = 24 200.

Hysteresis loss corrected = 86 per cent.
Eddy loss corrected = 14 per cent.

50-Period Example.

7 833-kVA single-phase shell-type 136 000/6 600-volt transformer.
Form factor of applied voltage = 1·25.
Estimated loss with normal voltage for sine wave = 32 000 watts.
Measured loss with normal voltage for form factor of 1·25 = 27 750 watts.
Separation of measured loss gives 76·1 per cent hysteresis and 23·9 per cent eddy loss.
Hysteresis loss corrected for form factor = 92 per cent of measured loss.
Total corrected loss = 115·9 per cent of measured loss.
Total corrected loss in watts = 32 150.

Hysteresis loss corrected = 79·4 per cent.
Eddy loss corrected = 20·6 per cent.

These typical examples show how necessary it is, even if only for the designer's information, that the form factor should be ascertained correctly or in some measure compensated for.

As a check on the above corrected losses and the percentage hysteresis and eddy loss, it is interesting to compare them with the percentage losses on a sample of iron at the same induction.

At 25 frequency, loss for sample = 88·5 per cent hysteresis and 11·5 per cent eddy loss.
At 25 frequency, loss for transformer = 86·0 per cent hysteresis and 14·0 per cent eddy loss.
At 50 frequency, loss for sample = 82·0 per cent hysteresis and 18 per cent eddy loss.
At 50 frequency, loss for transformer = 79·4 per cent hysteresis and 20·6 per cent eddy loss.

These comparative figures show conclusively that the corrected losses are in order, and also that the corrected measured losses are sufficiently accurate for commercial purposes. The slight variation in percentage in the corrected loss for the sample can be accounted for by the difference in pressure exerted on the punchings in

the transformers and sample, or by the building-in of a few more or a few less core punchings to that called for by the design.

The second method of correction for wave-form, namely, that of applying a compensated voltage value in line with the form factor, is simple and easy in operation, but depends entirely on the calibration of an instrument termed an iron-loss voltmeter. This type of meter is used by the American Westinghouse Co., and apparatus based on a similar principle is also used by the General Electric Co. of America. In brief, the so-called voltmeter indicates an equivalent voltage for a sine wave-form of applied voltage.

ratio of the two readings will be some measure of the difference in form factor.

Fig. 14 shows the internal connections of the iron-loss voltmeter and also its position in the iron-loss test-circuit.

Table 4 gives the results of tests taken with this type of instrument. These show clearly the increase in voltage necessary and also the error in the correction for loss measurement. The results are also compared with the correction method as previously explained, by correcting for form factor. The similarity, or almost equality, in the results obtained by the two methods is worthy of attention.

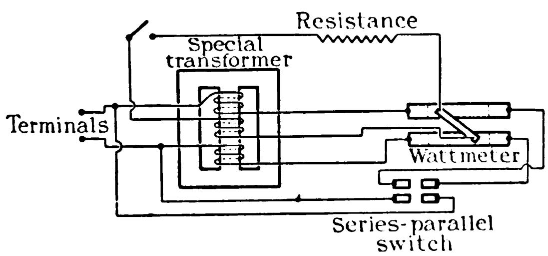
TABLE 4.

Test taken on a Large Single-phase Transformer at Normal Voltage (24 300).

Frequency	Voltage		Form factor	Loss		Normal volts measured on
	R.M.S.	By iron-loss voltmeter		Total measured	Corrected	
60	24 300	23 600	1·192	50 500 W	55 300 W	R.M.S. voltmeter
60	25 200	24 300	1·195	55 200 W	—	Iron-loss voltmeter

The voltmeter consists of a wattmeter movement permanently connected so as to read the loss of a standard transformer incorporated in the instrument. The meter is calibrated on a pure sine wave and the scale is marked in volts against the watt loss measured at various voltages. The dial also carries a watt scale, so that the watt loss in the meter may be taken care of in the corrected measurements. The accuracy of the instrument depends on the design of the standard transformer incorporated in it, and on its calibration

Special machines could be designed to give a better wave-form under the special conditions of loading, as occurs with iron-loss testing, but as the test load necessarily varies according to the size of the transformers under test, a wave-form to suit all such variable conditions would be impossible. Usually the wave-form on open-circuit conditions is as near as possible a sine wave, the distortion, which is due to the condition of loading, being compensated for by the method described above.



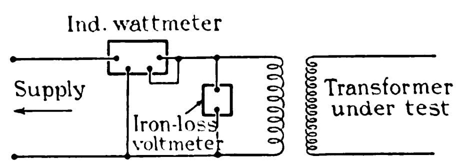


FIG. 14.—Internal connections of iron-loss voltmeter, and diagram of connections for testing.

on a true sine wave. When in use for testing iron loss, it is connected up in the same way as a standard voltmeter. A wattmeter is also connected in the circuit in such a way as to measure the total input of the transformer under test and the loss in the iron-loss voltmeter. The applied voltage is then adjusted at the correct frequency until the iron-loss voltmeter reads the normal supply voltage. The total power input is read on the wattmeter and the iron-loss voltmeter, and the difference between these two readings gives the true loss on the sine-wave voltage. If an ordinary voltmeter be also connected in circuit, this will give the actual effective voltage applied, and the

IRON-LOSS CORRECTION FOR TEMPERATURE.

Temperature has very little effect on the iron-loss measurements and is usually neglected. The permissible correction is that for the eddy-current loss component of the losses, which may be corrected for temperature. The eddy-current loss decreases slightly with increase in temperature, depending on the temperature coefficient of resistance, which for transformer iron is approximately 0·00077 between 20° C. and 100° C. In other words, the eddy-current loss may be reduced by 0·077 per cent for every degree increase of temperature. Thus, if the iron-loss measurements were taken at 20° C. and have to be corrected for

by 75° C., the eddy-loss component must be reduced by 4·23 per cent. As the eddy-current loss varies from approximately 15 per cent for 25-period, to 20 per cent for 50-period transformers, the adjustment for a temperature-rise of 55 degrees C. would mean a reduction of 0·634 per cent and 0·85 per cent in the total iron loss for 25- and 50-period transformers respectively.

As will be seen from the above figures, the permissible correction for temperature is very small and is rarely used, as it is within the possible errors of measurement due to visual, frequency, ratio, and meter errors.

Copper or Load Loss and Impedance Tests.

The measurement of copper loss is usually carried out by an arrangement of instruments similar to that used for iron-loss measurements, except that the one winding of the transformer, usually the l.t. winding, is short-circuited, and a supply capable of circulating the full-load current at the correct frequency is connected to the other winding, as in Fig. 15. The ammeter and wattmeter must be suitable for carrying the full-load current for the particular winding on which the loss is measured, but the voltmeter has only to measure the impressed or impedance voltage necessary to circulate the current, and this can be approximately ascertained from the design data.

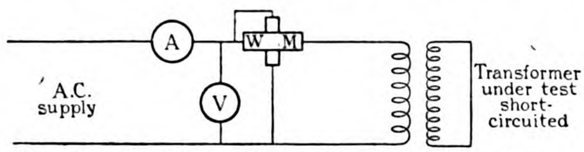

Fig. 15.—Simple copper-loss diagram of connections.

The measured loss is composed of two losses—that due to the ohmic resistance of the copper and that due to the stray losses termed eddy-current losses. The ohmic-resistance loss is the product of the ohmic resistance and the square of the current, being the arithmetical sum for the two windings. The stray losses are brought about by induced currents flowing in small local circuits within the copper windings, terminal straps and surrounding metal, and generally depend on the strength and extent of the leakage fields. This loss is proportional to the square of the frequency and to the resistivity of the particular metals.

The ratio of the ohmic loss to the eddy loss varies for different transformers, being dependent on the characteristics of the transformers, such as their reactance, current and copper section. High reactance and heavy currents are conducive to eddy-current losses. The separation of the losses can be carried out by two methods :—

(*a*) By calculating the ohmic loss from the measured resistances of the transformer windings and subtracting this loss from the measured loss, which gives as a result the eddy-current or stray losses.

(*b*) By separation of the losses. This is carried out by taking several readings of watts loss and frequency, keeping the load constant. The watts loss plotted against the square of the frequency is a straight line, and the loss at zero frequency is the true ohmic loss.

The applied voltage measured on the copper-loss test is termed the impedance voltage, and is usually given as a percentage of the rated voltage at a definite temperature.

When taking copper-loss measurements on three-phase transformers it is advisable to take three-phase measurements, i.e. to apply three-phase currents. Especially is this the case for transformers having a high internal reactance, as the eddy currents tend to become unbalanced and excessive when measured single-phase.

For carrying out these tests, measuring tables such as those described under "Iron-loss Testing," can be used. Low-power-factor wattmeters are desirable, as the actual readings on the meters are low on this test if the three-wattmeter method of measurement be used. Single-phase measurements with all three phases connected in series, either in open delta or Z connection, are liable to excessive errors and should not be used except for three single-phase transformers to make up a three-phase group. The test-figures in Table 5, taken on the same transformer, show the extent of the errors that may be obtained. The tests were taken on a large three-phase core-type transformer having 20 per cent impedance, obtained by inserting magnetic shunts between the windings.

Table 5.

Method	Phase volts			Amperes			Wattmeter reading $K = 60$			Total watts
	A	B	C	A	B	C	A	B	C	
3-phase measurement with 3-phase supply	3 030	3 042	3 072	72·3	72·7	73	142	163	172	28 620

	Total volts	Amperes	Wattmeter reading $K = 200$	Total watts
Single-phase, 3 phases in series or Z connection	8 930	72·2	149	29 800
Single-phase, 3 phases in open delta	7 000	72·2	242	48 400

All the above measurements were carried out on the h.t. windings with the l.t. side short-circuited, each phase separately, and the figures provide a very good reason why it is impossible to run high-reactance transformers on load by single-phase circulation either in open delta or Z-connected, as referred to later under full-load temperature runs. With transformers having magnetic shunts inserted between the h.t. and l.t. windings to increase the reactance, it is necessary that a curve of impedance should be taken up to a high value of overload to prove that the magnetic shunt does not become saturated within the loading limits and that the impedance at the higher values does not deviate from the straight line beyond the permitted tolerance.

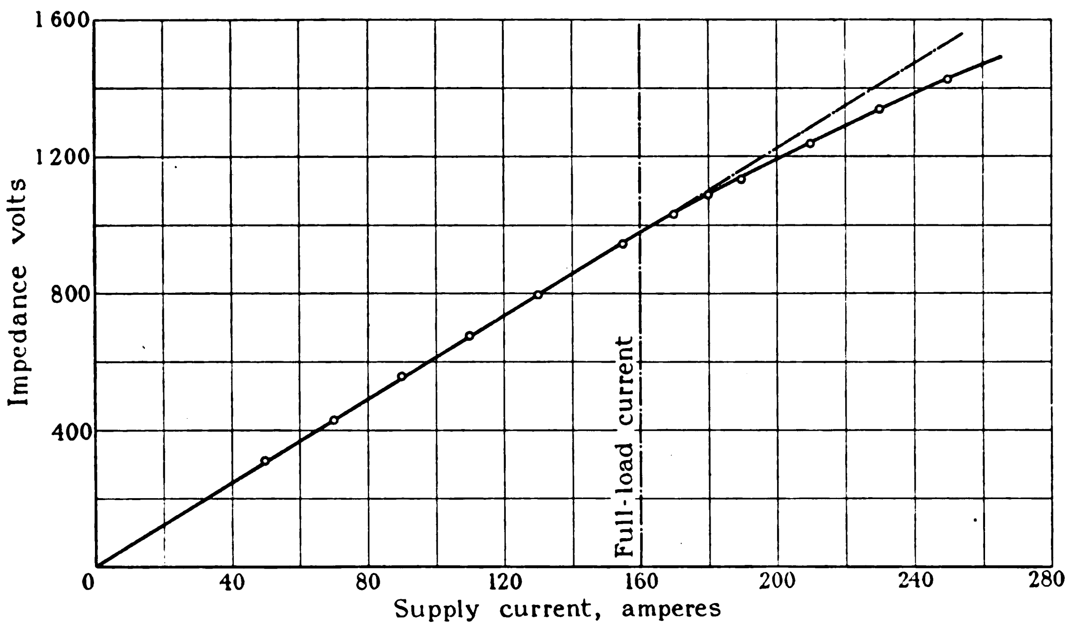

FIG. 16.—Curve showing the saturation of magnetic shunts on highly reactive transformers.

A typical example is shown in Fig. 16 for a large three-phase core-type transformer having 18 per cent internal reactance. On this particular transformer a straight-line characteristic of impedance was maintained up to 11 per cent overload, and deviated only by 5·1 per cent at 50 per cent overload.

Correction of load loss or copper loss for temperature.—The copper loss of a transformer is usually given, and is guaranteed at a specific temperature, but it is rarely possible to obtain the actual reference temperature on test, so that corrections have to be made to arrive at the copper loss for comparison with the guarantee.

This correction for the ohmic loss is an increase proportional to the temperature, and for the eddy currents or stray loss is a decrease in proportion to the temperature, assuming all the losses to be induced in the copper. The correction for ohmic loss is :—

$$\frac{\text{Ohmic loss at temperature } T}{\text{Ohmic loss at temperature } T_0} = \frac{234\cdot5 + T}{234\cdot5 + T_0}$$

The correction for eddy-current loss is :—

$$\frac{\text{Eddy-current loss at temperature } T}{\text{Eddy-current loss at temperature } T_0} = \frac{234\cdot5 + T_0}{234\cdot5 + T}$$

where T = temperature to which the losses are to be corrected, and

T_0 = temperature at which the total losses are measured.

The losses in the magnetic shunts due to the leakage flux which they carry are inseparable from the total parasitic losses by any known test methods. In the above corrections they are assumed to vary as the eddy-current loss for copper. Any error due to this assumption is small owing to the low value of these losses, which can be approximately calculated.

MEASUREMENTS OF RESISTANCE.

The cold resistance measurements are taken when the transformer is in a complete state, i.e. when it is fully mounted and all permanent connections are made on both windings.

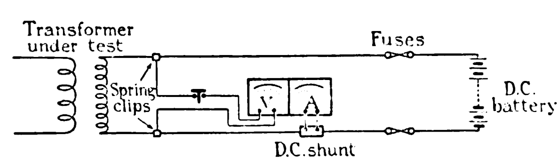

FIG. 17.—D.C. resistance measurement diagram.

An accurate measurement of temperature should be taken at the same time as the resistance, and special care should be observed to obtain the average value for the winding. Thermometers should be inserted between

the windings, in actual contact with the copper if possible. If the transformer is immersed in oil, the temperature of the latter is taken as that of the copper if the transformer has been immersed in the oil for six or seven hours at a steady temperature.

Several methods are in use for obtaining resistance measurements of the indirect or direct type. The direct methods include the use of such instruments as the ductor, Wheatstone bridge, Kelvin bridge, and standard balance. None of these methods are recommended for transformer-resistance measurements, as they are generally influenced by thermal and capacity effects.

The method recommended is the indirect one, using an ammeter, voltmeter and a d.c. battery as shown in Fig. 17. A precision ammeter and voltmeter should be used, perferably of the combined type with various ranges of shunts and resistances for the instrument, and the whole apparatus should be set aside for resistance measurements only. The voltmeter leads should be connected to the terminals of the transformer separately, so as to exclude the voltage-drop in the current leads where they are clipped to the terminals. A spring-release switch in the voltmeter circuit is essential for protection against induced voltages.

In measuring the resistance of transformer windings, it is very necessary to take care that all electrical circuits linked up by the same magnetic circuits are open-circuited before any readings are taken. If a d.c. supply is switched on to a transformer winding with the other winding short-circuited, a current is induced in the short-circuited winding which opposes the main current. This has a choking effect on the main current, causing it to rise very slowly, whilst at the same time the voltmeter reading is relatively high. This means that the magnetic circuit is damped and the flux, which has to rise to a maximum value before a steady reading can be obtained, rises very slowly, the whole system being in a state of change. Instances of this state of change having been maintained for a

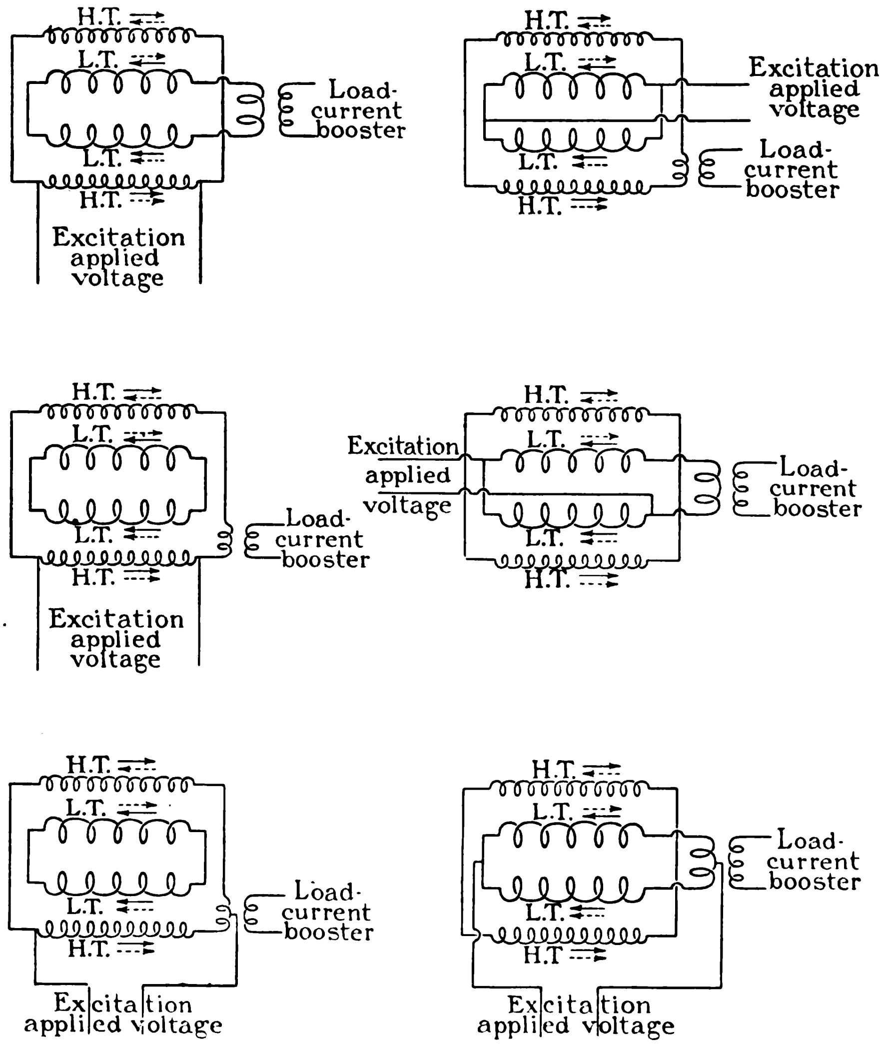

FIG. 18.—Full-load single-phase back-to-back connections.

period of 20 minutes after switching on are on record for heavy-current low-resistance windings. The d.c. supply voltage should be increased momentarily to a higher value than that intended for the readings, thus giving the circuit a dropping condition instead of a rising one.

As the circuit is very sensitive to slight changes in either the electrical or magnetic circuits, the use of a d.c. battery is essential if accurate readings are to be obtained, as the ripples or fluctuations in a d.c. supply are magnified by the coupling between the electrical circuits.

The resistances are usually measured on the particular tappings on which the temperature-runs are taken, as they will be the windings on which the hot resistances are measured.

Full-Load Temperature-Runs.

The load-run or temperature-run on a transformer is one of the most important tests to be carried out, for by this means only can the temperature-rise under full-load conditions be ascertained. The dead loading of transformers other than very small ones is out of the question, owing to the excessive cost, waste of power, extensive plant and high voltages which have at times to be catered for.

Load-runs in general are carried out on a test-bed in such a manner that the full-load losses are supplied without wasting useful power. There are many ways of approximating the load and losses, but those that are most nearly representative of true service conditions are here dealt with.

Single-phase transformers.—A single-phase transformer cannot in general be run on load by itself; it must either be run with a duplicate transformer or with one of larger size having the same ratio.

Approximate load-runs, so called, are often made on single transformers by either an overload short-circuit run or an over-excitation open-circuit run, the losses supplied in each case being equal to the total measured losses of the core and windings. These approximate runs give oil temperatures only and are liable to injure the core or windings by excessive local heating. Temperature-rises by resistance measurements are valueless under such conditions of loading.

The load-runs for single-phase transformers can be divided into two classes :—

(1) Unearthed windings.
(2) Earthed windings.

Unearthed windings are most common and are run as shown in Fig. 18 by connecting them back to back, or virtually in parallel. The core losses are supplied by exciting the two transformers in parallel, and the copper or load losses by injecting in the parallel link of either the h.t. or l.t. winding a current equal to the full-load current.

The most accurate method is to excite on one side and inject on the other side, i.e. if the excitation is supplied on the l.t. side the boosting or injected current should be on the h.t. side. If for reasons of voltage or supply considerations the excitation and boosting have to be supplied on the same winding, then one transformer will be slightly out of balance with the other for excitation, owing to the drop of voltage across the booster. To obviate this, the excitation supply should be connected to the middle point of the booster if this point is available. It is usual to supply the losses from two sources of supply, and for this reason it is essential that the frequencies be not the same, or hunting will take place due to the polarity of the excitation and booster being opposite. The excitation supply should be kept at the correct frequency, and the booster supply one or two periods higher or lower, the injected power being measured and adjusted to equal the winding or copper loss as measured.

For earthed transformers, which are usually for high-voltage service, the excitation and loading must necessarily be carried out on the l.t. side. This is due to the high voltage that would be present across the booster if loading were done on the h.t. side, for this voltage would be twice the impedance voltage of one transformer and would bring the earth point of at

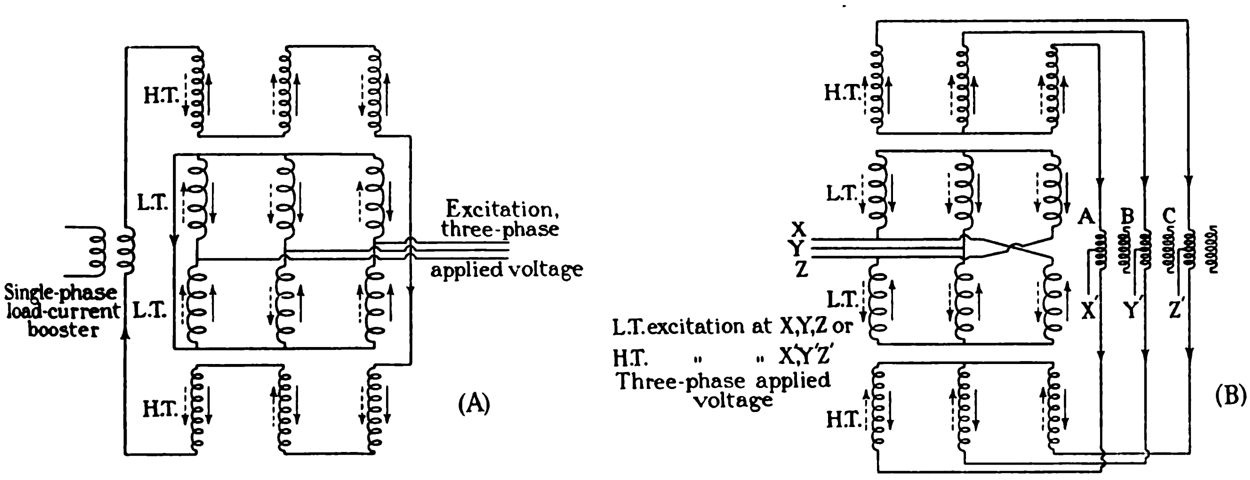

Fig. 19.—Full-load run diagram for three-phase star-star transformers back to back; single-phase or three-phase boost.

least one transformer to a possibly unsafe voltage above earth.

Three-phase transformers.—The loading of three-phase transformers is carried out in a similar manner to that of single-phase transformers, but due to the numerous methods of phase connection possible it presents a more difficult problem. The excitation is carried out by applying a three-phase voltage, and the load current injected is either single- or three-phase. With some forms of phase connection, as described later, three-phase injection of load currents is the only means possible.

Fig. 19 shows standard star/star transformers connected up for load-runs under alternative conditions. The method shown in A is one very commonly used, gives satisfactory results, and is simple to connect up, there being no necessity to phase out. This method entails the opening of the star connection and the re-connecting of the h.t. windings in series.

The advantages of this method are simplicity of connections, balanced conditions on the two transformers, service voltage conditions, and balanced loading of the two transformers. The disadvantages are: complex connections due to phasing out, a three-phase booster required, two three-phase supplies, and more losses in auxiliary apparatus. The method shown in A (Fig. 19) must on no account be used for delta transformers, i.e. a delta-wound transformer must never be temporarily connected in series or in Z-connection or undue stress will be put across the windings.

For transformers wound for delta/star connections the methods of loading shown in Fig. 20 (A and B) are most frequently used. In the method shown in A the high-tension or delta windings are left open and the two windings are connected in series through a booster. This method is not suitable for transformers of high reactance owing to excessive load losses, as described under copper-loss measurements. For transformers of this type the method shown in B must be used in order to give balanced service conditions.

The advantages of the method shown in B are similar to those described for star/star-wound transformers, and only one load-current ammeter and one three-phase supply required.

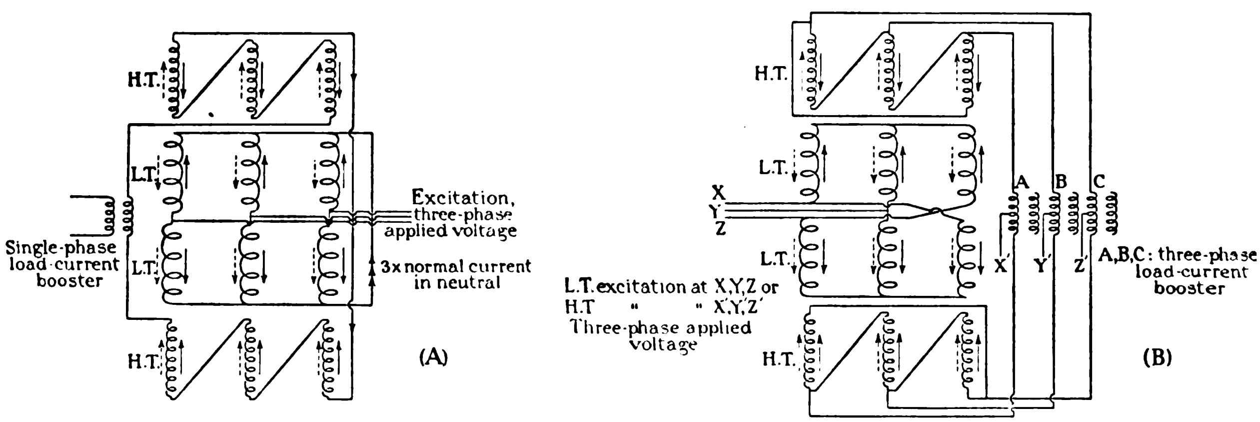

FIG. 20.—Full-load run diagram for three-phase delta-star transformers back to back; single-phase or three-phase boost.

The disadvantage is that, if the transformers have a high impedance, the voltage across the booster will be high, being approximately equal to the sum of the impedance voltage for the six legs of coils. There is also the disadvantage of temporary internal connections. This supply of the load loss by the series method does not give the true copper loss, as already explained under copper-loss measurements, and so the load current has to be adjusted to inject the equivalent of the true measured losses.

There are many variations of this method, such as exciting and boosting on the h.t. side, etc.

The method shown in B (Fig. 19) is not often used, but it is the most accurate method of loading giving balanced conditions throughout and voltage conditions exactly as in service. If in this method it is found necessary to excite the same windings as those into which the boost is introduced, the mid-points of the booster should be taken for the excitation, to maintain balanced conditions on the two transformers. The advantages of this method are: no temporary internal connections, service voltage conditions, and balanced loading of the two transformers, with the additional advantage that it can be used for such transformers if the h.t. winding is temporarily connected in delta. The disadvantages are the temporary internal connections and the necessity for strengthening the l.t. neutral temporarily to carry three times the normal current. This entails extra work and also adds slightly to the losses by those induced in the temporary neutral lead. The method shown in B has balanced conditions throughout and requires no temporary internal connections.

Star/interconnected-star transformer loading.—Transformers having interconnected-star windings are in a category of their own, the only possible means of fully loading being by the three-phase circulation method. This is due to the interconnections of the windings and the internal impedance set up on that account.

Fig. 21 shows the only scheme of connections possible for reliable results. Other methods such as unbalanced tappings rarely give full circulating-current conditions. The energy dissipated is difficult to measure accurately, and thus only approximate temperature-rise results can be obtained.

Extra-high-voltage transformers.—For transformers

wound for extra high voltage, i.e. for voltages above 33 000, star-connected and earthed or unearthed, the excitation and loading must be carried out on the l.t. side, as loading transformers are usually not available for such high pressures between windings and earth. For this type of transformer the scheme of con-

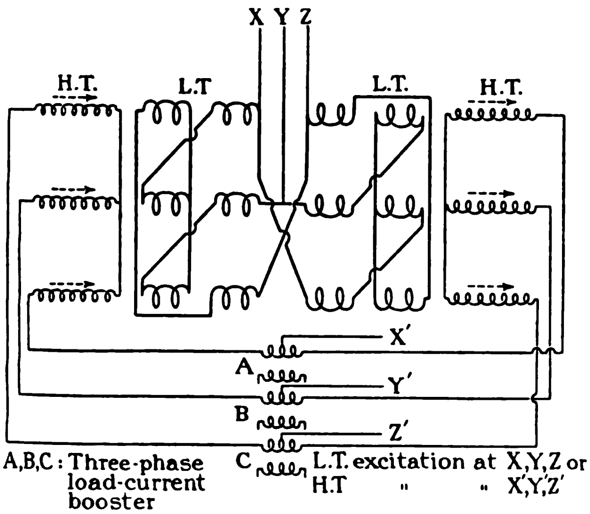

FIG. 21.—Full-load run diagram for three-phase star-interconnected-star transformers.

nections recommended is shown in Fig. 22. If the e.h.t. winding is delta-connected, then either of the two following methods may be used, and they are also applicable to any three-phase transformers of low impedance, so long as their windings are not inter-connected.

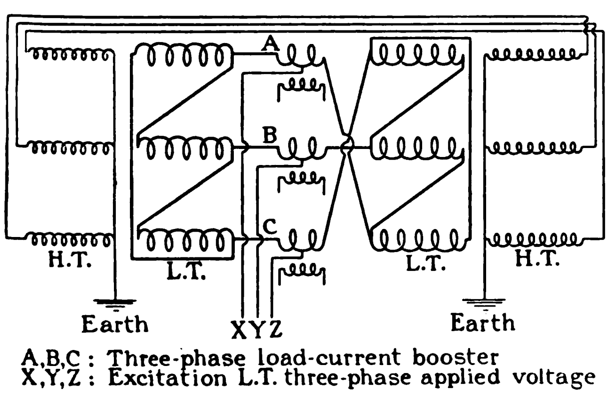

FIG. 22.—Full-load run diagram for star-delta transformers with high-tension earthed neutrals.

Fig. 23 (A and B) shows the connections, only one transformer being used. In A the booster is inserted in the h.t. delta and must be capable of withstanding the sum of the impedance voltages of the three phases to earth, for one side of the booster winding can be earthed. There is a disadvantage in this scheme apart from the slight out-of-balance of voltage in the phases, namely, that the terminals connected to the booster are not subjected to any severe potential strain during the temperature test. This is a serious disadvantage, for if the terminals be of the condenser type, for which the amount of internal heating should be tested during the run, they are not in their weakest condition when pressure tests have to be applied.

When transformers have to be connected temporarily in delta there is the common disadvantage that the stress or potential difference between phases is not equal to that under service conditions. In cases of this nature it is essential that the temporary connections be removed, the star formed and a three-phase over-potential test applied, to ensure soundness of insulation between phases and between primary and

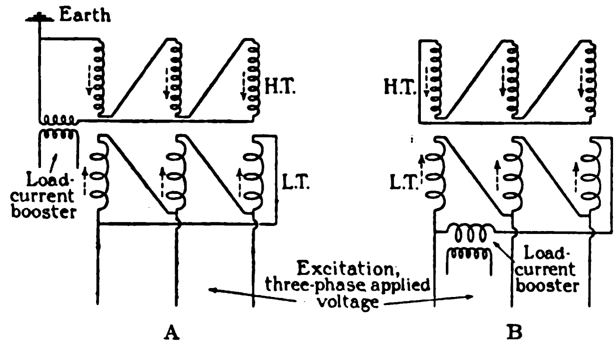

FIG. 23.—Full-load run diagrams for three-phase delta-delta connected transformers; high-tension or low-tension boost.

secondary windings. Fig. 23 (B) shows the same method with the booster inserted in the temporary delta on the l.t. side, thus leaving the e.h.t. windings free from any earth connections.

Whilst the above methods are suitable for a single transformer, it is advisable that if two are available a three-phase temperature test should be carried out as in Fig. 20 (B), but with the three-phase booster in the l.t. side and the excitation on the l.t. side applied to the mid-points of the booster.

Another method of loading is that of using two generator sets, one to supply and the other to load,

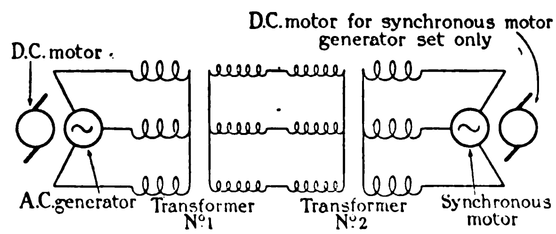

FIG. 24.—Back-to-back full-load run with a.c. generator and synchronous motor.

adjusting the excitation until full current is circulated in the transformers. One a.c. machine acts as a generator with the field adjusted to maintain full voltage on the windings, and the other as a synchronous motor under-excited to circulate the full kVA on the transformer windings at a low power factor. This method, shown in Fig. 24, gives a true heat test on one transformer only, as the voltage applied to the second transformer is reduced in proportion to the regulation of the first, causing a low iron loss on the

second transformer. It is usual to over-excite the one transformer by an amount equal to the reduction on the other, so obtaining an average figure for the heating.

The chief disadvantage of this method is the necessity for very large a.c. generators, at least equal to the kVA of the transformer under test, and also a very large range of voltage on the generator. One set consisting of three machines on the same shaft, i.e. two a.c. generators and one d.c. variable-speed motor, would be the ideal scheme for this method. The chief advantage of the method is that the transformer loading is all carried out at the same frequency.

The foregoing comprise the chief methods of transformer loading for shell-type as well as core-type transformers. The three-phase boosting method is that recommended by the authors, for the reasons that it gives a well-balanced and true loading and permits the transformers to be run without any temporary internal leads. They can thus be run in their completed condition with covers and all terminals in position, unless cable boxes are used instead of open-type terminals. The disadvantages are that more plant is required, and in each case it is essential that two transformers be available in order to carry out the test.

While from a customer's point of view the transformer should be run in a complete condition, this is, as already stated, often impossible due to the temporary leads required and the use of cable boxes which, for obvious reasons, cannot be connected up on a test-bed.

With every full-load run a full log should be kept. All readings required should be logged every half-hour and the temperature-rise characteristic plotted at the same time. The temperature of the oil should be obtained by means of distant-reading thermometers, in the interest of safety and to obviate the necessity for shutting down while such readings are taken. An ordinary mercury-bulb thermometer can be inserted in the oil as a check on the distant-reading thermometers, but this should only be read at the time of starting and shut-down. Air temperatures should be taken throughout the run and the air thermometer should be in a position free from draught and within 5 ft. or 6 ft. of the transformers. It is suggested that this air-reading thermometer be a mercury thermometer constantly immersed in a container of transformer oil at atmospheric temperature and pressure, thus eliminating the effect of rapid fluctuations of air temperature. These fluctuations, whilst they may give a true reading for the air at the instant, have little influence on a large transformer full of oil, hence, if recorded, errors in actual temperature-rise readings may easily occur.

The above readings are those required for oil-insulated self-cooled transformers. For other types, such as water-cooled, force-cooled, air-blast, etc., other records are necessary, and each and all must be taken with care and correctly logged. The temperature load-run should be carried on until the temperature-rise gradient is negligible.

Hot resistance measurements.—Immediately after the temperature test, the resistance must be measured and no time must be lost in obtaining this figure. The measurement is carried out in the same way as that already described for cold resistance measurements. The time from shut-down to the first measurement must be recorded, and for this purpose a stop-watch is recommended.

Several readings should be taken at half-minute intervals, the results plotted, and the curve traced back to the time of shut-down.

The correction for the resistance when hot at the time of shut-down, as given in the standard rules apart from extrapolating back to the time of shut-down, is based on the watts lost per lb. of copper in the transformer. If the loss does not exceed 7 watts per lb. 1 degree C. per minute is to be added to the temperature-rise calculated from the resistance, up to a maximum of 4 minutes. For higher losses per lb. up to 30 watts, the correction is the product of the loss per lb. and the following factors:—

1 minute, 0·19	3 minutes, 0·43
2 minutes, 0·32	4 minutes, 0·5

As a typical example of the similarity in results, the following test (see Table 6) is given, the temperature-rise being corrected by both methods.

The test was taken on a high-voltage transformer of 7 800 kVA rating, single-phase, 50 frequency.

TABLE 6.

Extrapolating-back Method.

Hot resistance after shut-down	Time after shut-down
1·872 ohms	3 minutes
1·869 ohms	3·5 minutes
1·863 ohms	4 minutes
1·858 ohms	4·5 minutes
1·858 ohms	5 minutes

Cold resistance at 32° C. = 1·76 ohms.

Extrapolating back to the point of shut-down gives 1·9 ohms, which with a cold resistance of 1·76 ohms gives an actual temperature of 53·5° C.

With an air temperature of 20° C. the temperature-rise is 33·5 degrees C.

Loss per lb. correction method.

The loss per lb. of h.t. winding = 11·75 watts at 75° C.

Time after shut-down = 3 minutes, and correction factor = 0·43.

The temperature-rise to be added to that after 3 minutes is thus:—

$$11\cdot75 \times 0\cdot43, \text{ or } 5 \text{ degrees C.}$$

The temperature-rise by resistance after 3 minutes, from the above resistance figures, is 28 degrees C. Thus the corrected temperature-rise is 33 degrees C.

The difference in the temperature-rises by the two methods is 0·5 degree C., a negligible figure. For accuracy and simplicity, it is recommended that the extrapolating back to shut-down be used whenever possible.

Transformers of different types having different methods of ventilation and cooling have, of necessity,

different cooling constants. Further, the methods employed when stopping a load run must be studied, or incorrect results will occur and cooling constants be affected. Self-cooled transformers are easily dealt with, but for artificially cooled units all means of cooling must be stopped at the instant of shut-down, and this in many instances is difficult. For instance, with air-blast transformers the fan takes time to come to rest, for water-cooled transformers it takes time to shut off the water supply, and for force-cooled units time is required for shutting down the pumps, i.e. oil and water circulation.

The methods employed for measuring resistance have already been described, but for hot resistance measurements it is necessary to have all instruments and leads ready for attaching to the transformer terminals as soon as the transformer is shut down. It is of advantage to have these leads fitted with spring clips.

The temperature-rise by resistance is calculated in the standard way where the resistance of copper is taken as proportional to the absolute temperature.

$$\frac{R_2}{R_1} = \frac{T_2 + 234 \cdot 5}{T_1 + 234 \cdot 5}$$

$$T_2 = \frac{R_2}{R_1}(T_1 + 234 \cdot 5) - 234 \cdot 5$$

$$T_2 - T_1 = \text{temperature-rise}$$

where R_2 = hot resistance at temperature T_2,
R_1 = cold resistance at temperature T_1,
T_2 = calculated final temperature, and
T_1 = initial temperature, both Centigrade.

The temperature-rise calculated from the increase in resistance does not give the maximum temperature of the transformer but the average temperature, and in some cases may give a result lower than the maximum oil temperature.

Insulation Tests.

Insulation tests should be taken with the insulation in its weakest condition, i.e. at the full-load temperature, so that these tests should follow immediately after the hot resistance measurements.

The insulation tests are as follows :—

(1) Over-potential tests.
(2) Pressure tests between the h.t. windings and the l.t. windings and core.
(3) Pressure tests between the l.t. windings and the core.

The above tests are those carried out on all double-wound transformers having h.t. windings fully insulated from the core and earth. If the h.t. windings have graded insulation, i.e. one end or the star point earthed, then test (2) is not possible and the test between the h.t. and l.t. windings is carried out at the same time as the over-potential test.

The value of the pressure and over-potential tests are stated in all standard rules, but at times customers depart from these standards, feeling that by increasing them they are securing a more robust and safe winding. This often gives a false sense of security. The order of the tests is usually that given above.

The over-potential test which tests the insulation between turns, layers, coils and phases, of a three-phase transformer is taken first while the insulation between the turns is in its weakest condition due to the effect of the expansion of the copper. With three-phase transformers it is advisable to apply the over-potential by means of a three-phase voltage and thus ensure a full test between phases ; incidentally it saves a considerable amount of time.

If the over-potential test is applied single-phase to each phase in turn, the stress between phases is not that to which they should be subjected, being only about 90 per cent of that required.

The over-potential test is usually at twice the normal voltage, and this is applied to the l.t. windings at a frequency approximately equal to, or higher than,

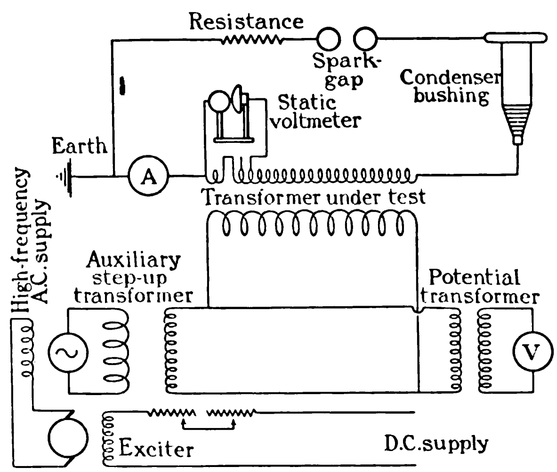

FIG. 25.—Over-potential test layout diagram.

twice the normal frequency. This is essential in order to keep the excitation of the core within saturation limits and the magnetizing current at a reasonable value.

The method adopted for the measurement of the induced voltage depends to a great extent on the type and line voltage of the transformer under test, or, in other words, it depends on the capacity of the windings to one another and of the h.t. windings to earth.

In general, for pressure tests up to 41 000 volts and over-potential tests up to 40 000 volts, i.e. for transformers rated up to 20 000 volts, the h.t. test pressure can with safety be taken from the transformer ratio of the testing transformer and the transformer under test respectively. For higher voltages the h.t. pressure must be measured by other means, due to the increase of voltage brought about by the capacity of the windings. This will be appreciated when it is mentioned that pressure-rises of 35 per cent above ratio voltages have been measured when testing transformers for 115 000 and 136 000 volts.

All insulation tests are given in R.M.S. values, assuming a sine wave of voltage, but the actual stress on the insulation is proportional to the maximum

value of the voltage wave. This value for a sine wave is R.M.S. × √2, but the effect of capacity in the circuit is to increase the second factor, and so the maximum value increases out of proportion to the R.M.S. voltage. Any instrument arranged to function on R.M.S. values of voltage will therefore give low and inaccurate readings.

The means of measurement are limited to spark-gaps and wave-crest voltmeters; the latter instrument is described later. Static voltmeters for very high voltages have not been found satisfactory owing to their delicate adjustment and susceptibility to vibration and draught, as they are usually dependent on the effect of a static field on a delicate diaphragm.

For over-potential testing, the spark-gap is recommended as the most reliable means of measurement, the calibration being that given in the Standardization Rules of the American Institute, with corrections for barometric pressure and temperature.

Fig. 25 shows a scheme of connections for an over-potential test on a high-voltage transformer, and is self-explanatory, but some notes may be of interest. Connected across the h.t. windings (in the case under review the h.t. terminal and earth), is a spark-gap with the correct size of spheres, and between the gap and earth is a high ohmic resistance of a value equal to approximately 1 ohm per volt of the test voltage. The best resistance is a column of water, preferably running water, so that a constant resistance is maintained. The absence of resistance in series with the gap is not advisable owing to the severe strain put on the windings when the gap flashes over. The tappings on the h.t. windings are bridged with a static voltmeter as an indicator. Inserted between earth and the earth end of the winding is an ammeter which gives the capacity current to earth and so is of service in determining the capacity of the windings to earth if the frequency is known. Across the l.t. side of the transformer under test is a voltmeter or a potential transformer, and a voltmeter is across the secondary side.

The gap is set to the required voltage and the high-frequency alternator runs up to the lowest frequency at which it is estimated that the required voltage can be obtained. The alternator is then excited with a weak field and this is gradually increased in strength until the gap flashes over. At this point the voltmeter reading is noted and the supply cut off. When the transformer is dead, the spark-gap is disconnected from the terminals and the voltage raised to the same value as that previously recorded on the voltmeter. The voltage across the h.t. side of the transformer will be that at which the gap sparked over, and the static voltmeter confirms this by giving the same reading as previously. The test voltage is maintained for the required period and then gradually reduced to zero and the supply cut off. While this test is being carried out a critical examination should be made of the transformer, and the instruments in circuit should be watched for fluctuations. If the oil is visible it should be closely watched for bubbles, which may burst into puffs of smoke, indicating creepage. Should a violent disturbance occur, it points to a flash-over. If the disturbance be accompanied by large volumes of smoke, then it is fairly certain that a breakdown has occurred which must be located later. Should any of the foregoing defects arise, the actual point on the oil surface will give some guide as to the region in which the failure has occurred. In many instances the oil is not visible, and in these cases the transformer must be carefully listened to by contact with the tank, and the instruments must be closely watched. Variations of hum or any crackling sounds, etc., should be noted.

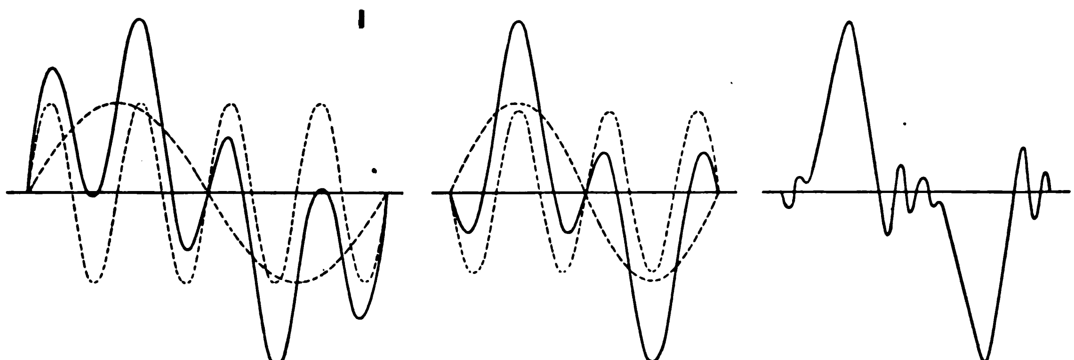

FIG. 26.—Superimposed waves.

If a failure occurs and the machine is automatically disconnected, the test should be repeated, and if the voltage can again be maintained the fault may be put down to a flash-over, which has probably occurred across the oil from the nearest point to earth or possibly between adjacent leads and tappings. Air bubbles are also liable to cause flash-overs, but ionization quickly disperses them.

If the voltage gradually falls with repeated tests, the fault is almost certain to be due to creepage across the insulation, which is thus being gradually weakened. If the voltage can be maintained only at a low value the fault is then certain to be a dead earth or a short-circuited turn or turns in the winding.

When abnormal tests are required, such as three or four times the normal voltage, a high frequency is necessary to obtain this test value. With high-voltage transformers very high frequencies are apt to bring

about complicated conditions and troubles. These high-frequency tests set up intense static fields and discharges under oil, causing flash-overs and disruption. Several instances of such trouble are on record, and it is recommended that a frequency not greater than 175 be used for high-voltage testing and over-potential testing.

Where abnormal tests are required necessitating a higher frequency than 175 periods, the authors have devised other means of obtaining the voltage without creating disturbing conditions. The method used involves two sources of supply, one at a high frequency, say 200, and another at 50 or 66·6 periods, and the superimposition of one supply upon the other. The resultant wave is a distorted one, but the period of maximum voltage is not less than the lower frequency of supply. To obtain the best condition the higher frequency should be a multiple of the lower frequency, thus giving a regular peak voltage.

Typical examples of superimposed waves are shown in Fig. 26. These curves show theoretical superimposed waves of ratios 4/1 and 3/1, and also a reproduction of an actual wave taken during a test under these conditions with a frequency ratio of 3/1.

Pressure Test.

If the transformer has unearthed windings, then a pressure test to the core or earth is required and is carried out by the application of a high pressure between the h.t. winding and earth, the l.t. winding being earthed during the test. The high pressure must be applied to both terminals of the h.t. winding being tested, and also to the tappings should there be any, so as to preclude any pressure-drop through the windings, which might occur if it were only applied at one point.

The test pressure should be obtained from a testing transformer of ample kVA capacity to deliver the full test pressure and energy required without strain or drop in voltage, and the frequency of supply should not be lower than that for which the transformer under test is designed.

The test pressure should be measured in a manner similar to that described under over-potential tests, i.e. by a spark-gap or a crest voltmeter.

Crest voltmeter.—This functions on the principle that the average charge current of a condenser is proportional to the maximum impressed voltage. To obtain the average value of the charge current it is necessary to rectify the alternating current and measure its value on a d.c. milliammeter.

In order to use the crest voltmeter the testing transformer must be fitted with a condenser bushing or a fixed standard condenser. The condenser bushing is generally used, the earth band of the bushing being insulated from the tank and the charge current passed through thermionic valves or mercury rectifiers to earth. The rectified current is measured by a d.c. moving-coil permanent-magnet milliammeter.

Two circuits which give satisfactory results are given in Figs. 27 and 28, which show the full-wave and the half-wave rectification respectively. The full-wave rectification method is to be preferred, as the current measured is approximately twice that of the half-wave rectification, depending on the total impedance of the valves and condenser circuit. The filaments of the valves must be heated by separate supplies, except where the two valve filaments are connected. Thus for full-wave rectification three separate sources of supply for filament heating are required, and two sources for the half-wave rectification. Accumulators are satisfactory where small rectifying valves are used, but it will be found more convenient and satisfactory to heat the filament from a transformer with the

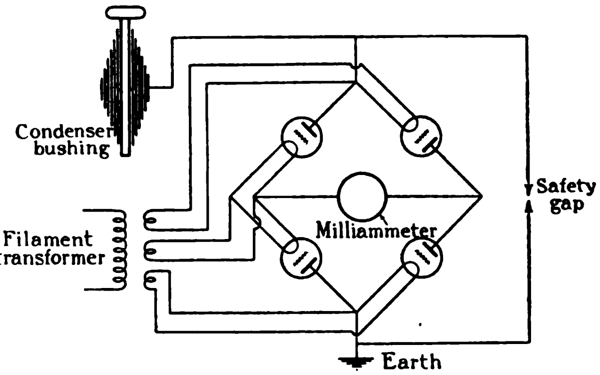

Fig. 27.—Four-valve crest voltmeter.

required separate l.t. windings. A very small pointed spark-gap is shown in the diagram across the condenser and the earth terminal. This is to take the main charge current when a heavy current passes through the terminal bushing condenser, which would otherwise spark across between the plate and filament of the valves and probably burn them out. Sparks pass across this gap at every breakdown of the h.t. circuit of the testing transformer, and therefore provide a good indication of a breakdown as well as functioning as a safety device.

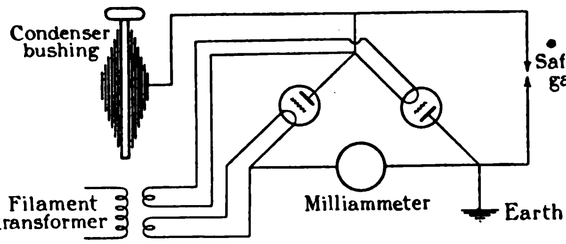

Fig. 28.—Two-valve crest voltmeter.

The charging current of a condenser being proportional to the frequency, capacity and voltage, it is very important that the frequency should be kept constant during calibration and when using the above method.

A zero error will be noticed when using either of the circuits, but this can be allowed for if necessary. It is caused by the emission of electrons from the filament to the plate sufficient to reduce it to a negative value lower than the filament and is called the space charge. When using the two-valve circuit this can be compensated for by inserting in the earth lead a

number of cells sufficient to reduce the plate voltage to a negative value low enough to stop the emission, but no very great advantage results from its use, except in connection with very low readings.

The possible errors and disadvantages of the crest voltmeter may be briefly summed up as those due to change in frequency of the charging current, and apparent change in the condenser capacity due to corona stresses and to the rectification characteristics of the valves. If the crest voltmeter is checked periodically by means of the spark-gap no trouble should be experienced.

The grids of the valves are left insulated as shown in the diagram, but if the voltage across the valve is sufficiently low they can be connected to either the filament or plate circuit.

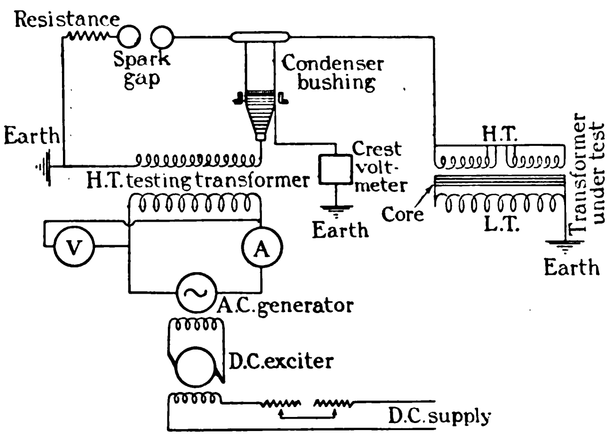

FIG. 29.—Pressure-test layout diagram.

In connection with the pressure testing of transformers, the testing transformer should be fed preferably from a variable-speed alternator, to give the desired frequency, with its field excited from an exciter on the same shaft, itself excited from an independent and constant supply such as a battery. This requirement is to ensure as far as possible a constant voltage.

The arrangement of the test is shown in Fig. 29 and the procedure is similar to that already described for over-potential testing. With this type of test the spark-gap is used as a measure of test voltage, and the crest voltmeter as an indication that the voltage has been reached when the gap is disconnected. A voltmeter is also used across the l.t. windings of the testing transformer calibrated in h.t. volts, and the reading recorded on this meter gives, when compared with the test voltage, a measure of the increase in voltage due to the capacity of the transformer under test. An ammeter inserted in the l.t. winding of the testing transformer will give a measure of the load, and any fluctuation in the reading during the test will give an indication of creepage. It is recommended that before the testing transformer is connected to the transformer under test the crest voltmeter be calibrated with the spark-gap for each test voltage required, and that during the test the spark-gap be cut out, thus eliminating possible surges due to the breakdown of the gap.

STANDARD REFERENCES.

In connection with all tests, such as those for losses and temperature, the results obtained should be corrected to certain standard references and basic values set up by the various Standards Committees, so that true comparison can, if necessary, be made.

These references cover wave-form, temperature, barometric pressure, etc., and are clearly stated in all standard rules, so that they need not be detailed here.

TRANSFORMER OIL.

All oil used for transformers should meet the required specifications, but of these only the question of moisture and breakdown value really affect the testing of transformers. All oil used must be dry and have a high breakdown value and must be clean.

Oil may be dried and cleaned in many ways, but the quickest and most efficient method is by the centrifugal oil separator, of which several different makes are on the market.

The oil in which transformers are tested should have a breakdown value of not less than 30 000 volts across a standard gap of 0·15 inch with 0·5-inch spheres.

The test for breakdown should be carried out at 50 periods, for the breakdown value falls slightly at high frequencies. The temperature at which the test is taken is not very important, as temperature has little, if any, effect over a wide range and is said by some to increase the dielectric value slightly up to 65° to 70° C.

CONCLUSION.

The authors have covered, in the foregoing, the main tests carried out every day in connection with transformers, and have endeavoured to point out the best means, to their knowledge, of obtaining the most accurate commercial test-results, the type of apparatus to use and its possible errors and accuracy.

There are many other tests in connection with transformers, such as surge tests, short-circuit tests, dielectric tests, etc., but as these are special and not general they have not been dealt with, as each would provide a subject on which an interesting paper could be written.

In conclusion the authors would like to express their thanks to the Metropolitan-Vickers Electrical Co., Ltd.

DISCUSSION BEFORE THE INSTITUTION, 21 JANUARY, 1926.

Mr. S. A. Stigant: I cannot too strongly endorse the authors' views with regard to the importance of tests which will give undoubted and undeniably accurate results, because, as the authors have said, such tests create a very strong feeling of confidence in the minds of users, and this is most important. At the same time I do not think that the apparatus to be used should be unnecessarily elaborate, and I consider that the authors have shown that modern transformer-testing practice is such as to remove any impression of that kind that a user or an inspector might have on visiting a maker's works. The authors refer to the use of the vacuum method for drying out transformers, and in very large works, where the special plant necessary for this method is available, I think it is probably the best method; but it is quite possible to dry out transformers, even for the highest voltages, without having to resort to the vacuum method, and transformers for 250 000 volts have been successfully dried out in that way by the Company with which I am associated. The authors also refer to the necessity for the use of low-power-factor wattmeters in the iron and copper loss tests. The majority of manufacturers have found that that is a really vital necessity, because very considerable errors are introduced into loss readings by the use of the ordinary commercial wattmeters that are really designed to operate on higher power factors. In connection with the measurement of iron losses, the testing facilities may not always be available for applying to the windings the voltage for which they are designed, and it is well to bear in mind (I am addressing my remarks now particularly to the makers of transformers) that the iron-loss test can be conducted equally well if the windings are fitted with a tapping which will give a voltage corresponding to that of the machinery which is available. That is to say, all that one has to do is to maintain the normal flux density in the core. Certainly one would usually get a higher magnetizing current, but the magnetizing ampere-turns would be the same. In their notes on heat runs the authors say that when testing three-phase transformers the copper losses should not be tested single phase because they give inaccurate readings, and further on they refer to a series and Z connection for the three phases. In those conditions, I agree, no single-phase test should be given, but it is quite permissible to test each limb single phase, i.e. apply a pressure to the winding on one limb, short-circuit the other winding on the same limb and have the windings on the other limbs all open-circuited. This method gives results practically identical with those of the various three-phase tests cited by the authors. This question of losses and heat runs is a very vital one, and is of particular importance in the case of large transformers. I should like to bring to the notice of the authors the use of static condensers to reduce the kVA of the testing plant required. If the condensers are shunted across the transformers the machines required for the heat runs or for the tests can be considerably smaller than when condensers are not used. Incidentally, if a public supply is used the power factor is improved, and it may be that the consumer can get better terms on that account. I am rather disappointed that the tests have not been illustrated by vector diagrams—diagrams showing the precise conditions which obtained under these different tests—because I know from actual experience, both with my own colleagues and in teaching junior students, that such diagrams are of very considerable use in explaining the precise cycle of events under these conditions. The authors refer to the rise in voltage which takes place when testing high-voltage transformers, and they say this is due to capacity current; this rise is of course due to the passage of the capacity current over the impedance of the transformer. That is the usual well-known phenomenon that occurs also when high-reactance rotary transformers are used for d.c. pressure regulation. It occurred to me when reading the paper, however, that the statement may be misinterpreted, and I should like to point out that the pressure-rise is due to a combination of voltage and current rather than to electrostatic capacity as such. We know that the three are bound up together, but it should be remembered that the electrostatic capacity of the different parts of a high-voltage transformer is generally considerably lower than that of transformers of much lower voltages. With regard to the question of the measurement of temperature-rise, it is also worthy of note that whilst the temperature-rise measurements by resistance give a closer idea of the maximum temperature inside the winding, we may get cases where the temperature-rise by resistance is only 1 deg. or 2 deg. more than that measured by a thermometer in oil, or it may even be lower. I believe that the authors have met these cases, and I should have liked to see a reference to them in the paper. In conclusion I think it is highly essential—and in this I am sure all makers and users of transformers will agree with me—that transformers should be tested, wherever possible, as nearly as possible under their actual service conditions. This particularly applies to the losses and the pressure test, where the supply should be at the rated frequency of the transformer.

Mr. S. W. Melsom: Dealing in the first place with the tests of insulation resistance, the authors use a megger, which is, of course, quite a good workshop instrument, although not necessarily capable of the highest type of accuracy for high values of insulation resistance. They refer to applying the voltage for at least 60 seconds. I think that Mr. Evershed in his paper laid stress on the need for applying the pressure for considerably longer than 60 seconds in most cases, and particularly with materials such as are used in transformers. A little further on in the paper the authors say that when the transformer is immersed in oil its megger reading will be much lower than that in air. It seems to me that the leakage current can only take its path through the oil, which presumably has a very high value of insulation resistance. I should like to know whether the fall of insulation resistance when the transformer is immersed is immediate or whether it only occurs after a time, i.e. whether the moisture

which is left in the insulation slowly diffuses into the oil. When discussing a workshop method of measuring copper resistance, the authors say that they have considered such methods as the Wheatstone bridge and the Kelvin bridge, but do not recommend them as they are generally influenced by thermal and capacity effects. I should like to point out, however, that although they have laid emphasis on the need for accuracy, yet they go on to measure the resistance of the copper by the ammeter-voltmeter method, and from that measurement determine the temperature-rise of the windings. The highest accuracy is required here, but the authors hark back to the very oldest known method of measuring resistance. They dismiss the other methods by saying these are influenced by thermal and capacity effects, but they do not explain what those thermal and capacity effects are. To my mind the method they use for determining the temperature-rise is roughly equivalent to that of determining the density of a metal by means of an ordinary spring balance. I am surprised that, when they really do need accuracy, they ignore the much more accurate and convenient method of the Kelvin double bridge. I have had considerable experience both of those and of various other types of apparatus for the measurement of resistance, and I cannot see anything special in a transformer which would induce thermal and capacity effects into the Kelvin bridge. On page 522 the authors suggest that the first reading of resistance is obtained 3 minutes after shutting down, and readings have to be taken up to 5 minutes to allow of extrapolation to the point where switching-off occurred. It is probable that the greater part of this 3 minutes is taken up in dealing with the arrangement (referred to later in the paper) of leads fitted with spring clips which are attached when the transformer is shut down. That method seems to me to be capable of improvement. It would seem that in a works, where switches are available, it should be possible to have proper switching arrangements such as I have used when making similar determinations with high-pressure cables. With proper switching and a Kelvin bridge for measuring, good readings could be obtained within 30 seconds of shutting down. I think the Kelvin bridge is condemned by most workshop people because it is an arrangement of resistances inside a box, but so far as a workshop method is concerned the time to obtain an accurate reading is less than with an ordinary ammeter or voltmeter, the bridge is much more accurate, and only one man, instead of two, is needed to operate it. Also it is portable. Perhaps the authors have found in the double bridge sources of error that have not hitherto been suspected; if so, I hope that they will explain these more fully.

Mr. A. F. W. Richards: On page 505 the authors say that accurate results are essential to create confidence in the mind of the customer, and with this remark I am in entire agreement. The information contained under the heading "Drying-Out and Insulation Resistance," if carefully observed, would largely reduce breakdowns on pressure and overpotential tests which frequently occur and certainly do not tend to create confidence in the customer. With regard to ratio testing, there are, as the authors point out, many inaccuracies which occur with both the voltmeter method and the standard transformer-ratio method, but I think that up to about a year ago only one manufacturer provided a resistance balance ratiometer, and even now I only know of two who have them. Iron loss is, as the authors say, very important. A very great deal depends on the use of proper instruments for the purpose of this test. The authors point out in Table 1 that the no-load current varies appreciably in each phase, but, unless it is specifically asked for, the current in all three phases is very rarely given in the test certificates. I think that that information should invariably be given. The more important point, so far as iron loss is concerned, is correction for form factor. One of my clients especially asks that an iron-loss voltmeter be used, or that sufficient information be given to enable the ratio to be deduced for an average value. I think I am right in saying that there is not a single test-bed in this country with an iron-loss voltmeter. What is generally provided to enable us to determine the form factor is an oscillograph record stated to be taken from the machine used for the purpose; but there is usually very little to give us real confidence that the oscillograph is a true record at the time of testing. The arrangement shown by the authors in Fig. 3 is very ingenious, and I hope it will become a commercial article. Under the heading "Separation of Losses" the authors give two examples which they used, apparently, for proving their own instruments. One gives a 30 per cent error with a form factor of 1·4, and the other 25 per cent with a form factor of 1·25. I should like to ask the authors whether those were artificial form factors or whether they are what we may expect when testing transformers and getting results which we send to our clients abroad. One would think that the measurement of resistance was the easiest test of all, yet in practice it gives more trouble than any other. Mr. Melsom has already referred to the subject and I hope this matter will be dealt with more satisfactorily by the manufacturers. As far as I am aware, there is only one test-bed on which fixed instruments with proper leads are provided for this test, and where the instruments are kept solely for this purpose. For load temperature-runs the authors give some very interesting diagrams of usual methods, but they have not given a very common form—using the voltage taps on the two transformers, putting the ratios slightly out of balance and so getting a circulating current. With regard to temperature results on small transformers, I think some warning should be given about the position of the thermometer. This may greatly affect the results. The authors give the American Institute Rules for determining the temperature at the moment of shutting down, and I am very interested in their remarks showing the close agreement between the extrapolation and losses-per-pound methods. When testing two transformers back to back one usually wants to take readings on both, and one has not time to extrapolate back. I am surprised that the authors do not mention the hot-spot method. I know the errors that are liable to creep in and the difficulty there is in getting the couples in the right place, but I think manufacturers' designers could help us if they were to try; and it is undoubtedly the most satisfactory method of measuring temperature-

rise. In conclusion, I should like to say that I know of cases where orders have been placed abroad solely because the purchaser was not satisfied that the methods of testing in use in this country would give him all the information he required. I hope, therefore, that manufacturers will benefit by this paper and improve their methods.

Mr. J. Bloome: The title of the paper suggests the testing of transformers irrespective of size, but the authors have dealt chiefly with large transformers which we are not at present accustomed to test every day. Fig. 2 gives a typical drying-out characteristic of a large high-voltage transformer under the vacuum process. I have at various times obtained similar characteristic curves on smaller transformers. In passing, I should like to mention a point of some interest. Two similar transformers were dried out, one by the circulation of dry air as described by the authors, and the other by heating up the transformer and supplying a current to the high-tension winding with the low-tension side short-circuited. I found that the shape of the curve was similar, the difference being that the time taken to go through the process was much shorter in the latter case. I cannot give any reasonable explanation of this; possibly it may be due to more localized heating. I should like to hear the authors' opinion. It would be of interest if they would indicate how the empirical formula on page 506 was obtained. With regard to the measurement of iron loss, I can substantiate the authors' statement that low-power-factor wattmeters are absolutely essential. Table 1 gives a comparison of readings obtained by the 2-wattmeter and 3-wattmeter methods respectively. The authors give this table to illustrate the variation of the power factor, and not really for a comparison of the watts, but I generally find when testing two similar transformers, one by the 2-wattmeter method and the other by the 3-wattmeter method, that there is a big difference in the readings. For high-voltage iron-loss testing the authors recommend the elimination of the current transformer and the earthing of the current coil of the wattmeter. Personally, I have experienced some serious discrepancies when measuring in this manner. This may possibly be due to some electrostatic action in the wattmeter. I have used a low-power-factor wattmeter in connection with calibrated current transformers and correction curves supplied by the instrument makers. I find these instruments quite accurate, and all that requires earthing is the secondary side of the current and potential transformers; complications are thus avoided. Having used both methods, for simplicity, accuracy and safety I prefer the latter. The arrangement for measuring frequencies described in the paper is very good, but I think the authors will agree with me that a well-designed tachometer used carefully and frequently calibrated is all that is required. The form factor plays an important part in the measurement of iron losses and is well worth the attention which the authors have given it. The examples given illustrate the errors that can occur due to bad form factors. I notice that in the first example of a large 25-cycle transformer the form factor is extremely bad, viz. 1·25. Was this due to the design of the transformer or to the method of testing? The authors recommend the three-phase measurement of copper loss with a three-phase transformer, but the copper loss can be measured single phase by short-circuiting each limb separately. With regard to resistance (by which I refer chiefly to the resistance for determining the temperature-rise) the authors recommend the use of a voltmeter and ammeter, but I find that an ohmmeter is more accurate. In addition, the visual error is minimized, since only one reading is taken instead of two. Also the ohmmeter is sufficiently robust to withstand heavy surges. I always recommend that the instrument be not moved between the hot and cold measurements of resistance. There is then no possibility of an error being introduced owing to the mishandling of the instrument, or anything of that kind. I can generally get the hot resistance in less than 3 minutes; I think that compares well with the time taken with a d.c. voltmeter and ammeter set. The authors must be complimented on their unique method of carrying out abnormal over-potential tests, which customers sometimes require, without increasing the dielectric hysteresis to a dangerous value. The authors recommend the use of a motor-generator set for the regulation of the voltage for pressure-testing. For this purpose I have used a motor-generator and an induction regulator, and I personally prefer the latter. This is easy to control; it does not require the same skilful attention as the motor-generator set, and if it is fitted with a well-designed compensating winding, and the iron circuit of the regulator is such that it will allow for small magnetizing currents on the lowest possible frequency likely to be used in testing transformers—25 cycles—everything is quite satisfactory. Further, one big advantage of the induction regulator is that it generally has a reactance of about 10 per cent which, when the transformer is put under short-circuit conditions due to flash-over or breakdown, will be a great protection for the testing transformer. Although the testing transformers are generally supplied with an air-core reactance used on the high-tension side, I have never found these to offer real protection. The induction regulator certainly does.

Prof. J. T. MacGregor-Morris: I particularly want to refer to the crest voltmeter described on page 513.

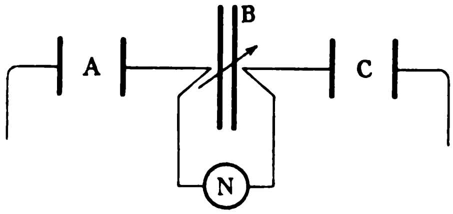

Fig. A.

I think it would be of material assistance to others who are using or intend to use this apparatus if the authors would give some values of the actual capacities of the bush when it is used and the value of the current, at some particular voltage and frequency, that flows through the milliammeter. The authors point out that this crest voltmeter depends on the frequency. A crest voltmeter has been developed by Mr. Ryall working in

my laboratories at East London College (and apparently simultaneously by Mr. Palm, of Hartman and Braun) which is independent of frequency. The arrangement is shown in Fig. A. Two high-voltage condensers, A and C, of small capacity, are connected in series with a variable condenser B of much greater capacity. Across the terminals of condenser B is connected a "beehive" neon lamp N. The capacity B is gradually decreased until the neon lamp glows. Then from the values of the capacities of A, B and C and the striking voltage of the lamp, the overall crest voltage is at once obtained. If certain precautions, well known to those who have worked carefully with such apparatus, are taken with the neon lamp, the striking voltage can be relied upon to, I believe, $\frac{1}{2}$ of 1 per cent. We have used it with entirely satisfactory results up to a pressure of 15 000 volts, and Mr. Ryall is continuing experiments in my laboratory which we hope will enable us to go very much further by the introduction of quite simple additions. I think that it is worth experimenting with, because the apparatus is simple and there does not appear to me to be any serious limitation in the voltage which can be measured by it.

Mr. F. S. Robertson: The valves used in the 2-valve crest voltmeter described appear to be 3-electrode valves, but the grids do not appear to be connected to anything. The object of using 3-electrode valves for this purpose is not apparent unless it is desired to make use of the grids by giving them sufficient negative bias to stop the circulating current which is the cause of the zero error observed by the authors. The circulating current is caused by the fact that some of the electrons are emitted from the filament with such large velocities that they can pass right across to the plate even against a considerable retarding potential. If a grid having a fairly close mesh is placed between the filament and the plate and is well insulated, some of these high-velocity electrons will strike it and in consequence may soon charge it to such a high negative potential that it is able to turn back the high-velocity electrons which were formerly passing through its meshes to the plate, and in this way shut down the main current through the tube. If the grid has a more open mesh, as appears to have been the case in the authors' experiments, a certain amount of current will pass and give rise to the zero error. It would seem to be a very great disadvantage to the method to have an insulated grid taking up an indefinite and unknown potential, seeing that the grid and its potential are controlling factors in the operation of the tube. Whatever type of tubes are used, one at least might have a grid with a negative bias on it sufficient to stop the zero error on the milliammeter. This could best be done by employing a cell or cells with the negative pole connected to the grid and the positive to the filament, or in the case of a close grid a high resistance between the grid and the filament, forming a grid leak, might be used.

Mr. F. E. J. Ockenden: Under the heading "Ratio Testing" the authors deal with methods of checking the ratio error of transformers, and they say "The procedure is so to adjust the dial switches as to obtain a true balance and a zero reading on the meter." In so far as the primary and secondary voltages have certain phase displacements, I do not see how an absolutely zero reading can be obtained on the wattmeter. It is doubtless possible to get a minimum reading, but that is unsatisfactory compared with a zero reading. The authors criticize the double-voltmeter method of ratio testing, but I have found a variation of this method to give very satisfactory results, avoiding the phase-angle troubles which are inherent in most wattmeter methods. In Fig. B, W_1 and W_2 are the transformer windings, R is a resistance, one end of which is subdivided as in a ratiometer, so that the ratio r/R may be continuously adjustable. V is a voltmeter, of either the electrostatic or high-resistance pattern. (In the latter case the value of its shunting effect across r must be allowed for.) K is a tapping key in series with W_2. The position of C is adjusted until, on depressing K, there is no change in the voltmeter reading when $W_1/W_2 = R/r$. This method of testing has the following advantages:—(1) The reading of the voltmeter V, when the key is closed, is influenced to

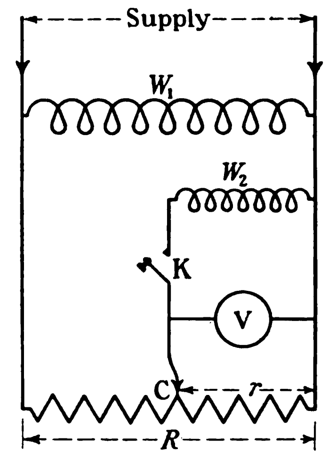

FIG. B.

an entirely negligible extent by the voltage-drop across r, the generated voltage in W_2 taking entire charge. Consequently, provided the voltages across W_2 and r are the same, no change will be caused in the reading of V, by difference of phase angle. Even when this angle is made 180° I have not been able to detect any error; the current consumed by R is of course small. (2) The voltmeter is easily arranged to read on the most open part of its scale, where small changes are easily detected; thus the lack of sensitivity of most a.c. instruments at the zero end is avoided. (3) Accurate calibration of the voltmeter is of no importance, since the same point on its scale is used for both the primary and secondary readings. Under the heading "Iron Loss and Magnetizing Current" the authors say that, to ensure accurate results, "For high-voltage iron-loss testing, provision has to be made for the insertion of potential transformers, but as the ammeter and current coil of the wattmeter are always earthed, no current transformers are necessary." They seem to think that this is an advantage, but I do not agree. The average phase angle of a really good voltage transformer is about 10′, and for an equally good current transformer

the figure is 12′ to 13′, both phase angles being in the same direction. This is an advantage in that the net phase-angle error introduced by the measuring devices is only 2′ or 3′ instead of at least 10′—an important consideration, in view of the extremely low power factor of all iron-loss measurements. Later in the paper the authors say that static voltmeters for very high voltages have not been found satisfactory, but I venture to think that they can have had no experience with the more modern instruments of this type. I know of a case where a 300 000-volt static voltmeter is successfully used in preference to a spark-gap, since, when both are checked against a high-resistance voltmeter of the most refined type, the accuracy of the electrostatic voltmeter is usually several per cent higher than that of the spark-gap however carefully the latter is manipulated. I consider that the so-called delicacy of the static voltmeter is very much exaggerated, great advances in the design of these instruments having been made in the course of the past few years.

Mr. H. M. Lacey: Under the heading "Three-Phase Core-Type Transformers" the authors give an explanation of a phenomenon which they describe as somewhat mystifying. It certainly is, and this is the first time I have seen any attempt at an explanation in print. Unfortunately, however, I find I cannot quite agree with that explanation. If the winding to which the pressure is applied is star-connected and the neutral is not connected to the neutral of the supply, then I think that the explanation may be right; but that phenomenon does occur even when the windings have their neutral point connected to the neutral point of the supply, and also in the case where the windings are delta-connected. In both these cases the voltage across the winding on each limb is definitely fixed by the supply, and therefore the flux in each limb also must be definitely fixed. I am not quite certain whether my views are correct, but I should be glad if the authors would add to what they have said in the paper on this matter.

Mr. H. S. Holbrook (*communicated*): I should like to support the author in emphasizing the desirability of making three-phase tests on three-phase transformers. Further, if one of the windings is normally delta-connected it is desirable that the delta be closed during tests, to duplicate as closely as possible the actual operating conditions. Similarly, should both windings normally be star connected, neither should be delta-connected during test. A more accurate method for full-load temperature-runs than any mentioned by the author, whilst still requiring a supply equal only to the sum of the losses, was suggested by me some years ago and tried out by the British Thomson-Houston Co. with success. Only one supply alternator is required. Current is circulated between the transformer under test and any other of convenient rating, and by means of a phase-shifter and an induction regulator, the applied voltage and the output current both in magnitude and in power factor are adjusted to the actual rated operating conditions. On some high-reactance designs, the operating conditions may make the question of power factor of great importance. The internal connections of the transformer under test are maintained as they would be in service. The alternative mentioned by the author of overload short-circuit is, as he indicates, a dangerous one to use on transformers with poorly ventilated windings, but on a modern transformer for use in a traction rotary-converter equipment guaranteed to withstand very heavy overloads it is quite a safe and good method. An approximation to the true temperature-rise of a winding under normal load current can be obtained by making in addition a short-circuit heat-run at rated current to determine the temperature-rise of the winding over the oil for rated current. The value thus obtained will be somewhat too great, as the actual oil temperature being lower than in normal operation, the oil viscosity will be greater than normal.

[The authors' reply to this discussion will be found on page 541.]

Western Centre, at Bristol, 1 February, 1926.

Mr. C. T. Allan: Can the authors recommend reliable, rough tests to find where a transformer is defective after it has broken down in service, when its weight and position may make it difficult and expensive to remove it to a test room, assuming that an ammeter, voltmeter, water resistance and megger are available, because sometimes it is found that a transformer may be repaired on site? Can they also indicate what are the worst conditions for producing oil sludge in a transformer? I am of opinion that the larger the oil-circulating ducts are, the less likely are they to hold sludge. Small ducts seem to have a compound effect on sludging. It appears inadvisable to filter oil in service when the inside of the case, carcase and the ducts are well sludged. The remedy should be more drastic, namely, removing the oil and washing all parts with a sludge solvent. Do the authors recommend forced oil circulation or forced water circulation for transformers? My experience is that the former is the better method.

Mr. W. R. Davies: With regard to voltage-testing, using sphere spark-gaps, can the authors say what is the ratio between a.c. and d.c. pressures as measured by means of spark-gaps, especially with various waveforms? I have experienced in the case of a 50-cycle, 50-kVA three-phase transformer a decrease of 15 per cent in the iron loss as compared with the maker's figures, using the 2-wattmeter method of measurement. Could this large difference be due solely to the waveform of the testing machine?

Mr. H. G. Weaver: The authors mentioned that resonance tests are sometimes carried out on transformers, and I should be glad if they would give a description of this test, as the conditions causing resonance in high-tension systems are difficult to reproduce on the test-bed. About 20 years ago a number of transformers were supplied to a certain railway company by a manufacturing firm with which I was connected. These transformers were installed in positions, in some

cases several miles, from the switches controlling them on the hign-tension side, and although they had been very severely tested at the works and gave no trouble there, they nearly all broke down immediately they were switched in. In every case the failure occurred in the end coils of the high-tension windings to which the terminal leads were attached, a number of turns being short-circuited. The trouble was traced to resonance effects and was completely cured by incorporating charging resistances with the switches. As the makers do not always know the conditions under which the transformers will be used I consider this test to be a most important one.

Mr. W. F. Chamen: I notice that the authors recommend that transformers should be overhauled at least every 18 months. It has generally been the impression that, transformers being static machinery, they should not require such frequent attention. Is oil the only liquid which has been utilized for cooling purposes?

Prof. D. Robertson: Have any experiments been made with regard to the use of carbon dioxide or other inert gas to keep the oil from contact with the air?

Mr. T. E. Lewis: Is there any difference between the tests taken on transformers for use in this country and those that would be installed in the tropics? There is a difference of from 70 to 80 deg. C. in the temperatures of working conditions.

Mr. W. J. Bache: What steps do the authors take to detect the presence of areas of excessive temperature in transformers, and do they recommend fitting large transformers with embedded temperature detectors?

Mr. S. Ogden: The need for periodical testing of the insulation resistance between primary and secondary and to the core is generally recognized. Is the oil as good after filtering as before, and, if not, how often should it be renewed?

Mr. R. Hodge: With regard to the use of centrifugal separators, what do the authors think of the desirability of using such a separator on a transformer in service? Would they recommend the use under such conditions of a special settling tank containing a reserve of oil? Do they consider that the installation of centrifugal oil purifiers with proper settling tanks in connection with transformers would tend to prevent the sludging of the oil in the transformer tanks?

Mr. O. Wheeler: The authors state that in the case of a transformer which had sludged badly it is not advisable to fill with new oil. Is the reason for this any special action of the new oil on the sludge still adhering to parts of windings which cannot be removed, and, if so, would it not be better practice to re-fill with the old oil filtered and cleared?

Mr. C. H. Cossens: If a transformer has become sludged is there any means of clearing it other than taking the transformer to pieces?

Mr. W. Nairn: Is there any agreement between the makers of transformers in this country with respect to polarity? The work of replacing a transformer with one of any other make and size ought to be purely mechanical, and if the makers agreed on a standard polarity test the work of the mains engineer would be greatly facilitated.

[The authors' reply to this discussion will be found on page 544.]

North-Eastern Centre, at Newcastle, 22 February, 1926.

Mr. F. H. Williams: Anyone acquainted with transformer-testing methods before the war, or even immediately thereafter, cannot but be impressed, in reading the paper, by the advances that have been made in the methods of carrying out routine tests. It has long been appreciated that iron-loss measurements are liable to considerable errors due to wave distortion, and the authors are therefore to be congratulated on developing a workshop method suitable for routine testing which will enable us to determine the amount of correction to be applied. They give an example where the wattmeter reading had to be corrected by 50 per cent. I had, a few years ago, some 7 800-kVA 20 000-volt, 25-period transformers to test, which gave an iron loss of about 14 kW. The guarantee was 22·5 and the calculated figure 21 kW. The wattmeters were checked and found to be accurate, but as an oscillograph was not available the wave-form could not be checked and the discrepancy was never definitely accounted for. It would now appear that the low figure was undoubtedly due to wave distortion. In connection with the measurement of ambient temperatures, I am glad to note that the authors advocate the immersion of the thermometer in a separate tank of oil. This is a much more satisfactory arrangement than that generally adopted of measuring the air temperature direct, and it is difficult to understand why it has not been adopted as the standard method. The tank of oil used for the purpose should, of course, be sufficiently large not to be affected by any temporary fluctuation of the surrounding air temperature. I regret that the authors have not told us anything about the measurement of "hot spot" temperatures. The tendency nowadays is to run alternators and transformers, etc., not on their rated output, which must be based on the assumption of the maximum ambient temperature, but on their actual temperature-rise, which, after all, is the more scientific and logical method, and, if full advantage is to be taken of this, accurate information regarding "hot spot" temperatures is essential and also a suitable method of giving warning when the limiting temperature is being approached. The authors make a passing reference to dielectric-loss tests. I consider that the possibilities of this test are not properly appreciated, especially in connection with the high voltages now used, and I should like to ask the authors whether they have any knowledge or experience of this test as applied to transformers, or of the magnitude of loss to be expected. They do not make any reference to the testing of tanks or terminals and bushings, all of which tests are of considerable interest to the purchaser. The crest voltmeter described in

the paper is of special interest, and the importance of using some such voltmeter in conjunction with a protective spark-gap to measure the voltage on the high-tension side cannot be too strongly emphasized. The practice, at one time fairly common, of measuring the voltage on the low-tension side of the testing transformer is sometimes not only very misleading, but dangerous. I made some measurements in connection with 20 000-volt 1 000-kVA core-type transformers and found that the charging current reduced the low-tension voltage necessary on the testing transformer for the pressure test by about 40 per cent. I am sorry that the authors have confined themselves to "the main tests carried out every day in connection with transformers." Whilst such routine tests are most important and are all that the ordinary purchasers of standard transformers of normal size and voltage can expect his apparatus to be subjected to, there are other special tests which are of great interest and of vital importance to engineers who require transformers for extra-high voltages or for connection to large power networks. The failure of such a transformer, apart from the local disorganization, may have far-reaching effects, and it is therefore necessary to specify that such transformers should comply not only with the ordinary standard tests but with other special tests. The first of these is the short-circuit test. All transformers for use in power stations or on large power networks should be capable of withstanding without damage a dead short-circuit across their secondary terminals, with the supply to the primary terminals maintained at full voltage and the high-tension oil switch set for instantaneous trip. This may sound a very severe test, but in actual practice a well-designed transformer has not the slightest difficulty in meeting it. Another important test is one to determine the factor of safety of the insulation between turns and between coils. To carry out this test special coils, exact duplicates of the transformer coils so far as the size of conductor and thickness of insulation are concerned, have to be made and tested to destruction. Research has proved that, in abnormal working conditions, the full line voltage is often applied across a comparatively small portion of the primary winding; hence the importance of this test and the reason for specifying for such transformers special reinforcement of the end turns. There is a test for another operating condition which I think our British manufacturers will have to develop, and that is a test to prove that the transformer will deal with surges and similar phenomena. The authors mention this test, which is known as a surge test, but so far as I am aware it has never been used except experimentally in this country. I believe that transformer breakdowns due to surges are, so far as this country is concerned, very few and far between, and it may be argued therefrom that such a test is unnecessary. The reply to such a contention is that in this country transformers are usually connected to cables, which, it is well known, are most effective in damping out surges and thus taking this form of shock off the transformer. With the increased use of overhead lines and higher transmission voltages, for which cables are not at present available, the direct connection of transformers to transmission lines will become more common and the need for a surge test imperative. In a copy of the German V.D.E. Rules, 1923, for testing transformers, a form of surge test is described in which oscillatory discharges are produced in the transformer under test by connecting one side to a condenser battery and spark-gaps while the other side is connected to the a.c. supply. I should like to ask the authors whether they have had any experience of this test and whether they can confirm that it is definitely specified as a standard test by the V.D.E. or merely as a suggested test.

Mr. W. T. Maccall: Do not the authors think that the wattmeter compensating coil (page 509) is liable to increase the error due to the inductance of the pressure circuit, which is particularly large at low power factors? Would it not be better to omit this coil and apply a correction to the wattmeter reading, calculated from the voltmeter reading? Fig. 11A would be clearer if the upper part were turned through a right angle to make A, B, C parallel to the corresponding current vectors in the lower half of this figure. In my opinion the authors have not made clear what they mean by "main flux" and "return flux." The flux in any limb has only one value, though it may of course be divided into components in any way desired.

(*Communicated*): The following alternative method of explaining the results appears to me to give a clearer and more accurate account of the phenomenon.

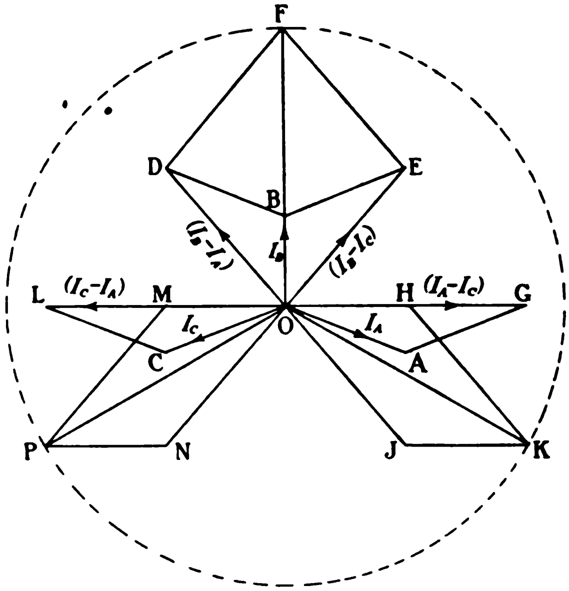

Fig. A.

In Fig. A the vectors OA, OB, OC represent the currents in the three windings (cf. Fig. 11A), neglecting the iron-loss components. OD is the vector difference, $I_B - I_A$, and so gives the M.M.F. and the flux in the circuit up limb B and down limb A (Fig. 9). Similarly OE gives the flux up limb B and down limb C. The vector sum, OF, of these two fluxes gives the total flux up limb B. Again OG, the vector difference $I_A - I_C$, gives the M.M.F. in the circuit up limb A and down limb C. But the flux in this circuit is only OH; where

OH/OG = (reluctance of circuit through limbs A and B)/(reluctance of circuit through limbs A and C). OJ is OD reversed, i.e. it is the flux up limb A and down limb B. The total flux up limb A is OK, the vector sum of OH and OJ. Similarly by adding OM (the reverse of OH) and ON (the reverse of OE) the total flux, OP, up limb C is obtained. The three resultant fluxes OF, OK, OP, are equal and at 120° to one another. The relative reluctances of the two paths (for the same case as worked out by the authors) is by this method very nearly 2 : 1, though this would be modified if the iron losses were taken into account. The remainder of the argument follows the same lines as in the authors' method, and the result is the same, but I submit that my method provides an explanation which is easier to follow.

[The authors' reply to this discussion will be found on page 545.]

North-Western Centre, at Manchester, 2 March 1926.

Mr. B. G. Churcher: The authors point out that accurate results are essential in the commercial testing of transformers. With this I fully agree. It should, however, be realized that the taking of careful readings on accurately calibrated instruments does not of itself ensure accurate results. In discussing any measurement, it is necessary first to define the quantity it is desired to measure and then to show that the method it is proposed to employ yields the desired quantity. In considering the subject of "ratio" measurements the authors speak of "voltage or winding ratio," but do not make it clear which they propose to measure. The ratio which is required for practical purposes is the no-load voltage ratio at full voltage. The three methods described, viz. the voltmeter method, the standard transformer method and the resistance potential-divider method, all measure the voltage ratio at the voltage employed during the test, which does not generally exceed one or two thousand volts. It is therefore necessary to consider whether a low-voltage test is admissible for high-voltage transformers. Consider the case of a transformer worked at a fairly high core induction and having considerable reactance. At full voltage, owing to no-load leakage, the primary and secondary windings will not enclose the same flux. At any voltage below about 80 per cent of normal voltage, the no-load leakage will become negligible and hence the flux enclosed by the two windings will be equal. Hence a low-voltage test will not give the voltage ratio for full voltage. It will, however, give the turns ratio with a fair accuracy. Another condition arises with very high-voltage transformers. It is well known that when such a transformer is excited from the low-tension winding, on the high-tension side a voltage exceeding that corresponding to the turns ratio is obtained. This is due to the large distributed capacity of the h.t. winding. The charging current, flowing through the reactance of the two windings, causes an appreciable voltage-rise. Now if the transformer is excited from the h.t. side, the charging current has a path of much lower reactance to flow through, and hence a smaller voltage-rise takes place. Thus the voltage ratio of such a transformer will not be equal to the turns ratio, and it will also depend upon which winding the testing voltage is applied to. The voltage ratio will probably not vary with the value of the testing voltage, since the reactance and distributed capacity are sensibly constant. From these examples, it is seen to be necessary to discriminate between the various "ratios" that may be measured. Of course in many, perhaps most, practical cases the effects discussed above may be negligible, but evidence on this matter is needed. In any authoritative survey of methods of testing such considerations should be dealt with systematically, as it is only by taking a comprehensive view of a problem that satisfactory methods of testing can be evolved. There is no technical difficulty in measuring voltage ratios at full voltage. With regard to the correction of iron losses for wave-form distortion, the reason why hysteresis loss varies with form factor for a given applied R.M.S. voltage is that the maximum induction varies with the form factor. For a given maximum induction the hysteresis loss does not vary appreciably with form factor. On the other hand, for a given induction the eddy loss varies as the square of the form factor. Since the greater part of the total loss in a modern transformer consists of hysteresis loss, it is best to arrange test conditions so that the normal hysteresis loss is obtained, and then to correct for the effect of form factor on the remaining eddy loss. Thus:

$$W = hfB^x + ef^2F^2B^y$$

where W is the total loss, h and e the hysteresis and eddy coefficients respectively, f the frequency, F the form factor, and B the maximum induction. If E is the normal R.M.S. voltage, the mean voltage E_m which should be applied to obtain the normal B is given by $E_m = E/1 \cdot 111$. This mean voltage can be applied by the use of a mean-voltage voltmeter. For a given mean voltage the induction in the core is independent of wave-form. Since the hysteresis term is unaffected by form factor, the normal hysteresis loss is obtained whatever may be the form factor, provided there are no inflections in the flux wave causing subsidiary hysteresis loops. Such inflections only occur under conditions of extreme wave-form distortion. Thus, so far as the hysteresis loss is concerned, there is no need to measure the form factor, but the latter is required for correcting the eddy loss. The eddy loss under the test conditions must be found by separation. The best way to do this is to keep B constant by means of the mean voltmeter and to take readings at two or more frequencies. The eddy loss is then corrected inversely as the square of the form factor. This procedure only involves accurately-known or measurable quantities, and no assumptions as to how the hysteresis or eddy losses vary with B need be made, since B is kept constant. Referring to Table 3, it would appear that a hysteresis exponent of 1·6 has been assumed by the authors, as in the expression given on page 514, col. 1. Now there is nothing fundamental about the value 1·6. It is a

value which Steinmetz found to hold for iron at low inductions, and cannot be taken as a universal constant for all materials under all conditions. With the 4 per cent silicon steel used in transformers, the exponent may have a value of 1·6 to 1·8 up to $B = 10\,000$, 1·8 to 2·2 up to $B = 12\,000$, reaching values from 2·3 to 3·0 at $B = 15\,000$, after which the exponent decreases. The exponent not only varies with B, but also from sample to sample of what is nominally the same material. It is therefore a very unsatisfactory quantity on which to base corrections to transformer iron losses unless it can be actually measured on the transformer in question, which is usually impracticable. In addition to this, the authors' method of correcting for form factor involves a much larger percentage correction than is necessary. Thus in the example at the top of page 514, col. 2, the observed watts are 17 850, whilst the corrected watts are 24 200, a correction of 35 per cent on the observed watts. Now in the method that I have described, in which the eddy loss only is corrected for form factor, the correction for a form factor of 1·4 would consist of dividing the observed eddy loss by 1·59, which amounts to a correction of 8 per cent on the total loss. Thus the method involves a definite correction of only 8 per cent, whilst the authors' method involves an uncertain correction of 35 per cent. From the values I have given for the hysteresis exponent, it is evident that methods of separating hysteresis and eddy losses, based upon an assumed value for the exponent, are inadmissible. To sum up, in measuring transformer iron losses the mean voltmeter is the fundamental instrument and should be used to set the normal induction in the core of the transformer. The R.M.S. voltmeter is used as an auxiliary to obtain the form factor for the purpose of applying a correction to the eddy loss. With regard to methods of measuring the mean voltage, the authors' valve-rectifier commutator is very convenient for test-bed work. Where the voltage to be measured is not less than about 100, the 0·5 per cent accuracy claimed by the authors can undoubtedly be obtained. The main advantage of the method is that it can be applied to any source of supply and requires no adjustment such as shifting the brushes of a rectifying commutator. It is, however, not correct to say that the brushes on a rectifying commutator require great care in adjustment. With a properly designed commutator the adjustment is far from critical and is quite simple. With a well-constructed commutator the form factors of voltages from several hundred volts down to 0·1 volt may be measured to 1 or 2 parts in 1 000. With regard to the "iron loss voltmeter," it would seem that such instruments are unnecessary where a dependable "mean voltmeter" is available. The compensation effected by iron-loss voltmeters is only approximate and the performance of such instruments should not be taken for granted. With regard to the statement on page 517, that the losses in magnetic shunts are inseparable from the total stray losses on short-circuit, the losses in such shunts can be obtained from the rate of increase of temperature of the shunt (measured by a thermo-couple) when the current is switched on, and the thermal capacity of the shunt, which can be calculated from its dimensions.

Mr. E. T. Norris: Insulation resistance is not mentioned in the list of tests required on transformers. At the present time most transformers are impregnated with some insulating composition, either liquid or solid, and it is necessary to dry the transformer out before it is impregnated. I am not sure whether the authors are describing the drying-out process before this impregnation or after, unless the transformers are being impregnated in their own oil. If not, and it is presumed the transformers have been properly dried out before impregnating, I do not think that 11 000 volts is a necessary limit for drying-out without vacuum. There would not be much moisture inside the insulation if it had been recently dried out before impregnation. I am very glad that the authors emphasize that a single measurement of insulation resistance with a megger with the transformer cold is no criterion of dryness. Where a transformer is being dried out in oil I think that a single measurement of the insulation resistance is no criterion, even if done with the transformer hot. In a works, however, air drying out is nearly always used. It is simpler and more effective, as the authors suggest. In Fig. 2 on page 507, in the diagram of temperature, vacuum, etc., the authors mention a vacuum of approximately 28 in. I assume that is based on a 30-in. barometer reading. It means that the vacuum is within 2 in. of perfect. For a large and high-voltage transformer, such as is indicated in Fig. 2, I should consider that poor. It is fairly safe to assume there is eight times as much air left inside the insulation with 28 in. of vacuum as with $29\frac{3}{4}$ in. or within $\frac{1}{4}$ in. of perfect. It is quite practicable to get within the latter value. The authors base their criterion of whether a transformer is dried out by plotting the curve of insulation resistance against time. I agree that that is a simple and very excellent way on a small, ordinary-voltage transformer, but for a high-voltage transformer it is possible to have a megger reading of infinity, and still not have the insulation dried out. The insulation resistance ought, at least, to be supplemented by some more sensitive method of moisture indication, such as a suitably arranged condenser. In this connection I am referring to transformers for voltages of 80 000, 100 000, or 200 000. There is a small point on page 508. Towards the end of the second column the authors say: "With large transformers the magnetizing current is almost equal to the no-load current, but with small transformers there is an appreciable difference." I do not think this equality or inequality is essentially due to the size. It depends upon the magnetic rating and the quality of iron. Even with the higher power factor of 0·2 given a few lines further down, there is only 2 per cent difference between no-load and magnetizing current. Then the authors go into the measurement of iron loss and the correction for form factor in very great detail. They give two examples which I expect are intended to show very forcibly the method of correction: they certainly do not represent average conditions in a transformer testing department. If a single-phase transformer is energized with the secondary winding open-circuited, the current is heavily distorted, mainly by third and fifth harmonics. If the generator or source of power is unable to supply this distorted current and maintain its sine-wave voltage, then both pressure and current wave-forms are distorted and the conditions

are fairly complicated. In the first example given on page 514 the form factor is 1·4, and, as has been previously pointed out, it involves a 35 per cent correction to the measured iron loss. As a general principle a method of test requiring 30 to 35 per cent correction is undesirable if it can be avoided. It is, of course, not always possible for a works to install machinery giving a pure sine wave with very heavily distorted current for all testing requirements. Where necessary, correction must be made as the authors suggest, but for the greater part of the transformer testing-work such correction should not be necessary. I would point out that for large and high-voltage transformers the methods of correction suggested by the authors will give entirely wrong dielectric losses. These losses are beginning to be of great importance even in high-voltage power transformers, and are often a limiting factor in testing transformers for voltages of 300 000 or 400 000 upwards. The form factor of 1·4 in that first example means, if we take the most favourable arrangement for displacement of the third harmonic, a distortion of something like 40 per cent from sine wave-form. I think, however, that it is very useful to have had the importance of the sine-wave voltage pointed out, and the precautions necessary if we have to depart from it. On page 522, where the authors are considering the measurement of temperature by increase of resistance, they give two methods of obtaining the correct resistance after shut-down. One is by means of factors dependent upon the watts loss per lb. of copper; the other is by measuring the temperature some minutes after shut-down and extrapolating back. The factors given for correcting temperature by the watts loss per lb. of copper, although they have been accepted by many authorities as standards, are based on experiments made some years ago on transformers which were typical of the usual thermal ratings at that time; they are purely experimental figures and are not necessarily true for present-day types of thermal design. For this reason the agreement given by the authors between the two methods of correction is not in itself a guarantee of the accuracy of either. As regard the extrapolation method, it is extraordinarily difficult to extrapolate back from a curve of changing slope. I do not agree with the authors' faith in this method where it can be avoided. They give an example of a correction where the resistance was measured 3 minutes after shut-down. Now on a large transformer, or on any transformer, it is usually possible to get one reading, one measurement of resistance, within 2 or 3 minutes after shut-down, but very often it is not possible to get both readings—high-tension and low-tension windings—in that time, and as the time between the instant of shut-down and the first resistance measurement increases, the inaccuracy of the extrapolation method becomes very much greater. The extrapolation method also necessitates the instant shutting down of all the cooling methods, as the authors state on page 523. It is very difficult to do this, and it involves another inaccuracy in the extrapolation method. It is well to remember the disadvantages and limitations of these methods, although an accurate method capable of general application is not yet available. In certain cases it is possible to obtain correction by means of embedded temperature detectors, and for this purpose it is not necessary that they should record the hottest spot temperatures of the copper. This method is the most accurate, but is of very limited application at present. The paper deals in a comprehensive and full manner with a subject which is not often discussed in detail, and in future years it will be a valuable record of the present-day practice and progress in the testing of transformers.

Mr. J. L. Carr: Usually one regards the testing methods adopted on works' test-beds as being somewhat crude, and it is no uncommon thing to see instruments used indiscriminately with shunt and series transformers without any allowance being made for the errors that such transformers will produce upon the instruments. A paper of this sort, which emphasizes the necessity for carrying out measurements of this kind with a reasonable degree of accuracy, is very valuable to those engaged upon test-bed work. In this connection I note that the authors have adopted the use of a total current dynamometer wattmeter of the precision type for the measurement of losses. This, I think, is a great step forward. It is perhaps not generally appreciated that when measuring power at a low power factor of, say, 10 per cent, a leading phase angle of 1° in instrument transformers will produce an error of 100 per cent in the indicating instrument. In connection with the determination of the turns ratio of transformers, the resistance ratiometer would appear to be the most satisfactory arrangement, but the method is one which does not necessarily give a true indication of what the open-circuit voltage ratio will be in normal operations. There are one or two points in connection with this arrangement which I think tend to produce slight inaccuracies, and it will be interesting to have the opinion of the authors as to the magnitude of the errors produced. For example, with instruments of this sort it is necessary to take a certain amount of current from the potentiometer, and that in turn, unless the conditions are very nearly balanced, is apt to disturb the reading, although the error may be only a small percentage. Further, with an instrument used in this way, it is to be expected that the phase angle of the wattmeter will tend to give rise to slight inaccuracies. Perhaps they will not be commercially important but, nevertheless, they exist. The use of the iron-loss voltmeter is very interesting, but I fail to see the necessity for one of these instruments if a mean voltmeter is used. The calibration of such an instrument as the iron-loss voltmeter would, I think, be somewhat tedious. The method of measuring resistance described by the authors as being most suitable for transformers is by means of an ammeter and voltmeter. I have had some experience in obtaining cooling curves on various electrical appliances and I was somewhat surprised to see this method preferred to some of the other methods of greater precision in common use. Here we have two instruments with a minimum inaccuracy in reading which is of the order of 0·1 per cent, and the error may be in one direction in one instrument and in the other direction in the other instrument. Great accuracy is therefore out of the question. Further, the two readings must be taken simultaneously, otherwise, as the appliance cools down very rapidly, very considerable differences may be obtained. Personally, I should

strongly recommend the use of a Kelvin double bridge, particularly during cooling. It is possible by the use of such an appliance (which is available in portable as well as laboratory patterns) to obtain very rapid and accurate readings of resistance. Readings can be obtained, after the transformer is shut down, more quickly than by the two-instrument method, and, in addition—and this is of importance, particularly when looking for small changes in resistance—the accuracy of measurement is considerably higher if suitable precautions be taken.

Mr. H. Diggle: The resistance ratiometer described on page 508 seems to be simply an elaboration of the old potentiometer method for comparing the voltages of two primary batteries, etc. I do not see the necessity for introducing the wattmeter. A previous speaker has mentioned that there may possibly be a slight error in the instrument itself due to a small difference in phase between the fields produced by the moving and fixed coils. It ought to be quite a simple matter, without any loss of efficiency, to connect the high-tension winding of the transformer across the maximum resistance and make a common point between the high-tension and low-tension windings at one end. The other end of the low-tension winding could be taken through a sensitive a.c. ammeter to the other dial. On page 509 the two-wattmeter method and the three-wattmeter method are mentioned for iron-loss measurement of three-phase transformers, and, from the results given in Table 1, it could be inferred that the one method is equally as good as the other. The total for the two-wattmeter method is 1·112 kW as against 1·12 kW in the case of the three-wattmeter method. Also, the suggestion is implied that owing to the two-wattmeter method having a better power factor on the instrument, it may be an advantage to adopt this method, although this is not definitely stated. I think the fact that the two-wattmeter method depends upon the difference between two relatively large readings renders it open to greater sources of error, and that the three-wattmeter method is preferable, particularly now that the objections on the score of low power factor on the instrument can be got over by the use of the new low-power-factor type of wattmeters which are available. On page 516 the question of the separation of the eddy-current losses from the measured copper losses is mentioned. As Mr. Churcher has mentioned, the square law is of rather limited application. I have applied it to several cases, and, in general, have found that on a transformer which has a comparatively low percentage of eddy-current loss the square law will apply and a straight line will result when watts loss is plotted against frequency squared. If, however, a transformer is of bad design, or if for any reason the eddy-current loss is a high proportion of the total loss, my experience is that the square law does not hold and the index figure is nearer 1·5. Mr. Norris has mentioned that the form factor in iron-loss measurements is shown as having a rather bad effect in the examples. From these a purchaser may be rather liable to imagine that he may not get a true reading when the ordinary test is taken. In most cases it is possible to arrange that the generator from which the iron loss is supplied is so big that its wave-form will not be particularly distorted when supplying the magnetizing kVA of the transformer; and I consider it desirable to mention that such discrepancies as are indicated in the paper will only occur when a big transformer is being tested and its no-load kVA is somewhere near the full capacity of the generator supplying the loss. On page 519 mention is made of full-load temperature runs. It is said that "a single-phase transformer cannot in general be run on load by itself." This is strictly true of shell-type transformers only. With a single-phase two-leg core-type transformer it is possible to carry out a load run by treating the two legs as separate transformers, putting one against the other, and then upsetting the balance by boosting to circulate the load current. Fig. 19 (B) on page 519 shows two star/star-connected transformers with the phases crossed. Whilst this is not incorrect, it is not necessary. The diagram can be simplified by connecting the phases straight across between the two transformers. In Figs. 21 and 22, which show similar crossings, the crossing is necessary and the diagram cannot be simplified. The question of connections for temperature-runs on all types of transformers was the subject of a paper read before the Students' Section of this Centre some 12 or 13 years ago, and an exhaustive treatment of this section of the paper appeared in the *British Westinghouse Gazette* for March 1918. I think that the method of overpotential test shown on page 524, viz. superimposition of high-frequency and low-frequency waves, requires a little more explanation than is given in the paper. The real object of this superimposition is to reduce the number of peak values in a certain length of time, and it seems to me that the effect shown by the authors could be achieved equally well by having a generator with a badly designed (peaked) wave-form. The object of using a high frequency in overpotential tests is simply to keep down the magnetizing current. It seems to me that the voltage wave on the right-hand side of Fig. 26 should give a magnetizing current not particularly different from that which would result from a sine wave at fundamental frequency. Perhaps the authors will explain this point further. In connection with the measurement of iron loss of a three-phase transformer by the three-wattmeter method, I think there is a slight error in the readings shown in Table 2 at 300 and 280 volts. In the power-factor columns there is a generally steady sequence, the power factor varying in one direction as the voltage is varied. At 254 volts the phase power factor of phase A is 0·0350, then it rises to 0·0406 at 280 volts, and then falls to 0·0325 at 300 volts. There is probably an error in observation due to the difficulty of obtaining accurate readings at these high values of flux density in the core. I have done a number of tests of this nature and I think that Fig. 10 would have been more interesting if a curve of total watts had been added. This would have been found to cross the curve for phase C if carried sufficiently high. Another interesting fact is the way the three wattmeter readings vary as a percentage of the total watts loss. Fig. B shows the results of tests made on a standard three-phase core-type transformer. The three wattmeter readings are expressed as percentages of the total loss and are plotted against voltage. On low voltages phase A takes

45 per cent of the total, the other two phases taking 27½ per cent each. Phase B maintains its figure constant at 27½ per cent, but phase A increases its value with rising voltage, and phase C reduces its value and becomes negative above a certain point. The curves for phases A and C are symmetrical but in opposite directions. At 100 per cent volts phase C is zero, and if the voltage is carried to a point where it has become — 27½ per cent, the reading of phase A is equal to the total loss. At any voltage higher than this, the reading on phase A is greater than the total loss. The initial proportions depend upon the particular core, but will not differ

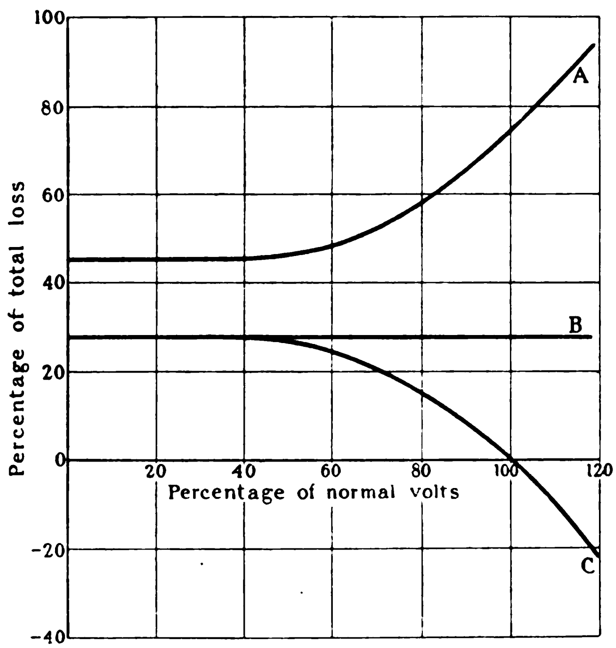

FIG. B.

much from the figures given. In the test given by the authors the figures for the three phases are A 48 per cent, B 27 per cent, and C 25 per cent.

Mr. A. Philip : With reference to the measurement of iron loss in three-phase transformers, and particularly to the case when the authors obtained a negative wattmeter reading in one phase, the transformer being quite symmetrical as regards the outer limbs it appears that either outer phase can give the negative wattmeter reading on no load, it depending entirely on phase rotation as to whether phase A or phase C does so. With reference to the vector diagram explaining the phenomenon, it would appear that the authors have set out to determine the total resultant flux in each limb of the transformer, but that they have later abandoned this plan in favour of using certain of the return-flux values to determine the phase relation of the currents in the three phases. With regard to the oil used in transformers during test, it is noted that the authors specify a breakdown value of 30 kV for a 0·15-in. gap, and I think it would be advisable that this figure should be adopted in B.E.S.A. specifications, as it is one which can be readily attained. The present figure of 22 kV is low enough to permit the use of an oil which is only of medium quality and which can be usually improved by centrifuging.

Mr. F. E. Hill : The authors have quite rightly stressed the importance of accuracy ; one of the chief factors in realizing this accuracy on the test bed is in the choice of testers who are suitable for this particular work. Routine transformer testing becomes very monotonous, and is only varied by special tests and tests on special apparatus. For this reason, unless the testers have a scientific interest in their work, carelessness may nullify the various precautions described by the authors to obtain a reasonable degree of accuracy. It cannot be too strongly impressed on the testers that, whilst production is important, it ranks second to accuracy as far as they are concerned. The authors point out the necessity of recording the temperature at which resistance measurements are made. It is equally important, of course, to do so when making copper-loss measurements. Customers' inspectors often have the copper loss measured after the temperature and insulation tests ; under such conditions it is difficult to ascertain the temperature of the windings without taking a further resistance reading, and, as this is rarely done, it is impossible accurately to correct the copper loss to the basic temperature. The copper loss should, wherever possible, be measured when the transformer has been standing at atmospheric temperature for a considerable period. I am surprised to find that the authors recommend the plotting of resistance against time and extrapolating to obtain the temperature-rise at the instant of shut-down at the end of a temperature test. The readings of resistance under such conditions which have come under my notice leave very much to be desired in this respect, as the first reading is rarely taken earlier than 3 minutes after shut-down, when the flatter part of the cooling curve is already reached. This is borne out by the figures in Table 6. If these had been shown in the form of a curve instead of a table it would have been seen why there had been little difficulty in obtaining results by this method which agree with the results by the alternative method to within half a degree. The alternative method of correcting by definite factors based on the rating of the copper and the time of the reading after shut-down was developed in America on account of the difficulty in obtaining accurate results by the extrapolation method,* and, although this method may not be strictly accurate, in the majority of cases it is probably the more accurate method. The method described by the authors of carrying out overpotential tests where a very high frequency is necessary is very interesting. The severity of such tests has been recognized in the latest edition of the American Standardization Rules, which now permit of a reduced length of time for the test if made at over 120 cycles per sec. ; for instance, at 240 cycles per sec. the test is for a period of 30 secs., and at 400 cycles per sec. for a period of 10 secs. It is to be hoped that similar figures will be incorporated in the forthcoming B.E.S.A. specification for transformers, as, although the authors' test is undoubtedly satisfactory, I think that the usual test for a shorter period of time will be looked upon by inspecting engineers with greater favour.

* V. M. MONTSINGER : "Cooling of Oil-immersed Transformer Windings after Shut-down," *Transactions of the American Institute of Electrical Engineers*, 1917, vol. 36, p. 711.

Mr. A. G. Ellis: I should like to emphasize what Mr. Norris said about the value of this paper as a record for the future. As has been pointed out by Mr. Hill, we are now testing regularly, in works, power transformers up to 20 000 kVA rating under full-load conditions, and up to working voltages of about 150 000.

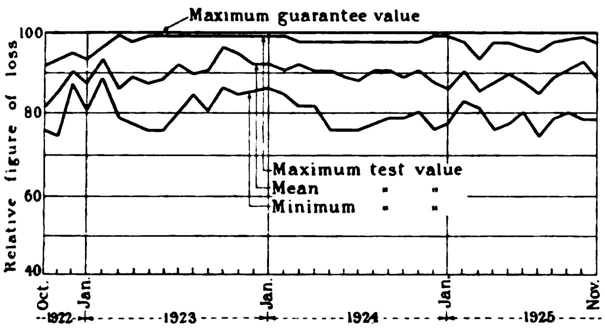

FIG. C.—" Figure of loss " for samples of transformer sheet-steel.

This involves generators for testing at normal frequency up to 3 000 and 4 000 kVA, from which one can visualize the size of the testing plant which has had to come with this development work. This matter is partly exemplified by the transformer referred to in Fig. 2, where the authors give data of the drying-out of a 7 333-kVA, 125 000-volt transformer. To give an idea of what is involved and of the time taken to dry out such a unit, I may point out that a transformer of this nature will weigh about 20 tons and will contain something like 2 tons of insulating material. This absorbs a tremendous amount of moisture in the course of manufacture, and the drying-out process is no light matter. I agree that the vacuum drying process is the best for such work. The authors say that air-drying is possible up to 11 000 volts. This doubtless refers to their method of drying transformers in a hot-air cupboard with steam-heated pipes in the bottom. Air-drying has, however, been used in America for very large and high-voltage units with a blast of hot air blown through the transformer itself. This is more applicable to drying-out on site, where one has not got all the facilities which are available in the factory, but wherever it can be done the vacuum process is probably the best. A good deal has been said about the accuracy of testing. One has to balance the expense of getting accurate testing in the shop with the results at which one is aiming. The object of shop testing is to check whether apparatus falls within its guaranteed performance figures. If it does so the customer is generally satisfied ; and extreme accuracy is really of secondary importance except to the designer, whom it will enable to make closer calculations on the next design. Now, apart from inaccuracy on test, there are a number of factors which cause wide variations in the figures produced. Variations in the uniformity of the material and in the workmanship, both in the core and in the winding, and so on, come in and play a very important part. To illustrate the variations in the quality of sheet steel for transformer cores, and the variations in the measured core loss on the finished transformer due to lack of uniformity in the quality of sheet steel and in the workmanship, I give in Figs. C and D measurements taken over a period of 4 years. Fig. C is a record of the figure of loss as measured on samples of sheet steel taken from bulk supplies from the manufacturers as received in the factory. The chart records the minimum, mean and maximum test-values and the maximum guaranteed value, above which latter limit the consignments are rejected. It will be seen that the maximum variation in figure of loss amounts to about 25 per cent. Fig. D is a record of the figure of loss (watts/lb.) on finished transformer cores on three different sizes of frame. Each spot on the chart represents a test on one finished transformer, the results being charted by

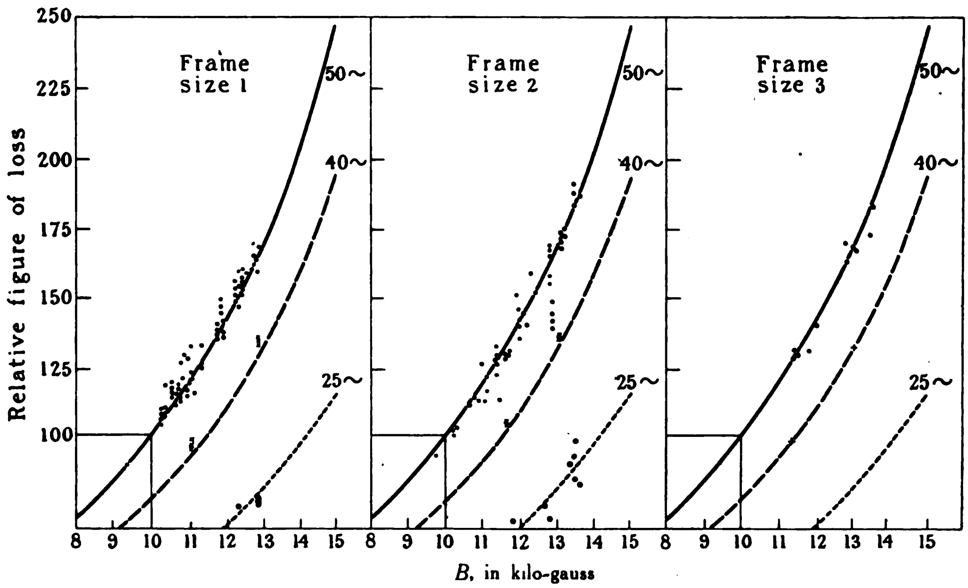

FIG. D.—" Figure of loss " for finished transformer cores.

plotting figure of loss (proportional to the watts per lb. of iron) against flux density in the core. The curves drawn for 50, 40 and 25 cycles represent the average curves which are worked to in designing. On the question of full-load temperature-runs, the authors have not mentioned the time taken for a very large unit to reach a steady temperature, which is often a matter of 20 to 24 hours. The time occupied in load-runs is a big factor in a works test-bed, and I should therefore like to ask the authors whether they advocate or make a practice of overloading these large units in the initial stages of the load-run; and, if so, whether they have had any experience of the danger of overheating the windings. The last point I will touch upon is the question of insulation tests on large high-voltage transformers with earthed neutrals. Where the neutral is earthed directly and permanently, the insulation test can only be applied by over-excitation. The American Rules specify in such cases a test at 2·73 times the phase voltage (i.e. the voltage from line to neutral). To do this it is necessary to raise the frequency in about the same proportion, as the authors have pointed out. Cases have come within my experience where a test voltage as high as 3·5 times the phase voltage has been specified. This means (on 50-cycle transformers) that we have to test with a frequency of 150 to 200 cycles. Mr. Hill has mentioned, in connection with tests at high frequency, that the breakdown voltage of the insulating material decreases with increasing frequency. For the materials usually employed the breakdown voltage at 200 cycles may be 20 per cent less than at 50 cycles. The strain on the insulation during test is greater than is often realized or warranted, and I would emphasize what the authors have said about a false sense of security being engendered by these abnormally high tests.

Mr. J. Longbottom (*communicated*): I should like to ask the authors what they consider to be the most reliable method of measuring the temperature on a transformer while it is being dried out under vacuum, as unless the element of the indicating apparatus is actually in contact with the transformer the true temperature of the latter will not be obtained, due to the absence of any heat-conducting medium. If vapour pressure-type thermometers are used these are liable to read low owing to the vast difference in pressure on the outside and inside of the bulb. I have found that thermo-couples soldered to pieces of copper which are bolted to the transformer core give the most reliable results, but considerable trouble was experienced in the upkeep of the insulation on the thermo-couples, since they had to withstand continuous working in dry heat. I am in thorough agreement with the authors on the method of measuring ratio, and have long since formed the opinion that the resistance ratiometer is the only satisfactory method of measurement. Ratio by voltmeter, though still used to some extent, leaves a large amount to be desired and should be avoided wherever possible. On the question of polarity I should like to ask the authors if they are acquainted with a three-phase polarity meter which will indicate such things as a reversed phase or incorrect delta connections, etc. I have not seen any instrument of this nature, but experience has shown that if one were in use on the test-bed, one cause of trouble on site would be avoided. I am rather surprised that the authors suggest obtaining polarity on a transformer by using direct current, with its attendant risks of shock, and would suggest that a far better method, though a very old one, is to join the tops of the l.t. and h.t. windings together, a convenient low a.c. voltage then being impressed on the two free ends. The voltage across the h.t. winding will then be greater or less than the supply, depending on whether the polarity is subtractive or additive. The authors do not definitely state which method of connection, two- or three-wattmeter method, is considered to be the better, but I think that the three-wattmeter method is desirable, since errors of observation are more likely in the two-wattmeter method, particularly where the supply to the transformer under test is of a fluctuating nature. The authors do not show any method of running a single-phase transformer by itself, and, in fact, they say that it must be run with either a duplicate or a larger transformer. I know of many cases where a single-phase transformer has been given a temperature-run by breaking the h.t. and l.t. windings into two equal parts and paralleling the like halves. A circulating current can be injected on either the h.t. or l.t. side and a magnetizing current applied across the l.t. windings; this, of course, should be equal to one-half the normal voltage. I have seen transformers up to 10 000 kVA and 100 000 volts run by this method. In using a spark-gap for measuring very high voltages the authors recommend a resistance of 1 ohm per volt, the best resistance being a column of water. I am surprised that water should be advised, as my experience has shown that as soon as the gap breaks down, if there is any delay in switching off, even if only 1 or 2 secs., the water is ejected with great force from the tube and falls on any apparatus that may be near. Wire-wound resistances can be obtained in sufficiently high ohmic values to be of convenient size and still have sufficient length to prevent a flash-over. I have seen very successful tests carried out with these wire-wound resistances. With regard to the authors' statement on page 526, col. 1, I do not consider it at all advisable that the grids should be left free, as they are liable to be charged to a potential sufficient to cause a breakdown to either the filament or the plate. I think that when the grids are connected to the plate there is far less risk of breakdown than when they are left free, even though the voltage from the plate to the filament may be lower in the latter case than in the former.

Mr. J. D. Peattie (*communicated*): I am very glad to note that the authors begin by insisting on a few elementary precautions to be taken, to ensure accurate and reliable tests. Incidentally, these precautions will amply repay the extra time and labour involved. That instruments should be cared for, checked and calibrated, may seem obvious when one reads it in cold print, but it is one of the points which do not always receive the attention they should. In a Continental test-room of which I have experience, well over 1 000 instruments were in constant use. These were controlled by an expert and a special staff. Every instrument was calibrated once a month (oftener, if necessary), and careful records were kept of its history, in addition to the calibration figures pasted on the case. The instrument-room standards

themselves were checked every year at the equivalent of the National Physical Laboratory and records kept of their behaviour. The unequal loss measurements referred to on page 511 in the three phases of a transformer can be regarded in another way, which I think may help to make clear the apparent anomaly. The energy stored in an ideal symmetrical three-phase field is constant in magnitude, although varying in distribution. In the case of the three-limb transformer shown in Fig. 9, its magnitude is not constant, but varies between a maximum and minimum value twice in every complete cycle. While it is increasing, additional energy has to be drawn from the supply, and while it is decreasing, the surplus energy is available for absorption by the losses, or, if more energy is available than these require, the balance is returned to the line. In the example given, phase C supplies the additional energy, and phase A benefits by the absorption of the surplus. The energy stored in the field varies as the square of the flux (or higher power if saturation is reached). The losses, as shown in the paper, vary as some power less than the square. The consequence is that the surplus energy available increases more rapidly with the voltage than do the losses, and on this account the input to phase A falls to zero and ultimately becomes negative as the voltage is raised, as shown in Fig. 10 and Table 2. With regard to heating tests, I should like to have the authors' views on testing for unequal temperature distribution. As the ultimate life of the insulation and oil may depend on this, it seems to me that some examination, on representative transformers at least, should be made in the test-room. In testing larger machines considerable trouble is taken to measure local temperatures, and it seems reasonable that one ought not to be satisfied, in the case of a transformer, with the measurement of average values only, as given by oil temperatures and increase in resistance of the windings.

The Authors' Replies to the Discussions at London, Bristol, Newcastle and Manchester.

Messrs. J. L. Thompson and **H. Walmsley** (*in reply*): Mr. Stigant in his remarks agrees with our views as regards accuracy, and this aim we have endeavoured to attain throughout the paper without the use of elaborate apparatus which, whilst it might be suitable for laboratory work, would be out of place on a modern works test-bed. The apparatus mentioned and described is such as is in everyday use on a modern test-bed, but it might be said that such apparatus has no definite finality since it is being improved upon in one direction or another month by month. We refer to and support the vacuum drying-out process, not because there are no other methods, but from the point of view of time and reliability. Time is one of the most expensive items in modern production, and must be reduced to a practicable minimum in order to obtain a maximum efficiency of output. The measurement of iron loss on transformer tappings is, in our opinion liable to serious errors, especially in modern transformers where, due to the high quality of iron available, it is possible to design transformers at high inductions, i.e. at values much higher than the bend of the B/H curve. Due to this fact it is necessary that the exciting ampere-turns embrace the full winding length of the core; otherwise serious flux leakage will result and thus cause erroneous readings. Copper-loss measurements of three-phase transformers are referred to by Mr. Stigant, who supports the single-phase and summation method. This method is approximately correct for small transformers with low reactance characteristics, but for large transformers, especially those of high internal reactance, it is liable to serious error. This error is due partly to the loss in a neutral lead being measured three times and also to the load leakage flux not being in its normal path as when measured three-phase. The use of static condensers for improving the power factor of machines giving load to the test has been mentioned. It is not a new suggestion, but we fear that their use, unless particular care were taken as regards their values, might lead to serious voltage-rises in some instances; and therefore to simplify the plant on a test-bed we do not recommend them. Mr. Stigant is disappointed at the absence of vector diagrams illustrating the tests. These diagrams are simple and can be easily drawn by those who are interested, but we do not think that they would have added much to the value of the paper, which is already of considerable length. Mr. Stigant states that the pressure-rises when pressure-testing are due to well-known phenomena. We agree, but we have stated that this rise must be taken into account, for the values obtained cannot be accurately calculated and, as the high-tension voltages for transformers are rising year by year, it is imperative for the manufacturers to provide means of measuring this high-tension pressure accurately. This provision ensures that no abnormal stresses are put upon the transformers on test, and thus eliminates the possibility of straining the insulation beyond the necessary limits. Mr. Stigant refers to the temperature-rise by resistance and by a thermometer in the oil; we agree that the difference in the temperatures thus obtained is not a definite figure for self-cooled units, though with artificially cooled units, such as water-cooled and oil-circulated, force-cooled units, there is a definite relation. The reason is found in the head of oil above the transformer in the self-cooled unit; the greater the head, the less the difference. Instances have occurred where the temperature-rise of the oil has been higher than the temperature-rise by resistance, which is, after all, only the average temperature-rise of the windings and not a maximum temperature-rise. There is possibly a definite relation between the average temperature-rise of the oil and the average temperature-rise of the transformer as measured by increase of resistance.

Mr. Melsom questions the accuracy of the megger as used for testing insulation resistance. We agree, if it were intended to use such an instrument for obtaining any actual insulation-resistance values. In the use to which we have put this instrument the accuracy of the actual figures obtained is unimportant as long as the figures

obtained with the same instrument are relatively accurate. In other words, as we have stated in the paper, it is not the value of the insulation resistance, but the characteristic of insulation resistance with time at constant temperature that is required. The period of time—60 seconds—given in the paper is suggested as being too low. If Mr. Melsom wishes, he may apply it for a longer period, but our experience, covering transformers up to 20 000 kVA and for service voltages up to 136 000 volts, has proved that up to these limits of size and voltage the stated time gives ample margin for a steady reading to be obtained, i.e. for the transformer condensers to be fully charged. With regard to the fall of the insulation-resistance value with oil immersion, the fall is immediate and Fig. 2 clearly demonstrates this. Our suggested method for obtaining resistance measurements comes under Mr. Melsom's severe criticism. We would point out that we are dealing with commercial and not laboratory accuracy, and whereas highly accurate instruments can be obtained in the laboratory, it is an entirely different matter when such instruments are used in a works test on commercial testing. It will probably interest Mr. Melsom to know that we have not made our statement in the paper without any foundation, for many methods have been used, as has been stated, and in each case the method has had to be abandoned. We think that most transformer manufacturers will confirm our opinion. Any bridge method of measurement, using high resistances to form the balancing limbs, are liable to errors due both to resistance changes with temperature and also to thermo-couple effects. The resistance elements and the copper or brass terminals constitute couples at different temperatures, and thus tend to upset the balancing. Although the bridge method is a " null " one, current is only nil in the bridge and galvanometer, while current is flowing in the arms of the bridge of which the transformer winding is one arm. This current is changing until balance is affected. Such balance is difficult to obtain, due to the inductive and capacity effects of the transformer winding. We have carried out experiments with a portable Kelvin double bridge, as suggested by Mr. Melsom, using several different values of resistance, and we found that to obtain an accurate result the greatest care had to be taken with joints and connections, far greater than that required for the method recommended, in order to obtain accurate values for the standard resistances and the resistances under test. Inspecting engineers frequently demand currents of relatively high values, such as one-third full-load current, for resistance measurements, and this demand leaves no alternative. With the double-bridge and similar instruments using a standard resistance for comparison, thermal effects are liable to occur if additional instruments are not inserted to regulate the current in the main circuits of the bridge. With regard to the time taken to obtain resistance values, the greater part of the initial time is taken up in the shutting down of supplies and cooling auxiliaries, and by taking care of surges produced by switching on the d.c. current to the inductive transformer winding as referred to on page 519. This occurs when using any other method and is generally independent of current value, due to the relative sensitivity of the instrument used.

Mr. Richards refers to the resistance-balance ratiometers and confirms their suitability, but states that they are not commonly used. We have three such instruments in daily use and have had them some two years. Mr. Richards is in error in his remarks about iron-loss voltmeters. We have two such instruments, but find their use and service very limited. The voltmeters have a very limited range, due to the fact that each instrument is only suitable for the frequency for which it is designed, and considerable errors are present when it is used on other frequencies. With regard to the form-factor examples for iron loss given in the paper, we wish to state that they are exceptional, although they are true tests picked out for demonstrating our point. The example with a form factor of 1·4 is exceptional and was due to the machine supplying the no-load kVA being of low rating, and also to the fact that single-phase load was taken from a three-phase machine. The other example with a form factor of 1·25 is quite a common occurrence when testing large single-phase transformers by loading one phase of a three-phase machine. Mr. Richards refers to resistance measurements. We have stated in the paper, and also carry it out in practice, that definite instruments should be set aside for resistance measurements and used only for that purpose. We state on page 519 under " Full-load temperature-runs " that there are many ways of approximating the load and losses, but those that are most nearly representative of true service conditions are here dealt with. To have described all the possible methods would have been too lengthy a task for a paper of this nature. Load running by the use of tappings is suggested by Mr. Richards as being a common practice. We ourselves never use this method, as it is rarely possible to find tappings equal to the impedance percentage of the transformers, and only an approximate load can therefore be obtained. Further, the generator supplying such a load is often severely loaded. Mr. Richards is surprised that we do not mention the hot-spot method. Unless Mr. Richards means the use of thermo-couples, we are at a loss to understand the point or test referred to. We suggest that the use of thermo-couples on standard tests is a dangerous procedure, from the points of view of the test-hand, possibly of the inspector, and of the transformer itself. They are dangerous because the hot spot is usually on or about the point of highest service potential, and it is not always possible to earth that point during a test run. Further, we suggest that thermo-couples if inserted and insulated do not necessarily give the exact temperature of the winding, due to the temperature gradient across the insulation between the conductor and the couple. We suggest that thermo-couples should not be used for standard tests but that they are of great service when used for investigation work, on transformers of new design, in order to give to the engineer information as to the efficiency of any particular method of winding and ventilation ; and that they should be limited to this service. For obtaining the maximum temperature we would suggest that the safest and best method for service conditions is the insertion of standard resistance elements in that part of the winding of a transformer which has been proved by exhaustive tests on similar

types to be the hottest spot. The increase in value of this standard resistance with the operating temperature of the transformer will then give the temperature-rise at that point. Such a scheme is outlined in Fig. E. Mr. Richards will probably be interested in an article on transformer temperatures in the *Electric Journal* (1925, vol. 22, p. 551).

Mr. Bloome refers to two methods of drying-out and is at a loss to explain the difference in the time taken. The insulation characteristic curve will be similar in both instances as Mr. Bloome states, but the rate of drying depends solely on the quantity of heat supplied and the method of supplying the same. Possibly the transformer dried out by short-circuiting had a very high internal temperature which is difficult to ascertain, and that possibly overheating and rapid drying have consequently taken place, with a risk of internal damage to the winding insulation. There should be no appreciable difference in the results obtained by the two- and

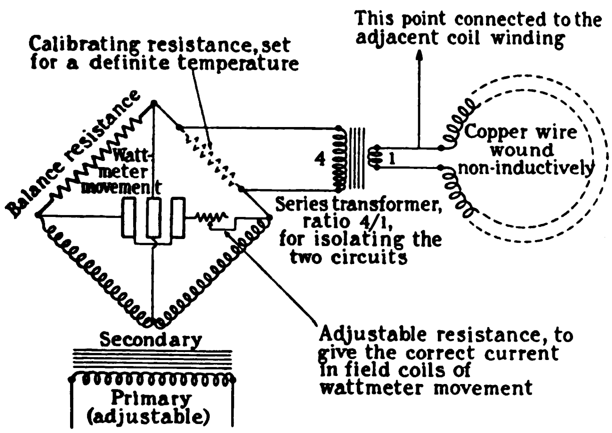

FIG. E.

three-wattmeter methods, provided suitable instruments and precautions are taken. The measurement of losses direct in the line is the safest procedure, notwithstanding calibration curves of instrument transformers. Cases do arise at times where a series transformer is essential for current values and also for safety, and in these cases precision instruments should be used and also two readings with reversed polarity, the average being taken. By studying the following figures it will be appreciated that series transformers may result in erroneous readings :—

Power factor	Error in phase angle	Error in measurements
		per cent
0·1045	30′	+ 7·7
0·2079	30′	+ 3·85
0·1045	1°	+ 15·4
0·2079	1°	+ 7·7

The method used for obtaining frequency readings depends on the size of the test plant. If the plant is small and the generators are close to the transformer under test a tachometer will probably give satisfaction. If the plant is large, however, and the machines are some distance away, then some distant-reading device is advisable to correct the frequency with load. The question of form factor has already been dealt with in reply to Mr. Richards. Mr. Bloome suggests that an ohmmeter is a satisfactory instrument for resistance measurements. We do not agree, however, as such instruments are affected by the unstable nature of the interlinked magnetic and electrical circuits, and time constants are almost impossible. For cold-resistance measurements the ohmmeter may be permissible but is not recommended, whilst for hot resistance where the circuit characteristics are continually changing it is practically inadmissible. The time required to obtain resistance measurements depends on the size and condition of the transformer under test; we do not state any limit but merely that the first reading should not be later than 3 minutes after shut-down. For pressure-testing, a motor-generator set is essential for true testing, even if an induction regulator be used; for the frequency of the test pressure should not be lower than that for which the transformer under test is designed.

Prof. MacGregor-Morris refers to crest voltmeters and bushing capacities. The following table will probably be a guide, though different makes and designs of bushings have different capacities:—

Bushing voltage	Capacity	Charging current for full-wave rectification
volts	μF	mA
500 000	approx. 0·000226	approx. 35·5
150 000	approx. 0·00022	approx. 10·35
110 000	approx. 0·00021	approx. 7·25
75 000	approx. 0·000138	approx. 3·25
36 000	approx. 0·000123	approx. 1·39

Further information on the above can be obtained by reference to the *Electric Journal* (1925, vol. 22, p. 571). We are very interested in Prof. Morris's remarks regarding experimental work on high-voltage measurement, using a neon lamp as detector or indicator, which is being carried out in his laboratories. The scheme seems to have possibilities, and further tests will probably perfect such a method of measurement.

Mr. Robertson refers to the open circuit of the grids in the crest voltmeter diagrams. It is fully explained in the paper on page 526. Three-electrode valves are used because they are easy of replacement, being commonly used in wireless work. If the grid is connected to either the filament or plate circuit the valve impedance is reduced. Lower readings are more accurate, but it is the higher readings that are required together with valve safety, i.e. a higher impedance, therefore on the instruments which we have in use—three in number—the grids are left insulated. We agree with Mr. Robertson's closing remarks.

Mr. Ockenden questions the possibility of obtaining a zero reading on the wattmeter movement used in the resistance ratiometer. There are, of course, limits of ratio to which the accuracy extends, but within the limits for which the apparatus is designed there is a

zero reading provided the ratios correspond. The method suggested by Mr. Ockenden is, of course, simple and accurate to a degree, but as it is a direct-reading instrument the same accuracy cannot be relied upon, for obvious reasons. For further sensitivity and to eliminate possible phase-angle errors as suggested, the authors have devised a thermionic valve balance to replace the wattmeter movement. This measures, in reality, the out-of-balance current flowing. Being a null method and also a polarized one, one can see at a glance whether the ratio is + or −. This method is shown in Fig. F, and we are now using, with satisfactory results, apparatus on the same principle in place of the wattmeter movement. With reference to this speaker's remarks relating to series transformers and static voltmeters, we still adhere to the statements in the paper. The 300 000-volt static voltmeter can be used, but its readings are liable to serious fluctuation depending on position, atmospheric condition, etc., and usually its readings are low.

Mr. Lacey questions the accuracy of the explanation under three-phase core-type transformers. We fail to

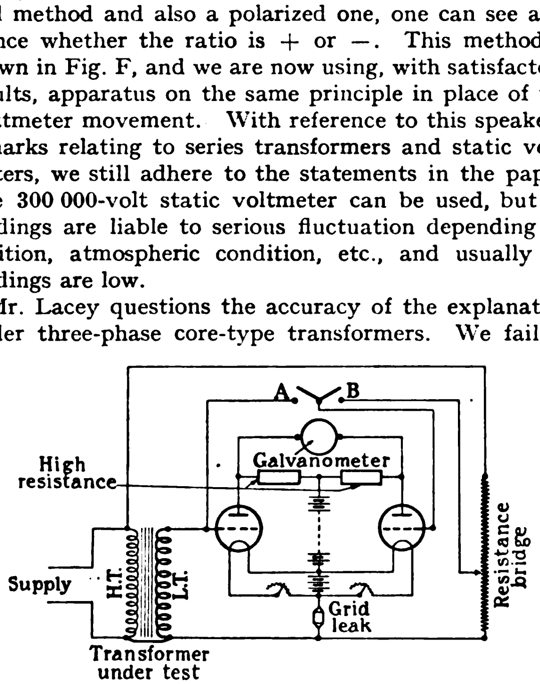

FIG. F.

see any error in our explanation however the transformer is connected, for it is based on actual physical conditions that cannot change. If Mr. Lacey had drawn a vector diagram to explain or illustrate other possibilities we think that he would reverse his decision.

Mr. Holbrook agrees with us on three-phase measurements and he points out the necessity for delta connection to be made when measuring losses. We agree, and especially is it necessary if three-phase shell-type transformers are in question. We are interested in Mr. Holbrook's method of load running, and should have been pleased if a diagram of the same had been included. The only objection that we see in this method is the capital expense involved in having to provide a phase-shifter and induction regulator. It means more auxiliary apparatus and probably two or three different sets and ratios, together with extra losses and therefore increased test charges.

Bristol Discussion.

In reply to Mr. Allan, several rough tests can be made on a defective transformer on site, depending on the voltage ratio and characteristics of the transformers. Megger tests might first be taken between windings, and between windings and the core, and if this gives no indication a useful test may be made by connecting the main supply across the two windings in series through a water resistance, or other means of limiting the current. Short-circuits will be indicated by excess current in the mains, and, if the cover is removed, bubbles and smoke will be detected rising through the oil. Some such test will generally indicate the trouble to be looked for when opening up. The conditions most conducive to the production of sludge in transformer oil are indicated by the standard tests on oil for sludge deposits. This is carried out by passing a current of air through the oil for 45 hours with the oil maintained at a temperature of 150° C. in the presence of bare metallic copper. Thus free air surfaces and high temperatures, together with bare copper, increase the sludging propensity of the oil. Periodical filtration of the oil reduces the risk of solidified sludging, especially when the oil is taken from the bottom of the tank and filtered into the top again. We agree that forced oil circulation is generally recommended, as the cooling device then becomes a separately controlled unit with oil under pressure, and so reduces the risk of water leaking into the oil; also the temperature of a force-cooled unit is more uniform and hot spots are less likely to be present.

In reply to Mr. Davies the sphere-gap functions on the maximum value of the a.c. voltage, although for convenience the gap is calibrated on R.M.S. values. Comparing d.c. and a.c. values, the d.c. flash-over voltage will correspond to $\sqrt{2} \times$ R.M.S. a.c. volts for sine wave only. To estimate this ratio for various wave-forms it would be necessary first to obtain the amplitude factor of the a.c. wave. Thus, amplitude factor = (maximum value/R.M.S. value). Mr. Davies does not indicate the size of the machine used for testing the 50-cycle 50 kVA three-phase transformer; as, unless this output was very small compared with the magnetizing kVA, it is improbable that form factor could account for such a difference. A 15 per cent decrease would represent a form factor of 1·22, a highly improbable figure for such a small transformer unless the wave-form of the machine on open circuit was very poor.

We would refer Mr. Weaver to our reply below to Mr. Williams in the Newcastle discussion with reference to surge tests. These tests are very indefinite and are not yet standard. Consumers can usually so arrange their cable system that such surges are negligible.

In reply to Mr. Chamen, the condition of a transformer can usually be judged by the state and amount of sludge in the oil; and, as filtration has now become an easy operation, were commend that each transformer be so dealt with at least every 18 months. Centrifugal separators of small size are now available, and these can be arranged to operate without removing the transformer from site. Oil is the only commercially successful cooling and insulating medium so far in use for transformers. Air-cooled (dry) transformers are in use up to 500 kVA and 10 000 volts, but for higher voltages and sizes oil is in general use, as the cost of large dry transformers would be prohibitive.

Experiments have been made by filling the upper reaches of the transformer tank with inert gases, as Prof. Robertson suggests. The American Westinghouse Co. have put on the market such a product in which the upper reaches of the tank are filled with an inert

gas and a breather attachment is fitted so that displaced gas due to breathing is replaced on cooling by chemical action in the breather.

With reference to Mr. Lewis's remarks, there are, in general, no special tests called for on transformers for operating in tropical climates. Special temperature-rises are usually specified and corrections made for special air temperatures and barometric pressures. Structural points have to be considered due to sudden changes of air temperatures, and usually these take the form of breathers or expansion chambers.

We would refer Mr. Bache to our remarks in reply to Mr. Richards, which cover the point he raises.

We agree with Mr. Ogden that periodic tests on site are a good insurance; the condition of the transformer can be gauged from such tests. Our experience is that transformer oil is quite satisfactory after filtration with modern filters. Centrifugal separators tend to drive off the lighter constituents of the oil, but no great change has been observed in its sludging value or electric strength. We cannot tell Mr. Ogden any solvent for sludge, which can only be wholly removed by stripping the transformer, but the major portion can be removed by a jet of oil at high pressure.

We would refer Mr. Hodge to our replies to previous speakers on this point, but would add that filtration while transformers are in service must be done with care. Large settling tanks are necessary for de-aerating the oil.

In reply to Mr. Wheeler, sludge in oil tends to accelerate sludging action, and so should be removed before filling transformers with new oil.

In reply to Mr. Nairn, we are unaware of any agreement on standard polarity, but we believe that it is under consideration at the present time by the British Engineering Standards Association.

Newcastle Discussion.

Mr. Williams refers to iron-loss errors. We agree that his assumption is now correct and that probably the error or low-loss measurement was due to the low kVA rating of the machine supplying the load, together with the single-phase loading of a three-phase machine. We note Mr. Williams's agreement with our method of measuring the ambient temperature. We actually immerse permanently a thermometer in a large glass bottle of transformer oil, which, being transparent, allows the temperature to be read easily without moving the thermometer or container. Mr. Williams has referred to hot-spot temperatures. This point has already been fully replied to and we would refer him to our reply to Mr. Richards in the London discussion. Dielectric-loss tests interest Mr. Williams, but we feel that they are as yet far from being accurate and cannot be called standard tests, and they have therefore not been referred to in detail. Much remains to be done in this connection and we hope to be able to continue tests on this subject and so add a little to the now scanty information. No reference is made to the testing of tanks or terminals, for these are not transformers but only auxiliaries and are tested in their respective manufacturing departments or factories. Mr. Williams's experience of pressure-rises when testing transformers some years ago was very common, but with the use of modern voltage-measuring appliances such errors do not now occur. Mr. Williams regrets that short-circuit tests have not been detailed. Such tests cannot possibly come within the scope of main commercial testing. Plant for such tests would be prohibitive and they could only be made on the mains or generators of large power supplies on account of the large kVA required. Surge testing is also referred to, and again we must submit that at present this does not in Great Britain constitute a standard test. Such tests are quoted in the V.D.E. rules up to a 60-kV rating for transformers. Tests of a similar nature are also carried out in Switzerland by Messrs. Brown, Boveri, and an interesting article on the subject will be found in the *Brown Boveri Review* for March 1925 (vol. 12, p. 47).

Mr. Maccall refers to the compensating coil of the low-power-factor wattmeter and suggests its elimination. The manufacturers of the instrument guarantee an accuracy of 0·1 per cent at 0·2 power factor with the compensating device, and this is quite satisfactory for commercial testing. The compensating coil is one of low inductance added to the field coils of the wattmeter to compensate for the current taken by the pressure coils of the instrument. With reference to the explanation in connection with Fig. 11, the terms "main flux" and "return flux" are used to clarify as far as possible the explanation and the relation of the reluctances to the return flux. In other words it is treated, as suggested, in component parts. Mr. Maccall's diagram (Fig. A) and explanation are interesting, but lead to the same conclusions and results as those in the paper. Whether the one method or the other is easier to follow depends to a great extent on the theoretical reasoning of the reader.

Manchester Discussion.

Mr. Churcher in his remarks on ratio measurement questions the meaning which we attach to ratio measurement. We intend to convey the idea that the ratio of the turns is to be measured accurately, and that is what is attained by the methods suggested in the paper. The full voltage ratio on no load and full load is, or should be, the designer's problem. The arrangement of coil design, the structure and dimensions of the core, and the flux densities to which the core is subjected, all influence the voltage ratio, more or less. In general, the ratios of the voltages and the number of turns are practically the same, and it is only in the case of extra-high-tension windings and high-reactance windings that a variation of ratio is apparent to any extent. Mr. Churcher takes us to task on our correction of iron-loss measurement for form factor. We know fully the reason for the errors to be corrected, but up to the present no satisfactory means have been available for making that correction on a commercial test-bed. Mr. Churcher suggests that the correction would be more accurate if the loss were measured on a mean voltmeter and the result corrected by adjusting the eddy-current component in proportion to the square of the induction. This method will give the same result as ours, which is dependent on the hysteresis exponent. We suggest first that

there is no "mean voltmeter" available except that which we have designed and which we term the "form-factor meter"; and secondly, that this method requires two corrections, one for voltage and one for eddy-current loss, whilst our method only requires one correction. Both methods require a separation of the losses curve and both require the same total percentage correction, though part of Mr. Churcher's correction is covered by the mean voltmeter or form-factor meter. Mr. Churcher has also queried the exponent used, namely 1·6, and so do we on page 514, col. 1, of the paper. The exponent used in the paper is Steinmetz's original figure and gave satisfactory results, but if there is any variation of this figure for different induction values, such figures could be used. The exponent of 1·6 is that obtained on numerous test samples at inductions of the same value as those used in transformer design. Further proof that this figure is approximately correct can be seen by studying the figures given in Table 4 on page 515. We agree that iron-loss voltmeters are not necessary where a good form-factor meter is available. With reference to the measurement of losses in magnetic shunts, we state in the paper that they are inseparable by any known test method, and to this statement we still adhere, for Mr. Churcher's suggestion resolves itself into a calculation.

With reference to Mr. Norris's remarks on impregnation, we include transformer windings which are varnish-treated and also those which are oil-impregnated; for drying out finally is essential in connection with both types of winding. We do not state that 11 000 volts is the limit for drying out without vacuum, but we give this voltage as a manufacturing limit where time and production are the limiting factors. Mr. Norris considers a 28-in. vacuum poor for high-voltage transformers. Probably he thinks that he is getting a perfect vacuum, but we suggest that a perfect vacuum is hardly possible, especially with varnish-impregnated coils. The vacuum will naturally depend on the atmospheric pressure at the time, the nature of the contents of the chamber under vacuum, the size of the pump and the container. We are quite satisfied with 28 inches, even for the highest-voltage transformer manufactured, for with this vacuum and a temperature of 75 to 80° C. any moisture present will be readily vaporized and extracted. Air drying is used for small transformers and in small manufacturing concerns, but where production is vital more up-to-date methods are employed. We have stated that a single insulation-resistance value obtained by means of a megger is of no value but is a guide when the transformer is hot, for if the transformer is damp the insulation resistance will fall rapidly when it is heated up. The insulation characteristics for very high-voltage fully-insulated windings are difficult to obtain, as stated by Mr. Norris, and in such cases experience is the only guide, dependent on the quantity of insulation embodied in the structure, which we can recommend. The condenser method suggested by Mr. Norris was tried by us some two years ago but with very indifferent results, and we therefore did not consider such a suggestion to be a practical possibility. Mr. Norris discusses the iron-loss correction; this has already been fully dealt with in our replies to Mr. Richards and Mr. Churcher. Mr. Norris suggests that our corrections for high-voltage transformers will give wrong dielectric losses. He quotes 300- and 400-kV transformers, but these are only special cases. The highest service voltage transformer made in this country is for only 136 kV. We agree that dielectric losses will have to be considered with high-voltage work, but we suggest they are a very small percentage of the no-load losses and so do not affect to any great extent our correction for form factor. Methods for separating dielectric loss from iron losses are not yet fully developed and provide a large field for future investigation. Mr. Norris has referred to resistance-measurements, and we would refer him to our reply to Mr. Richards and Mr. Melsom.

Mr. Carr refers to possible inaccuracies in the resistance ratiometer, and we would refer him to our remarks on the subject in reply to Mr. Ockenden in the London discussion. Iron-loss voltmeters and mean voltmeters are also discussed in our reply to Mr. Churcher. Resistance measurements have also been dealt with in our reply to Mr. Melsom.

Mr. Diggle does not see the necessity for the wattmeter movement. It is provided to enable one to see at a glance if the ratio is in error in a + or − direction. Further remarks on this point will be found in our reply to Mr. Ockenden. Further, the instrument suggested is altogether too insensitive. With reference to the separation of eddy-current losses from the total load loss, Mr. Diggle questions the square law of adjustment. If the windings are efficiently designed with conductors having reasonable section the square law for eddy currents holds good; if, however, abnormal sections are used we agree that the skin effect comes in and the index figure will be different, depending on the section. The question of iron loss has already been dealt with in our replies to several speakers, and further comment is unnecessary. On the question of temperature-runs on single transformers, we maintain that our statement is correct. As Mr. Diggle states, approximate load-runs can be carried out on single-phase core-type transformers if the leg-windings are balanced and treated as two single-phase transformers. High internal reactance will often result in these temporary connections, so that the load loss must be measured and full-load current must not be circulated or heavy losses will result and high temperatures be obtained. Over-potential tests are mentioned and superimposition is discussed, and a badly designed generator is suggested as an alternative. We submit that it would be waste of money to build a special bad-wave generator when the requirements can be obtained in simpler ways with standard apparatus which can be used for other test purposes. Mr. Diggle points out the irregularity of the figures in Table 2 at 300 and 280 volts; we agree that his assumption is probably correct and that the errors have occurred in observation.

Mr. Philip refers to three-phase core-type iron-loss measurements. We agree that upon the phase rotation depends whether the phase A or C is the negative reading; this is clearly seen if Fig. 11 is examined. We have not disregarded anything in our explanation of Fig. 11, for it is all bound up together. The return flux is quoted to show the effect of the reluctance of the

paths, and this in turn affects the magnetizing current. The oil-test values quoted in the paper are those used in our testing department, and no transformer oil is considered satisfactory unless it reaches the figure shown.

Mr. Hill stresses the point of test-hands having a scientific interest in their work. With this statement we agree. The only way to maintain this interest is to have test-hands with average technical ability controlled by a highly technical supervisor. Further, test-hands should be given every assistance by the designers, receiving full information of the tests required. Temperature measurements when taking copper or load losses are essential for accurate corrections to be made to the basic temperature at which the transformer is guaranteed. Resistance measurements appear easy to obtain, but in practice they are most difficult. This point has been raised by Mr. Richards and has been dealt with in our reply to his remarks. We agree with Mr. Hill's remarks regarding over-potential testing, and feel that some definite time-limit of high-frequency tests should be standardized and incorporated in the B.E.S.A. specification.

Mr. Ellis refers to air-drying for very large and high-voltage units and states that it is in use in America. We agree that it can be used satisfactorily, but from a production point of view it is not recommended as a shop or manufacturing process. This method is more adaptable to erection work where final drying after shipment is required. Accuracy of testing is referred to and we wish to state that we refer to the accuracy of the actual tests on the completed unit and not to the accuracy of the tests as compared with calculated figures. The diagrams given by Mr. Ellis show the difficulty which the engineer has in arriving at basic loss figures, and illustrate the possibility of accurate testing giving high or low losses when compared with estimated figures. The time taken to attain full-load temperature can be roughly gauged from the following values for self-cooled transformers:—

Up to	10 kVA,	50 periods	8–9 hours
	50 ,,	,,	9–10 ,,
	100 ,,	,,	10–11 ,,
	250 ,,	,,	11–12 ,,
	500 ,,	,,	12–13 ,,
	1 000 ,,	,,	13–14 ,,
	2 000 ,,	,,	14–16 ,,
	3 000 ,,	,,	16–18 ,,
	5 000 ,,	,,	18–20 ,,

The time required for the load-run maximum temperature can be reduced by starting up the transformers in hot oil or by starting with a 25 per cent overload for a period. The period of overload is limited by the possible hot-spot temperatures. If the temperature-rise is estimated at 50° C., then the overload can be maintained with safety until the transformer oil temperature reaches approximately 60 per cent of the final expected temperature-rise. If this period of time is carefully adhered to, no damage due to internal heating should result from an initial overload. Mr. Ellis, like Mr. Hill, refers to over-potential tests at high frequencies and we would refer him to our remarks in reply to Mr. Hill.

Mr. Longbottom asks for information on temperatures under vacuum. We gauge the temperature of units drying out under vacuum by distant-reading recording thermometers. The actual temperature of any unit is then obtained by a correction based on exhaustive tests taken, giving the distribution of heat in the chamber under vacuum. Mr. Longbottom agrees with our recommended method of ratio measurement. On the question of polarity the subtractive and additive method is quite in order, but high ratios and fluctuating voltage-supplies make it difficult to obtain wholly satisfactory results, whilst it is also not positive for three-phase measurements. We have no definite apparatus to suggest for three-phase polarity. With reference to the d.c. method, we do not suggest it but state that it is a means that can be used for obtaining polarity. We understand that it is almost universally used in the States. Methods of three-phase loss measurement are referred to. We claim that either method is equally accurate, and we use the method which is most convenient and suitable to the transformer under test. For fluctuating voltages we recommend in the paper an additional voltmeter for checking and maintaining the voltage constant during the test. Reference is made to load-runs on single, single-phase transformers; this has already been dealt with in our reply to Mr. Diggle. Mr. Longbottom comments on our recommendation of a column of water as a high resistance in a pressure test-circuit. Whilst a column of stationary water does behave in the manner suggested at times, yet the resistance of running water should overcome the difficulty. He also refers to the crest-voltmeter grid connections, and we would refer him to our reply to Mr. Robertson.

Mr. Peattie agrees with us in insisting on the necessity for elementary precautions. The elaborate checking scheme quoted is very interesting and shows the care which some manufacturers deem necessary. The descriptive explanation of the three-phase iron-loss measurement is of interest and will probably clarify the phenomenon to many who would otherwise be in difficulties. We would refer Mr. Peattie to our replies to several speakers on this point. We agree with Mr. Peattie that heat-distribution tests in transformer units should be investigated on typical examples of various constructions. Such tests are usually carried out by large manufacturers before putting forward any particular line of apparatus. For very large units such a course is financially impossible, and here it is necessary to base one's calculation on similar, though smaller, units. If the relation between maximum temperature and oil (or average) temperature is generally known for any particular type of construction, then we submit that Mr. Peattie's reasoning is quite sound and that oil temperatures and increase-in-resistance measurements should give safe evidence for judging the safety of the unit under full-load service conditions.

NEW METHODS OF IMPROVING THE SYNCHRONIZING TORQUE AND WEIGHT EFFICIENCY OF SELF-EXCITED SYNCHRONOUS INDUCTION MOTORS.*

By VALÈRE A. FYNN, Member.

(*Paper first received 24th April, and in final form 28th August, 1925.*)

SUMMARY.

Polyphase self-excited synchronous induction motors, including the latest types, are analysed with special reference to weight efficiency, conversion efficiency, and configuration of synchronizing torque. It is shown that the weight efficiency of such machines is low compared with that of polyphase asynchronous motors, because the secondary must be designed to carry polyphase load currents as well as unidirectional load and exciting currents. The alternating currents must be carried in a polyphase winding, the unidirectional currents in a single-phase winding. Although the latter may be a part of the former, it nevertheless follows that it is practically impossible to make the maximum synchronous torque of a given frame equal to the maximum asynchronous torque of the same frame. It is further pointed out that, even with a unidirectional and pulsating synchronizing torque, such motors do not run asynchronously with a sufficiently uniform peripheral speed of the revolving member to permit of the general utilization of their asynchronous overload capacity.

To overcome these drawbacks the author has conceived the idea of providing self-excited synchronous induction motors with a constant synchronizing torque, to run the machines synchronously from no load to a little beyond full load, and to run them asynchronously for all higher loads. The manner in which a constant synchronizing torque is produced is explained in detail and it is shown how the somewhat conflicting requirements of synchronizing torque and acceptable compounding characteristic are harmonized. Several embodiments of the resulting new motors are described, their synchronous performance being analysed by means of the circle diagram.

INTRODUCTION.

No synchronous induction motor, either self-excited or separately excited, can be manufactured at a sufficiently low figure and be successfully utilized in practice unless :—

(1) Its weight efficiency and conversion efficiency are high.
(2) It performs satisfactorily at starting.
(3) It synchronizes positively, without hunting and with a torque approximately equal to the maximum synchronous torque.
(4) It is automatically compounded so as to operate with a high power factor from no load to maximum load and, in particular, without ever taking an excessive leading current.
(5) It is capable of carrying overloads at constant or practically constant peripheral rotor speeds when operating as an asynchronous motor beyond its synchronous range.

The weight and conversion efficiencies are, of course, closely related and a figure as to one has little significance unless accompanied by the corresponding value of the other. The weight efficiency largely depends on the length of the air-gap and on whether or not the non-synchronous peripheral speed of the rotor is sufficiently uniform to permit of torque-demands exceeding the maximum synchronous torque being satisfactorily handled asynchronously.

It is quite easy to secure a satisfactory starting performance, and short air-gaps are of considerable assistance in this connection. Automatic compounding, i.e. automatic control of the quadrature component of the load current, is necessary in all machines which are to operate without constant attendance, and is imperative in the case of synchronous induction motors with standard induction-motor air-gap. Rationally-designed synchronous induction motors with short air-gap generally have a maximum synchronous torque amounting to some 60 per cent of the maximum asynchronous torque.

The configuration and magnitude of the synchronizing torque determine not only the quality of the synchronizing performance but whether or not the asynchronous overload capacity of the machine can be utilized. The importance of the configuration and magnitude of the synchronizing torque of synchronous induction motors cannot be exaggerated.

The author soon realized these conditions and directed his principal efforts to the configuration of the synchronizing torque. The first synchronous induction motors possessed alternating synchronizing torques of slip frequency or double slip frequency and equal positive and negative maxima. Whilst an alternating synchronizing torque will synchronize a motor it will not always do so without hunting, and this practically precludes the use of the machine as an asynchronous motor for any but the starting stage. The author's undirectional and pulsating synchronizing torque * eliminated the negative wave of the old synchronizing torque and made it easily possible to make the amplitude of the new pulsating torque equal to the maximum synchronous

* The Papers Committee invite written communications (with a view to publication in the *Journal* if approved by the Committee) on papers published in the *Journal* without being read at a meeting. Communications should reach the Secretary of the Institution not later than one month after publication of the paper to which they relate.

* See paper entitled "A New Self-Excited Synchronous Induction Motor," presented at the Spring Convention of the American Institute of Electrical Engineers, Birmingham, Alabama, April 7, 1924; also "Another New Self Excited Synchronous Induction Motor," presented at the Mid-winter Convention of the Institute, New York, February 9, 1925.

torque in machines with induction-motor air-gap. As a result his new synchronous induction motors are quite free from hunting during the synchronizing period, but asynchronous operation under overloads is still unsatisfactory, because so soon as the motor lapses into asynchronism the pulsating torque reappears. There is no danger of the motor coming to a stop, as is the case when the synchronizing torque is purely alternating, but the speed of the motor varies or pulsates continuously in an attempt to adjust the resultant torque, i.e. the sum of the pulsating synchronizing and of the induction motor torque, to the torque demand.

Having solved the problem of synchronizing and also of compounding (see the papers already referred to),

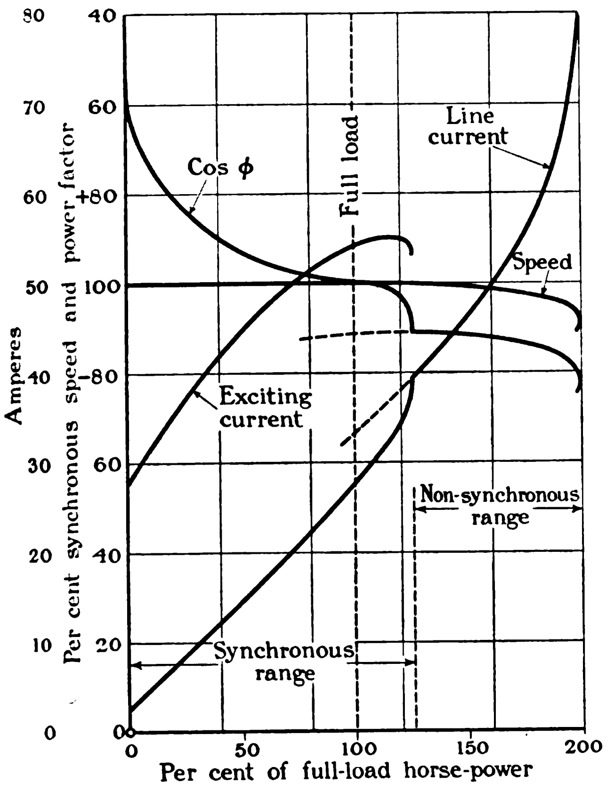

Fig. 1.—Character of performance curves of new self-excited synchronous induction motors (Fynn form 5).

the author addressed himself to the problem of increasing the weight efficiency of these machines. It occurred to him that the most natural way to achieve this was to render available for practical use the very large asynchronous overload capacity of such motors. If this could be done, then the machine could be designed for a maximum synchronous torque equal to about 60 per cent of the maximum asynchronous torque, and so rated as to cause the full-load torque to fall within a few per cent of the maximum synchronous torque. Under these conditions an overload would soon bring the motor to non-synchronous operation, and an overload capacity of some 100 per cent would be available. The character of the performance curves of such a motor is shown in Fig. 1.

Self-Excited Synchronous Induction Motor with Constant Synchronizing Torque.

The solution of the problem just outlined must be obvious to anyone who has read the author's Birmingham paper * and seen Fig. 37 therein. It amounts to producing two unidirectional and pulsating torques and displacing them by a quarter period, or producing three such torques and displacing them by one-third of a

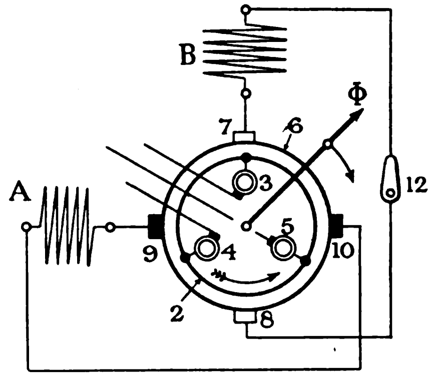

Fig. 2.—Elements and connections necessary for the production of a constant synchronizing torque in a self-excited synchronous induction motor.

period, and so on. Broadly speaking, it amounts to producing a polyphase synchronizing torque.

One way of producing a constant synchronizing torque in a polyphase synchronous induction motor is shown in Fig. 2. The rotor carries a primary winding 2 adapted for connection to a polyphase supply by means of the slip-rings 3, 4, 5, and a commuted winding 6 with which co-operates a two-phase arrangement of brushes 7, 8

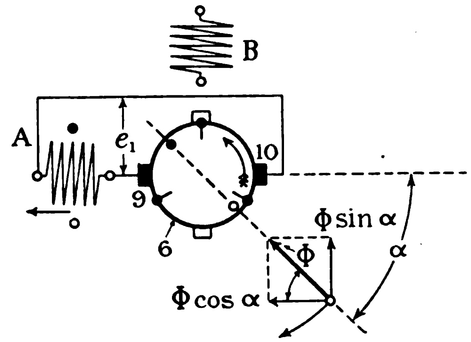

Fig. 3.—Showing how first component of constant synchronizing torque is produced.

and 9, 10. In order to eliminate all doubt as to the location of brushes with reference to the rotor and stator windings, they are supposed to be resting directly on the commuted winding 6. In practice a commutator would, of course, be used. The same clarifying assumption is made throughout this paper. The stator carries two identical windings A and B, displaced by 90 electrical degrees. The brushes 7, 8, are located in the axis of B and connected to it as shown. The brushes 9, 10, are located in the axis A and connected to this winding as shown.

* See footnote on previous page, col. 2.

Connecting the slip-rings to a polyphase supply produces a flux Φ revolving synchronously with respect to the rotor. If the connections are such that Φ revolves clockwise, as indicated by the curved arrow attached to the vector representing Φ in Fig. 2, then the rotor will revolve in a counter-clockwise direction. This revolution is due to the induction motor torque produced by the interaction between Φ and the currents generated in A and B by the relative motion between these windings and the revolving flux Φ. These secondary currents close through the brushes and the commuted winding. This induction motor torque starts the motor in the usual satisfactory manner and brings it near to synchronism. As the rotor speed

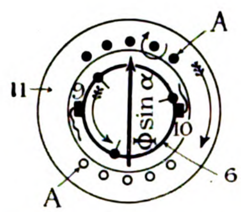

FIG. 4.—Diagram for determining direction of synchronizing torque produced by elements of Fig. 3 or of Fig. 6.

increases, that of Φ diminishes. At synchronism, Φ is at a standstill.

Very near synchronism the machine needs an additional torque over and above the induction motor torque which becomes zero at synchronism, in order to bring its rotor into synchronism. This additional torque is now known as the synchronizing torque; in Fig. 2 it is absolutely constant, as will be shown with the help of the following figures.

Consider what occurs near synchronism, taking one secondary winding at a time. In Fig. 3 the primary winding 2 is, for the sake of simplicity, supposed to

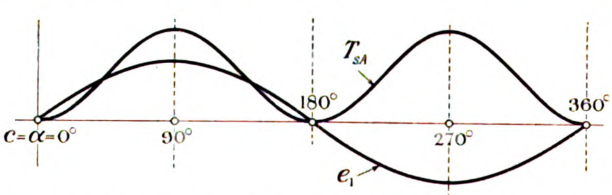

FIG. 5.—Configuration and phase of component synchronizing torque produced by elements of Fig. 3.

be combined with the commuted winding 6 and the slip-rings are not shown. B is disconnected, the rotor is supposed to revolve counter-clockwise at nearly synchronous speed, and Φ clockwise at slip speed—as would actually be the case in Fig. 2 just prior to synchronization.

Beginning to count time when Φ coincides with the axis of the brushes 9, 10, and is directed from right to left, consider the instant when Φ has travelled through α degrees. Because of the counter-clockwise rotation of the winding 6, the direction of the voltage generated therein by Φ is as indicated by the small empty and full circles. The empty circles indicate throughout an upwardly directed voltage or current, and the full circles the opposite or downward direction of either. The voltage e_1 appearing at the brushes 9, 10, sends a *conduced* current through A, distributed as shown by the small circles placed alongside of A, and produces a magnetization directed from right to left as indicated by the straight arrow. Let this direction of e_1 be positive. Because e_1 is of slip frequency the current for which it is responsible in A is practically in phase with e_1. The ampere-turns *conduced* into A, as against the ampere-turns *generated in* A by the relative motion between Φ and A, can and do produce torque in co-operation with Φ. This torque is independent of the induction motor torque superposed thereon and is here referred to as the synchronizing torque.

The magnitude of the synchronizing torque is always proportional to the number of ampere-turns in A and the concurrent magnitude of that component of Φ which is at right angles to the axis of A. These ampere-turns are clearly proportional to e_1, which is proportional to sin α. The effective component of Φ in this case is $\Phi \sin \alpha$, and the synchronizing torque T_{sA} due to A is therefore proportional to $\Phi \sin^2 \alpha$. It is clearly zero

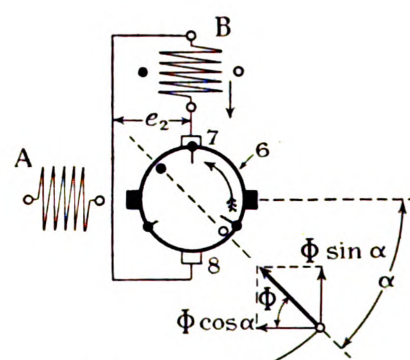

FIG. 6.—Showing how second component of constant synchronizing torque is produced.

for $\alpha = 0°$ and for $\alpha = 180°$, and a maximum for $\alpha = 90°$ and $\alpha = 270°$. The direction of T_{sA} may be determined by the ordinary electromagnetic rules with the help of Fig. 4. Under the conditions of Fig. 3, T_{sA} as exerted on the stator 11 is clockwise, whilst as exerted on the rotor it is counter-clockwise and positive since the rotor revolves counter-clockwise. It is also clear from Fig. 3 that T_{sA} remains positive for all values of α between zero and 180°. For greater values of α the polarity of e_1 reverses as shown in Fig. 5. This reverses the direction of the ampere-turns in A, but the effective component of Φ reverses its direction simultaneously, now pointing down instead of up as in Fig. 3, with the result that T_{sA} remains positive. T_{sA} is plotted in Fig. 5 together with e_1 for all values of α from zero to 360°.

Fig. 6 discloses what goes on simultaneously in so far as the winding B is concerned. For the same displacement α as in Fig. 3 the conduced ampere-turns in B are proportional to e_2, which is proportional to cos α. Let the now prevailing direction of e_2 be referred to as positive. In this case the effective component of Φ, that capable of producing torque with the conduced

ampere-turns in B, is $\Phi \cos \alpha$, and T_{sB} is therefore proportional to $\Phi \cos^2 \alpha$. The direction of T_{sB} can be readily ascertained with the help of a figure such as Fig. 4; it is clearly the same as that of T_{sA} and therefore also positive. It is further evident that T_{sB} is a maximum when T_{sA} is zero, and vice versa, also that T_{sB} remains positive when α exceeds 90°. Both e_2 and T_{sB} are plotted in Fig. 7 in correct relation to α. The resultant synchronizing torque T_s is the vectorial sum of T_{sA} and T_{sB}. It is shown in Fig. 8 and is clearly absolutely constant.

Having secured the desired constant synchronizing torque by means of the arrangement of windings and brushes shown in Fig. 2, the question arises, How will such a machine operate under load? The torque of

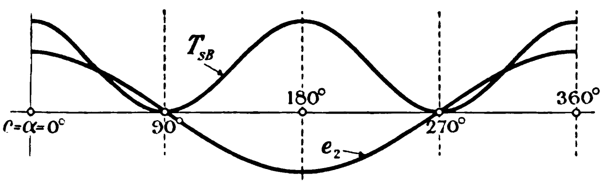

FIG. 7.—Configuration and phase of component synchronizing torque produced by elements of Fig. 6.

the motor depends on the magnitude of the projection of the resultant secondary ampere-turns N_s on the perpendicular to the resultant motor magnetization Φ, and an insight into the operation of the machine under load will be gained when it is known how the magnitude of N_s and its space relation to Φ can and do vary. The magnitude and space location of N_s depend on the magnitude and direction of the ampere-turns in A and B. At synchronism these depend on the brush voltages. The brush voltages e_1 and e_2 depend in turn on the position of the axis of Φ with relation to the axes of the two brush sets 9, 10, and 7, 8.

Referring to Fig. 2 and bearing Figs. 3 and 6 in mind,

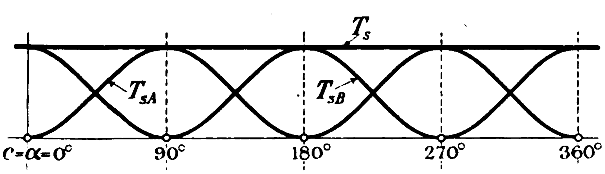

FIG. 8.—Constant synchronizing torque T_s resulting from proper combination of the component torques of Figs. 3 and 6.

when the axis of Φ coincides with that of the brushes 9, 10, and Φ is directed from right to left, the only stator magnetization is that due to B, and the ampere-turns N_B in B are a maximum; N_B lags 90° behind Φ. After Φ has travelled through 90°, the ampere-turns N_A in A are a maximum and those in B are zero; N_A now lags 90° behind Φ. Since the maximum ampere-turns in A are equal to those in B, and since the former vary as the sine while the latter vary as the cosine of any angle at which Φ is inclined to the axis of the brushes 9, 10, it is clear that the vectorial sum N_s of the conduced ampere-turns in A and B must be constant and that its axis must always remain at right angles to that of Φ, irrespective of the space position of Φ. Fig. 9 graphically depicts this condition. When Φ travels clockwise through 360°, N_s also travels clockwise through 360°, always keeping 90° behind Φ. This means that at synchronism the unidirectional ampere-turns on the secondary of Fig. 2 remain constant regardless of the space position of Φ, and that the synchronous torque is constant. Consequently there is but one load for which such a motor will run synchronously; the corresponding value of the primary ampere-turns N_p is shown in Fig. 9.

Nothing short of changing the machine or its constants will disturb the quadrature relation of N_s and Φ at or near synchronism. A departure from synchronism does, however, change the magnitude of N_s. At synchronism no voltage is generated in either A or B. At sub-synchronous speeds the voltages generated in these windings are of the same phase and sign as the respective impressed brush voltages, and the total ampere-turns in A and B increase, being due to the sum of the impressed and generated voltages in each circuit. At super-synchronous speeds the voltages generated in A and B are of opposite sign and now oppose the impressed or conduced brush voltages. As a result the ampere-turns in A and B are reduced. But torque is, in this case, proportional to the vectorial sum of the ampere-turns due to A and B, in other words to N_s.

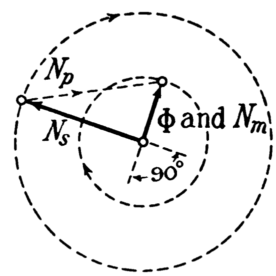

FIG. 9.—Diagram showing operating conditions of the motor of Fig. 2.

If the torque demand is less than the torque which corresponds to the synchronous value of N_s the motor must run super-synchronously at a speed at which N_s is reduced to correspond to the torque demand. If the torque demand is in excess of the torque which corresponds to the synchronous value of N_s, the motor must run sub-synchronously.

The machine of Fig. 2 runs synchronously only at one load and exhibits no compounding or power-factor-controlling characteristic whatever. There are, however, a number of ways in which it can be modified in order to make it operate synchronously under varying load, and to cause it to exhibit a practically useful compounding characteristic without sacrificing its most desirable synchronizing-torque configuration.

The simplest way to cause this motor to operate synchronously is to render one of the stator windings A or B inoperative upon synchronism being reached. This can be done, for instance, by interrupting the circuit of winding B of Fig. 2 by means of the switch 12.

Before determining the synchronous operating characteristic of Fig. 2 with the circuit of B open, it is well to fix upon some likely ratio of $N_{s.max}/N_m$, where N_m represents the ampere-turns required to produce Φ, and to base all comparisons between synchronous operating

characteristics on one and the same ratio of these values. Furthermore, since in dealing with synchronous induction motors one repeatedly passes from asynchronous to synchronous operation, and vice versa, it is as well now to fix our ideas as to the exact interrelations between those factors which control the asynchronous and those which control the synchronous operation of such machines.

In Fig. 10 is a current or ampere-turn vector diagram of a loaded polyphase induction motor. The primary current I lags ϕ degrees behind the terminal voltage E_t, and is the vectorial sum of the magnetizing current I_m and of a current $-I_2$ equal and opposed to the secondary current I_2. The current vectors can also represent ampere-turns and, in case of low densities,

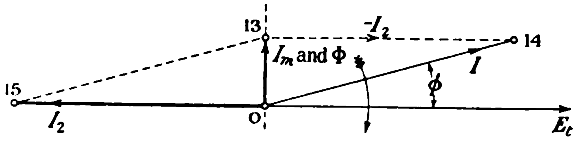

FIG. 10.—Vector diagram of loaded asynchronous motor.

they may stand for the magnetizations or fluxes produced by these ampere-turns. The facts that the flux Φ, the revolving flux produced by the primary, actually lags slightly behind the magnetizing current I_m, that I_2 lags by a little more than 90° behind Φ, and that the phase difference between E_t and I_m is not exactly 90°, have been purposely disregarded as immaterial in connection with the points under investigation in this paper.

If it be desired to reproduce the exact operating conditions of Fig. 10 when the machine passes from asynchronous to synchronous operation, how is the magnitude of the unidirectional magnetization to be chosen? To answer this question it is necessary to remember that so long as the terminal voltage remains

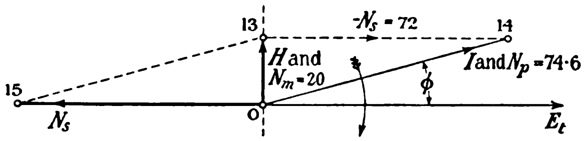

FIG. 11.—Vector diagram of synchronous motor operating at same load and power factor as the asynchronous motor of Fig. 10.

unchanged the magnitude of the resultant motor magnetization must remain the same and retain the same phase relation to that voltage. The resultant magnetization H of the synchronous motor must then be equal in magnitude to and of the same phase as the revolving flux Φ of the asynchronous machine. The primary current I is to remain unaltered and retain the same phase relation to the terminal voltage E_t. The ampere-turns N_p produced by I of the synchronous motor, usually referred to as armature ampere-turns, must therefore be equal to the total primary ampere-turns of the asynchronous machine, and I must lag ϕ degrees behind E_t, as shown in Fig. 11. Now it is known that N_m of the synchronous motor, which determines H, must be the resultant of N_p and N_s, with the result that the unidirectional ampere-turns N_s on the secondary of the synchronous motor must be equal to the ampere-turns produced on the secondary of the asynchronous motor by the secondary load current I_2. The answer to the question propounded at the commencement of this paragraph is therefore: In order to duplicate the asynchronous performance characterized by Fig. 10 after the motor has stepped into synchronism, it is necessary to make the unidirectional ampere-turns of the synchronous motor (usually but inaccurately referred to as " exciting ampere-turns") equal to the secondary load ampere-turns of the asynchronous motor of Fig. 10.

Holding to the simplifying assumptions on which Fig. 10 is based, a few simple relations can be stated, to throw further light on the true functions and magnitude of the unidirectional ampere-turns on the secondary of a synchronous motor. A clear conception of the design limitations, particularly in respect to conversion and weight efficiency of synchronous induction motors, cannot be had without a full comprehension of the true significance of these unidirectional ampere-turns.

In both motors the torque is proportional to that component of the secondary ampere-turns (vector 0–15 in Figs. 10 and 11) which is at right angles to the motor magnetization Φ or H. In the asynchronous machine the phase of this vector changes but little when the load varies from zero to the guaranteed overload, slowly increasing its lag behind Φ. This change in phase is brought about by an increasingly great and permanent departure from the synchronous speed. Its magnitude is determined by the time constant of the secondary. In the synchronous motor this vector may travel through about 90° within the same load limits, its change in phase, really in space position, being brought about by accelerations or decelerations of the revolving member of extremely short duration, in fact by momentary departures from synchronism. With constant unidirectional ampere-turns on the secondary an increase in load increases the lag of N_s behind H.

For a given number of unidirectional ampere-turns N_s on the secondary of a synchronous motor the maximum synchronous torque is available when N_s is at right angles to H, as in Fig. 11. When this occurs I lags behind E_t and $\tan\phi = N_m/N_s$. All of the resultant motor magnetization is supplied by the primary; the secondary carries nothing but load ampere-turns, and N_s is equal to the total load ampere-turns of the motor. Fig. 11 illustrates this limiting case for the synchronous machine. An increase in torque demand causes the motor to lapse into asynchronism, unless N_s is simultaneously increased to a sufficient extent, and this for the reason that for a given value of N_s its projection on the perpendicular to H is a maximum when N_s is itself perpendicular to H.

The unidirectional ampere-turns on the secondary of a synchronous motor are sometimes spoken of as ampere-turns which neutralize the primary working ampere-turns. The author has often followed this practice, but it is thought that it is distinctly misleading. The unidirectional ampere-turns on the secondary of a synchronous motor are the true load ampere-turns on the machine, for they are in the same direction as the load ampere-turns on the secondary of an asynchronous motor,

and replace these when the motor steps from asynchronous to synchronous operation. All or part of these secondary ampere-turns are, as a matter of fact, neutralized by the primary ampere-turns.

When $N_p = N_s$, as in Fig. 12, one half of the resultant motor magnetization H is supplied by N_s, the other half by N_p. The primary current still lags behind the terminal voltage, and the phase angle is given by $\sin\phi = \frac{1}{2} N_m / N_s$.

When the power factor is unity, $N_s = \sqrt{[N_p^2 + N_m^2]}$ and all the resultant motor magnetization is supplied by the unidirectional ampere-turns on the secondary (see Fig. 13).

Even if an automatic regulator is used to control the ampere-turns in the secondary circuit of a syn-

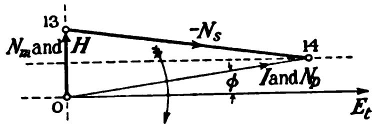

FIG. 12.—Vector diagram of synchronous motor when primary and secondary ampere-turns are equal.

chronous induction motor so as to keep the power factor at unity as long as possible, these ampere-turns will be in excess of the necessary working ampere-turns right down to the point of maximum synchronous torque. Except near the breakdown point they will be equal to the vectorial sum of load and exciting ampere-turns. Any designer, wishing to keep the conversion and weight efficiencies of a polyphase synchronous induction motor operating as a synchronous machine the same as the conversion and weight efficiencies of a corresponding polyphase asynchronous motor, is faced with the very serious difficulty of so distributing the available secondary copper in the secondary windings that they will be capable of carrying, without increased losses or

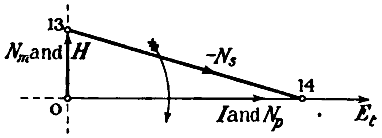

FIG. 13.—Vector diagram of synchronous motor when power factor is unity.

heating, polyphase load ampere-turns for the non-synchronous, and unidirectional load and exciting ampere-turns for the synchronous, operation. The difficulty is enhanced by the facts that the unidirectional ampere-turns must be carried in a single-phase winding, i.e. one having but one axis per pole-pair, that these ampere-turns very greatly exceed the corresponding polyphase ampere-turns at all loads other than the maximum synchronous load, and that the polyphase ampere-turns must be carried in a polyphase winding. This polyphase winding cannot be discarded because it is needed at starting.

It is quite true that the whole or any part of the polyphase winding is available for carrying the unidirectional ampere-turns in synchronous operation, but this relief, whilst most welcome, is not as far-reaching as might at first appear. The reason is that, in practice, a part only of the polyphase winding can be used to carry the unidirectional ampere-turns in synchronous operation. A given number of ampere-turns will produce the maximum number of magnetic lines when the winding is a concentrated one, each turn embracing all the pole area. Distributing the same number of turns over the whole pole requires just twice the number of ampere-turns to produce the same flux. Since, for a given amount of copper, the losses increase with the square of the ampere-turns, it is clear that, in so far as losses are concerned, the concentrated winding is by far the most advantageous, but its cooling facilities are the poorest and its leakage coefficient a maximum. A compromise is clearly indicated. The best that can be done in practice is to use one phase of a two-phase secondary winding, or one or two phases of a three-phase secondary winding, to carry the unidirectional ampere-turns in synchronous operation.

These brief considerations make it quite evident that if the weight of copper on the secondary is not increased the conversion efficiency must suffer, as the increased heating necessitates a reduction in output, and this means that less money can be collected by the maker for the same amount of material. If the weight of copper is increased it necessitates an increase in other material, and means the same amount of money collected for a machine requiring more material.

The author's suggestion is therefore to use practically the same amount of material and thereby limit the maximum synchronous load, but otherwise so to design the machine as to make it possible for it to meet overloads asynchronously. In this way it becomes possible to utilize part of the material on the secondary to the best advantage from the point of view of power factor during normal operation, and to utilize all of this material to the best advantage from the weight-efficiency standpoint during the overload periods.

After this discussion it will be easy to select a reasonable ratio of $N_{s.\,max.}/N_m$ as a basis of comparison for synchronous performances. Suppose that the magnetizing current of a polyphase induction motor is 20 amperes per phase, while its full-load current is 54 amperes with a torque component of 48 amperes; then a synchronous motor built into the frame of this induction motor will show a 50 per cent overload capacity if the ratio of its maximum unidirectional ampere-turns on the secondary, $N_{s.\,max.}$, to the constant ampere-turns, N_m, required for producing H, is as 72 to 20. This is the conservative ratio used hereafter. Fig. 11 applies to a machine embodying this ratio, and shows its theoretical breakdown point or point of maximum synchronous torque.

Turning back to Fig. 2, its inherent *synchronous* performance characteristic with B on open circuit, i.e. when in the form of the motor of Fig. 14, can be rapidly analysed by means of a circle diagram. The machine is self-excited and the exciting voltage e_1 depends on rotor speed, magnitude of H, and angular relation α of axis of H (or of Φ) to the axis of the brushes 9, 10. Speed is synchronous and therefore constant, and, as a first approximation, H may be assumed constant, which makes e_1 proportional to $\sin\alpha$. But e_1 determines the magnitude of N_s for a given number of turns in A and a given

resistance of the circuit comprising A and the brushes 9, 10; consequently N_s is proportional to sin α. The maximum of N_s and the value of H are known; it is also known that sin α, and therefore N_s, are a maximum when H is at right angles to the axis of the brushes 9, 10. In addition, H lags 90° behind the terminal voltage E_t and is always due to the resultant of N_s and N_p. The angular relation c between H and N_s is zero at no load, and 90° at full load. In the case of Fig. 14 the axis of N_s, which must coincide with that of A, coincides with the brush axis, and $c = \alpha$. To acquire information as

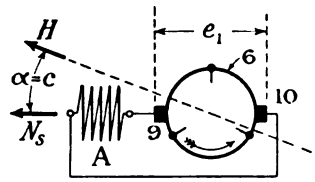

FIG. 14.—Self-excited synchronous induction motor with brush axis coinciding with axis of secondary winding to which brushes are connected (Fynn form 1).

to the conditions under different loads, one may imagine H and E_t stationary in space and displace the brush axis together with the axis of N_s, or vice versa. The former plan is selected because it is more convenient.

In Fig. 15, which is to scale, H is 20 and at right angles to E_t. On the rearward prolongation of E_t the distance 0–16 represents the maximum value of N_s, which is 72. This value of N_s is reached when $\alpha = 90$, and the axis of the brushes 9, 10, therefore coincides with 0–16; at this time I equals 16–13. For the value of α specifically shown in Fig. 15, the value of N_s is 0–15 and that of I is 15–13. The locus for the end of the vector N_s

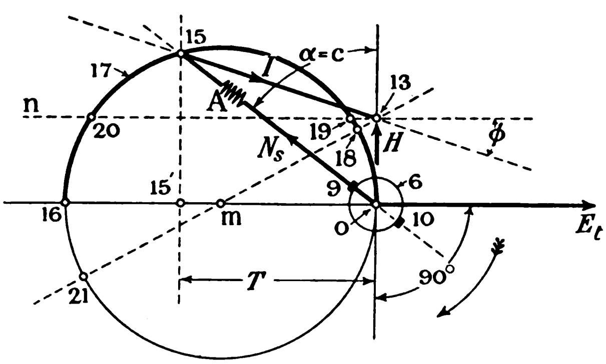

FIG. 15.—Circle diagram for self-excited synchronous induction motor of Fig. 14 running synchronously.

is the circle 17 drawn about the half-way point (m) on the line 0–16 with a radius equal to $\frac{1}{2}N_s$. The torque for any value of N_s is proportional to the projection of N_s on the perpendicular to H. Thus when N_s equals 0–15 the torque is proportional to 0–15′. The direction of the torque is determined by the relative directions of H and of the projection of N_s on the perpendicular to H. The primary current is proportional to the vector 15–13, and the phase angle ϕ between the terminal voltage and primary current is the angle between 15–13 and OE_t or n, where n is a parallel to OE_t drawn through the end 13 of the vector H. The speed is constant.

At no load, H coincides with N_s. In Fig. 15 the brush axis, that of A, and that of N_s are then vertical, $c=0$, $\alpha = 0$, $N_s = 0$, $I = H$, and $\phi = 90°$ lagging. As α increases, I decreases and reaches a minimum when N_s equals 0–18, at which point I is coaxial with a diameter of the locus 17. Thereafter I increases to a maximum, which is reached when N_s equals 0–21. This occurs after α has travelled through an additional 90°. When $\alpha = 180°$ the current I is again equal to H. The phase angle ϕ diminishes very rapidly at first as α increases, and becomes zero, which corresponds to unity power factor, when N_s equals 0–19. Thereafter α becomes positive or leading, reaches a positive maximum when I is tangential to the locus 17, and is back at zero when N_s equals 0–20. For greater values of α the angle ϕ is

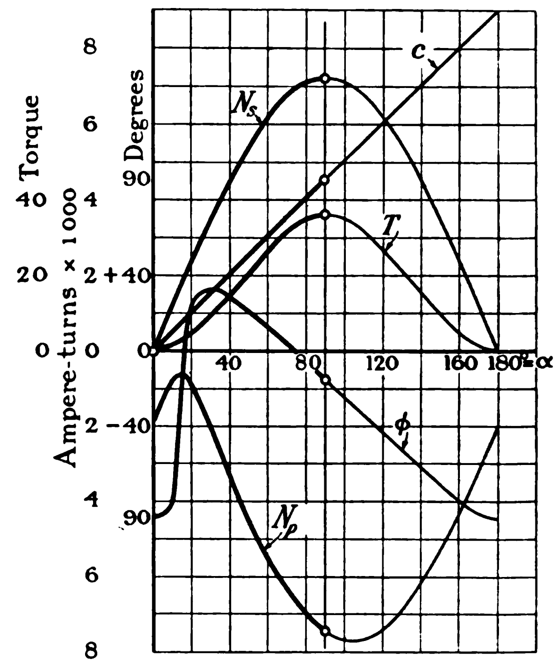

FIG. 16.—Synchronous performance curves of self-excited synchronous induction motor of Fig. 14.

negative or lagging, and goes back to 90° lagging when $\alpha = 180°$. The angle c increases steadily with α. As soon as α exceeds 180° the polarity of e_1, and therefore of N_s, reverses. If the machine synchronizes for any value of α between 0° and 90° when Φ is positive, it will synchronize for any value of α between 180° and 270° when Φ is negative, otherwise the performance is identical and the diagram of Fig. 15 holds for either polarity.

Fig. 16 shows the synchronous performance curves of the motor of Fig. 2 with B circuit open, or of that of Fig. 14, as calculated from the circle diagram Fig. 15. These curves are plotted against α on the basis of the arbitrary assumption made in connection with Fig. 2, that from right to left and from top to bottom are positive. Positive values are plotted above, negative values below, the horizontal.

The torque curve T at once indicates that conditions

become unstable for values of c in excess of 90°. Since c *increases* with increased demand for torque, the motor must break down when c exceeds 90°, for beyond that point the torque diminishes with increasing c. The useful portions of the performance curves of Fig. 16 and of the locus for N_s in Fig. 15 are shown by heavy lines.

The motor of Fig. 14 will operate synchronously from zero to maximum torque and may synchronize on either polarity of Φ. If it synchronizes when Φ is positive it will be because N_s is positive at the time, and the

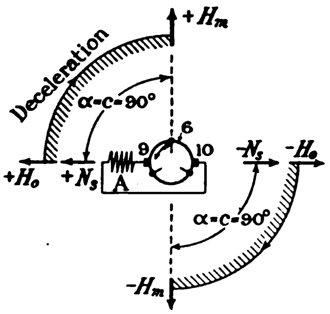

FIG. 17.—Showing synchronous angular relations under varying load of secondary ampere-turns N_s and resultant motor magnetization H for the two possible secondary polarities of motor of Fig. 14.

resultant motor magnetization H will oscillate between position ($+H_0$) for zero torque and position ($+H_m$) for maximum torque, as shown in Fig. 17. If it synchronizes when Φ is negative, H will oscillate between ($-H_0$) and ($-H_m$). In Fig. 17 the primary revolves counter-clockwise; it accelerates upon a reduction of load and decelerates upon an increase in load.

The synchronous performance of the motor of Fig. 14 is not very desirable from the power-factor point of view and the machine is very unstable at fractional loads,

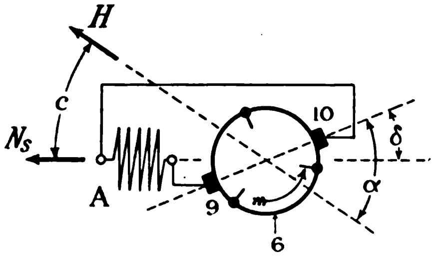

FIG. 18.—Self-excited synchronous induction motor with brush axis displaced from axis of secondary winding to which brushes are connected (Fynn form 1).

a slight change in load at light loads or a small displacement of the brushes, such as may be due to wear, causing wide variations in line current and power factor. In short, the compounding characteristic of this machine is not satisfactory. This can be very simply remedied by displacing the brush axis from that of the secondary winding A, or vice versa. Let the brushes be displaced from the axis of A in the direction of rotation of the primary and by $\delta = 22{\cdot}5°$, as shown in Fig. 18. This angle is chosen because it is a convenient fraction of 90, but any angle of about this magnitude gives good results.

The circle diagram for Fig. 18 is shown in Fig. 19. Let the line 0–16 represent the maximum value of N_s and equal 72. Halve 0–16 and describe the circle 17 about its middle point (m) with a radius $\frac{1}{2}N_s$. When the axis of A coincides with 0–16, that of N_s must also coincide with it. N_s is a maximum when H is at right angles to the brush axis, but according to Fig. 18 the brush axis is displaced by δ degrees from the axis of A against the (in this case) clockwise direction of rotation of the revolving flux set up by the primary. This means that for $N_{s.max.}$ the resultant H must be displaced in like manner from the perpendicular to $N_{s.max.}$. In Fig. 19, H is therefore inclined by $(90 - \delta)$ with respect to the line 0–16 representing $N_{s.max.}$. This fixes the location of E_t, which must be at right angles to and must lead H. The circle 17 is again the locus for N_s.

Fig. 20 shows the performance curves calculated from Fig. 19 and plotted against α. It is to be noted that in Fig. 19 the angles c and α differ by the constant angle δ. For $\alpha = 0$, $N_s = 0$ and the primary current I equals

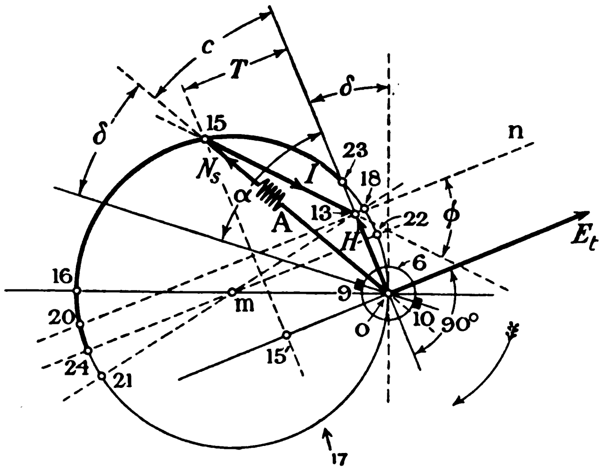

FIG. 19.—Circle diagram for self-excited synchronous induction motor of Fig. 18 running synchronously.

N_m or H. As α increases, I diminishes until N_s equals 0–18. This is one intersection with the locus of that diameter of 17 which passes through 13. Beyond this point I increases, reaching a maximum when N_s equals 0–21, the point 21 being the other intersection of the diameter just referred to with the locus 17. Thereafter I diminishes, becoming again equal to H for $\alpha = 180$. The phase angle ϕ is negative and lags 90° for $\alpha = 0$, increases to 180° lag (or lead) when N_s equals 0–19, decreases to 90° lead when N_s equals 0–23 and to zero when N_s equals 0–20, thereafter gradually increasing back to a 90° lag. Points 19 and 20 are the intersections of n, a parallel to E_t through 13, with the locus 17. The point 19 is not shown because it falls very close to point 18.

Zero torque occurs for $\alpha = 0$ because N_s is then zero, and also for $\alpha = 22{\cdot}5°$ because the axis of A then coincides with that of H. Between these two values of α the torque is negative. As α passes the value of δ the projection of N_s on the perpendicular to H changes sign and the motor torque becomes positive. The maximum positive and negative torques are determined by the two

intersections of the locus 17 with a parallel to E_t drawn through m. Point 24 fixes the value of the maximum positive torque and point 22 that of the maximum negative torque.

The useful parts of the performance curves of Fig. 20 and of the locus for N_s of Fig. 19 are shown in heavy line in these figures.

Fig. 21 corresponds to Fig. 17 and indicates, for either polarity, how H varies in relation to the brush axis and to that of A when the synchronous torque varies from zero to its maximum. It is seen that the range of c is reduced from 90° to 78·75° as compared with Fig. 17; $c = 90 - \frac{1}{2}\delta$.

The maximum constant synchronizing torque is secured when each brush set is coaxial with the secondary

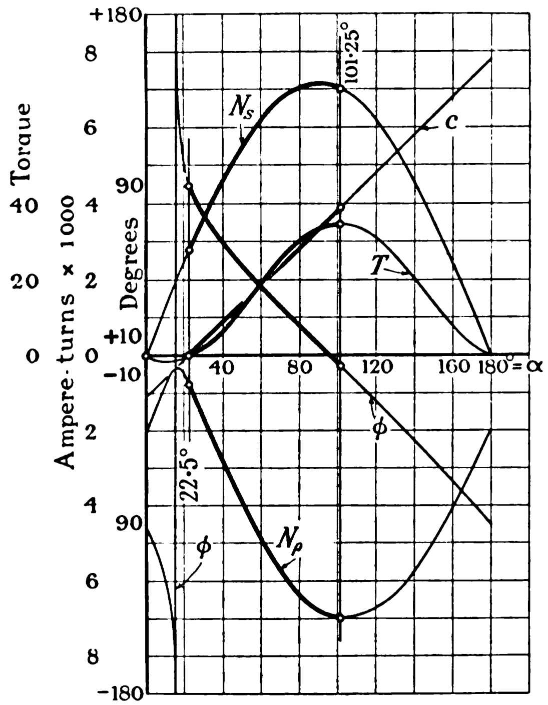

FIG. 20.—Synchronous performance curves of self-excited synchronous induction motor of Fig. 18.

winding to which it is connected, as shown in Fig. 2. One way to secure synchronous operation and a compounding characteristic is to open the circuit of one of the secondary windings upon synchronism being reached. One method of securing a more generally useful compounding characteristic is to open the circuit of one of the secondary windings and to displace the brushes of the other set by a small angle δ. From a practical standpoint brush-shifting is not desirable in connection with general-purpose motors, and the question arises how and to what extent the starting and synchronizing performances will be affected if one or both brush sets are permanently displaced by that small angle δ which yields the desired compounding characteristic. Also, just how do the inclusion of the brush voltages in the secondary circuits and the contemplated brush displacements affect the starting performance of the machine?

Let us answer the last question first. The amplitude of the brush voltages is constant at all motor speeds, and is small as compared with that of the voltages generated in the secondaries A and B by the revolving flux Φ when the rotor speed is zero. For this reason the influence of the brush voltages on the static torque is not very great. When the axis of a brush set coincides with the axis of the secondary to which the brush set is connected to produce a positive synchronizing torque, the brush voltage is in phase with that generated in the secondary and increases the starting current and the starting torque but does not affect the starting torque per ampere. When the axis of a brush set is displaced from the axis of the secondary to which the brush set is connected, the voltage at the brushes may lead the voltage generated in the secondary or may lag behind it. In either case it increases the starting current and affects the starting torque per ampere. A leading brush voltage increases the static torque per ampere by decreasing the lag of the secondary current, whilst a lagging brush voltage increases the lag and reduces the torque per ampere at starting.

The displacement of the brush axis shown in Fig. 18 results in a leading brush voltage. If one set of brushes

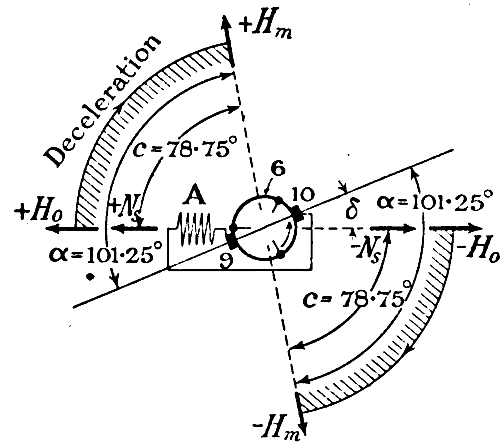

FIG. 21.—Showing synchronous angular relations under varying load of secondary ampere-turns N_s and resultant motor magnetization H for the two possible secondary polarities of motor of Fig. 18.

is displaced as in Fig. 18 and the other is left coaxial with the secondary to which it is connected, then the conditions at starting will be somewhat unbalanced. Whilst this difference is not at all serious for small values of δ, yet in so far as starting performance is concerned it is better, if a displacement is called for, to displace both brush sets to the same extent and in the same direction.

The effect of brush displacements on the synchronizing torque is of greater interest. When the axis of a brush set coincides with the axis of the secondary to which it is connected, the synchronizing torque produced by that particular secondary is strictly unidirectional, as in Figs. 5 and 7, and its amplitude is proportional to the maximum ampere-turns in that secondary. For the winding A the maxima occur for $\alpha = c = 90°$ and for $\alpha = c = 270°$. When one set of brushes is displaced by δ degrees as in Fig, 18, the synchronizing torque produced

by the secondary winding connected to it becomes alternating, with unequal positive and negative maxima. As δ increases, the negative maxima increase and the positive ones decrease; for $\delta = 90°$ all maxima are of equal amplitude, and the synchronizing torque is a purely alternating one. For any value of δ the negative maximum d_1 is proportional to $\sin^2 \frac{1}{2}\delta$, and the positive maximum d_2 is proportional to $\sin^2 \frac{1}{2}(180 - \delta)$. It is

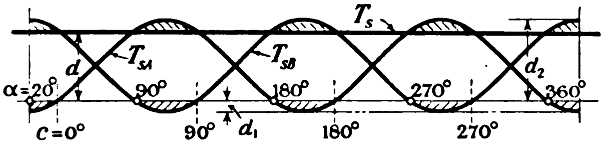

FIG. 22.—Showing resultant constant synchronizing torque when axes of polyphase arrangement of brushes on the primary are displaced from the axes of polyphase arrangement of windings on the secondary to which the brushes are connected.

important to note that when δ differs from zero the positive maxima occur for values of c which differ from those at which the maxima occur when $\delta = 0$. When δ differs from zero, $c = a - \delta$. It is seen that if only one set of brushes of Fig. 2 is displaced the synchronizing torque must be the resultant of a strictly unidirectional torque and of an alternating torque with unequal maxima. In addition, the positive maxima of these torques are displaced by more or less than 90°. The

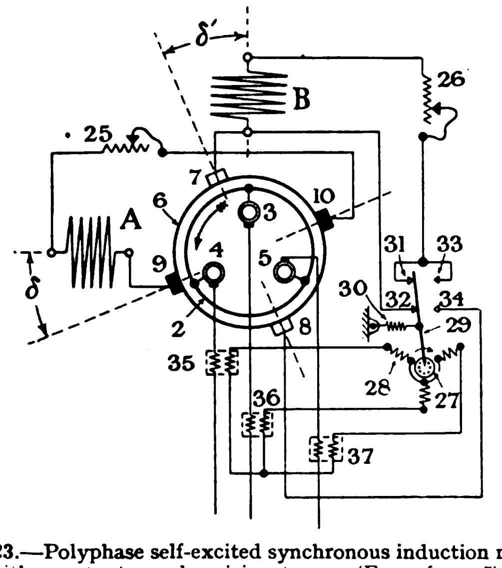

FIG. 23.—Polyphase self-excited synchronous induction motor with constant synchronizing torque (Fynn form 5).

resultant torque cannot be constant, but is very nearly so for small values of δ.

If, in Fig. 2, the brushes 9, 10 are displaced by 22·5° from A and the brushes 7, 8 are left coaxial with B, the synchronizing torque conditions change as follows:—B produces a unidirectional torque as before, its maximum being proportional to $N_{B\,max.} \sin^2 90$ or, say, to unity. A now produces an alternating torque, its maximum positive value proportional to $N_{A\,max.} \sin^2 78 \cdot 75$, or to 0·961, and its maximum negative amplitude to $N_{A\,max.} \sin^2 11 \cdot 25$, or to 0·039. In addition, the angular displacement of the positive maximum of the torque due to A from the maximum of the torque due to B is not 90° as before the brushes 9, 10, were displaced, but $90° \pm 11 \cdot 25°$ according to the direction in which the brushes 9, 10, have been moved.

If both brush sets of Fig. 2 are displaced in the same direction and by the same angle δ, then the resultant synchronizing torque remains absolutely constant but diminishes with increasing δ, becoming zero for $\delta = 90°$. As δ increases, the positive and negative maxima vary as stated in the preceding paragraph, but the angular displacement of the maxima of the component torques remains constant and equal in magnitude to the angular displacement of the two sets of brushes. This case is illustrated in Fig. 22. The amplitude d of the resultant synchronizing torque T_s is equal to the difference $(d_2 - d_1)$ of positive and negative amplitudes of the component torques. For $\delta = 22 \cdot 5$, $d_1 = 0 \cdot 039$ and $d_2 = 0 \cdot 961$, provided $N_{A\,max.} = N_{B\,max.}$ as is here

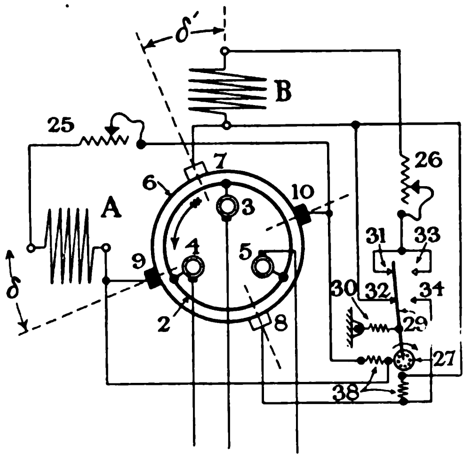

FIG. 24.—Polyphase self-excited synchronous induction motor with constant synchronizing torque (Fynn form 5).

assumed. Under these conditions $d = 0 \cdot 922$, which means that T_s is only 7·8 per cent less than for $\delta = 0$.

On the whole it is therefore preferable, for the sake of the starting as well as for the sake of the synchronizing performance, to displace both brush sets by that angle δ which corresponds to the desired compounding characteristic, and it is desirable from every viewpoint to keep δ small. Values around 20° give very good results. The author's polyphase synchronous induction motors of form 5 have been constructed on these very lines, and three self-excited examples of this form are shown diagrammatically in Figs. 23, 24 and 25.

Referring to Fig. 23, the rotor is the primary and carries a winding 2 adapted for connection to the supply through the slip-rings 3, 4, 5, and a commuted winding 6 with which co-operate the two brush sets 7, 8, and 9, 10. The stator, here the secondary, carries the windings A and B. The brushes 9, 10, are displaced by δ degrees from the axis of A, the brushes 7, 8, by δ' degrees from the axis of B. The brush axes are displaced in the direction of rotation of the primary and against the direction of rotation of the revolving flux Φ set up by

the primary at starting. In this example $\delta = \delta'$; this equality is preferable but not necessary. The secondary A is permanently connected to the brushes 9, 10, with the interposition of the adjustable resistance 25. The circuit of the secondary B includes the adjustable resistance 26, and is under the control of the relay or switch 27, 28, 29. Normally the relay blade 29 is under the control of the spring 30, and B is short-circuited or closed over any part of 26 at the contacts 31, 32. In the other position of this blade 29 it bridges contacts 33, 34, and this connects B to the brushes 7, 8, with the interposition of 26. The relay consists of a rotor 27 carrying the blade 29 and provided with a squirrel-cage winding, and of a stator carrying the three-phase winding 28 connected to the secondaries of the three star-connected series transformers 35, 36, 37, the primaries of which are in series with the slip-rings of the motor and carry line currents. The connections between these transformers and the relay are made to produce a clockwise torque in the rotor 27, tending to overpower the spring 30.

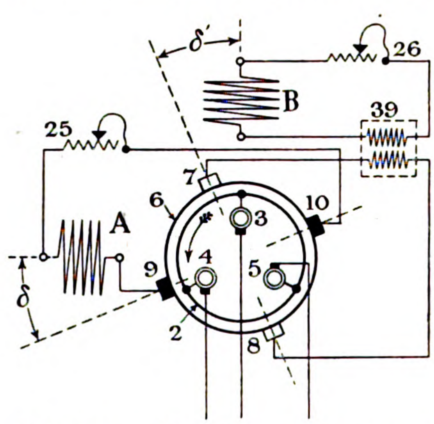

FIG. 25.—Polyphase self-excited synchronous induction motor with constant synchronizing torque (Fynn form 5).

The magnitude of this torque increases with increasing line currents, and the adjustments are so made that when the line current exceeds that value which corresponds to the maximum synchronous torque, the blade 29 moves to bridge the contacts 33 and 34.

The operation of this new machine is as follows. So long as the starting current does not exceed that which corresponds to the maximum synchronous torque, the connections remain as shown in Fig. 23, the value of the starting torque being determined by the terminal voltage and the magnitude of the resistances included in the circuits of A and of B. The synchronizing torque is alternating but with very unequal positive and negative maxima and is, in fact, substantially unidirectional. It is equal to the maximum synchronous torque when 25 is set to its synchronous or normal operating value. The machine steps into synchronism very smoothly and operates synchronously for any torque demand from zero up to and including a value equal to the maximum synchronous torque. The compounding characteristic depends on the value of δ.

For $\delta = 22 \cdot 5°$ the compounding characteristic is that shown in Fig. 20; when 25 is set to its normal operating value the synchronizing torque is $N_{A\,max.} \sin^2 78 \cdot 75 = 0 \cdot 961$ and the maximum synchonous torque is of identical magnitude.

When the torque demand exceeds the maximum synchronous torque, the motor slips out of synchronism and the secondary B is simultaneously connected to the brushes 7, 8. Because of this automatic connection of B to 7, 8, the synchronizing torque which appears when an overload forces the motor into asynchronism is absolutely constant instead of being pulsating, as is the case when the secondary A is alone connected to a brush voltage.

For $\delta = 22 \cdot 5°$ the value of this constant synchronizing torque is proportional to $0 \cdot 922$, as explained in connection with Fig. 22, and therefore only 4 per cent less than the maximum synchronous torque which corresponds to the same value of δ. The result is that the transition from synchronous to asynchronous operation cannot be detected without reference to the ammeter and wattmeter. Detection is all the more difficult since the theoretical maximum synchronous torque is never reached, because of the primary impedance, whereas the theoretical synchronizing torque is much more closely approached.

The action of the relay is very positive because of the sharp rise in line current which occurs at the time the maximum synchronous torque is very closely approached. This sharp rise is well shown by the performance curves of Fig. 1.

With this constant synchronizing torque the motor speed under overloads is quite as smooth as that of any asynchronous motor, and such a machine is suitable for any service capable of being handled by the ordinary non-synchronous motor.

The new motor of Fig. 24 differs from that of Fig. 23 in that the relay controlling the circuit of the second secondary winding B is wound for connection to the brush voltages instead of being made responsive to changes in the line currents. To this end the stator of the relay is provided with a two-phase winding 38, one phase of which is connected to the brushes 7, 8, and the other to the brushes 9, 10. The operation of this motor differs somewhat from that of Fig. 23. Here the torque of the relay depends on the nature of the brush voltage. So long as the brush voltage is alternating, the rotor 27 exerts a clockwise torque tending to bridge contacts 33, 34, and thus connect B to brushes 7, 8. As soon as the brush voltage becomes unidirectional, in other words, instantly upon synchronism being reached, the relay torque becomes zero and spring 30 is left in undisputed control of the blade 29. Since the amplitude of the brush voltage is independent of speed and depends only on the magnitude of Φ, the relay torque increases with decreasing brush-voltage frequency. According to the manner in which the design constants of the relay are chosen, the blade 29 may connect winding B to the brushes 7, 8, at the moment of connecting the motor to the line or at some sub-synchronous speed during the period of acceleration, but in any case the contacts 33 and 34 are bridged at the very instant the maximum synchronous torque is exceeded and the brush voltages become alternating owing to the lapse of the machine into asynchronism because of an overload. At such

time the current in the relay windings 38 is a maximum and the relay torque a maximum.

The novel arrangement shown in Fig. 25 is perhaps the most interesting. Here the secondary A is in *conductive* connection with the brushes 9, 10, as before, but the connection between the secondary B and the brushes 7, 8, is *inductive*, being accomplished by means of the static transformer 39, one winding of which is connected to the brushes 7, 8, whilst the other is connected to the secondary winding B. At synchronism the inductive connection between B and the brushes 7, 8, is quite inactive, because the brush voltages are unidirectional, and the compounding characteristic of the motor is determined by the secondary A and the angle δ in accordance with a circle diagram such as that of Fig 19. Upon departure from synchronism, no matter how small that departure may be, the inductive connection between 3 and the brushes 7, 8, becomes active and the machine exhibits a constant synchronizing torque such as is obtained in Figs. 23 and 24 when the blade 29 of the relay bridges the contacts 33, 34.

The motors shown in Figs. 23, 24 and 25 start with a higher torque per ampere than the ordinary asynchronous motor, operate synchronously and with high power factor on all normal loads from zero to a little beyond full load, and operate non-synchronously on all overloads, but without the least irregularity of speed or any kind of periodic variation or oscillation of the peripheral velocity of the revolving member. As a result, the weight efficiency of these machines is considerably greater than that of any other synchronous induction motors, and their range of utility is also much greater.

Whilst the motors specifically described have revolving primaries, identical results are obtained by placing the primary on the stationary member and revolving the brushes with the rotor. The several means shown and described for rendering the second component of the synchronizing torque effective at the proper time are applicable to separately excited * as well as to self-excited synchronous induction motors.

NOTES ON THE CONSTRUCTION OF HEATING AND COOKING UTENSILS.*

By Professor H. BOHLE, Member.

(*Paper first received* 19*th February, and in final form* 14*th December,* 1925.)

SUMMARY.

The paper deals with temperature tests and life tests on heating-wires for electrical heating and cooking utensils and with tests on hot-plates, and describes new types of elements and utensils.

(1) GENERAL.

It is a somewhat remarkable fact that after nearly half a century of electrical engineering the use of electricity for general domestic purposes is still the exception and not the rule. With the exception of the people in the larger towns of North America, probably not even 5 per cent of the public employ electrical appliances throughout their homes, in spite of the many advantages which the use of electricity offers. The reasons are, however, not far to seek. Whereas the generation and distribution of electricity are in the hands of the few who have concentrated their forces, the application for domestic purposes is in the hands of the multitude, the inexperienced, with the result that most mental energy has been expended on the perfecting of generation and distribution. The super-power station of to-day generates from the same amount of coal more than three times the amount of energy that the smaller station did 25 years ago. Even the heat produced by the generators is now usefully included in the complete heat-cycle of a modern station.

In some countries, such as Great Britain, the gas industry has an enormous hold on the country, and English people are very conservative. There are, however, further reasons for the lack of progress in the general domestic use of electrical energy. The apparatus on the market has been by no means very reliable, and, even where energy was cheap, repair bills and the inconvenience connected with frequent repairs have retarded the more general employment of electrical cooking and heating appliances. Moreover, the first cost of electrical appliances is still high, in many cases the efficiencies have been low, and, lastly, the mental inertia of the man in the street is large. It always takes time to persuade people to adopt entirely new methods of working. Yet none of the difficulties enumerated here are such that they cannot be overcome.

In the first place it seems, of course, absurd to change heat into electrical energy and then back again into heat. The advantages of electricity are, however, so manifold that the double conversion is fully justified. They are too well known by the expert to be enumerated here, yet, incidentally, it may be mentioned that in a fully electrically-equipped house the servant question is easily solved. Also, with a reasonable tariff the monthly expenditure for electricity is lower than with other fuels—assuming, of course, that the most up-to-date utensils are employed—and the life of the kitchen staff is very greatly improved. It is to be hoped that in large towns the use of coal for heating and cooking will before long be prohibited, not only from the standpoint of the conservation of fuel resources, but also for the sake of keeping towns free from soot and smoke. How much more agreeable would life be in a city like London if every smoking chimney had disappeared. It is a great pity that even architects are on the whole very backward in this respect and still design houses without making the necessary arrangements for the general application of electricity for domestic purposes. Perhaps the founding of a society on the lines of the Illuminating Engineering Society, which has done so much for improving lighting, would greatly accelerate the hitherto much retarded progress in the universal use of electrical cooking and heating appliances.

(2) PROPERTIES OF RESISTANCE MATERIALS USED FOR HEATING.

Practically all heating and cooking utensils of to-day use elements made of nickel-chromium alloys. It appears, however, that the properties of such conductors are still not fully understood. This is borne out by the regulations which have from time to time been drawn up by various engineering societies for the use of electrically-heated cooking appliances. I refer here especially to the rule published by one society, which states that all cooking utensils should be tested at 40 per cent in excess of the normal watts. No mention of any maximum temperature is made, although this is the main criterion as regards the life of an element. This is fully proved by the tests which the author has carried out during the past two years, the results of which are partly given in the figures below.

It is well known that conductors which are run at a high temperature not only oxidize but apparently also crystallize, and this occurs the more rapidly the higher the working temperature is. Moreover, nichrome alloys do not recuperate after cooling down, and once oxidation and crystallization have been well advanced, the conductor has become useless.

The investigations of the author deal with (1) the mechanical strength of nichrome materials as a function of the temperature, and (2) the mechanical strength at a given temperature as a function of the time of flow of the current.

A number of wires of different makes were tested,

* The Papers Committee invite written communications (with a view to publication in the *Journal* if approved by the Committee) on papers published in the *Journal* without being read at a meeting. Communications should reach the Secretary of the Institution not later than one month after publication of the paper to which they relate.

their composition being as given in Table 1. The different materials are represented by the letters (*a*) to (*e*), which are not their trade terms.

All the wires tested were new. Wires (*b*) and (*c*) were identical; wires (*a*) and (*e*) come from one country, (*b*), (*c*) and (*d*) from another.

TABLE 1.

Composition of Wires Tested.

Material	Nickel	Iron	Chromium	Remainder
	per cent	per cent	per cent	
(*a*)	58·60	27·97	10·97	Insoluble, mainly carbon
(*b*)	62·40	24·53	11·43	Insoluble, mainly carbon
(*c*)	61·70	25·24	11·26	Insoluble, mainly carbon
(*d*)	83·20	2·11	13·84	Insoluble, mainly carbon
(*e*)	57·41	30·00	11·17	Insoluble, mainly carbon

If we compare this table with the results given in Fig. 5 it appears that the material improves as the percentage of nickel increases and that of iron decreases. But the improvement may be mainly due to the increase

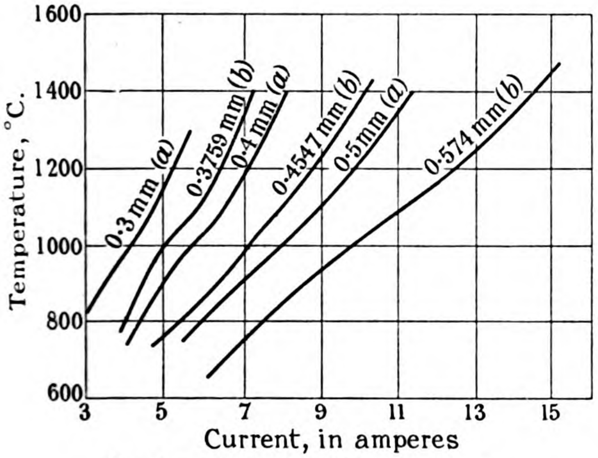

FIG. 1.—Temperature/current curves.

in the percentage of chromium, independently of the percentage of iron. Tests to settle these points are being carried out at present for percentages of chromium up to 35.

Fig. 1 illustrates the temperature/current curves for materials (*a*) and (*b*). The temperatures given are somewhat lower than those stated by the makers for the same currents, probably due to the different methods of suspension employed. The wires under test were stretched between two stout terminals in a rectangular box lined with asbestos (without a lid) in order to prevent the wires being cooled by draughts. The length of each wire was 19·5 cm. If very long wires are used it will be found that at very high temperatures the wire stretches on account of its own weight, so that there is a reduction in the cross-section and a subsequent increase in the temperature for a given current. The temperature was measured when stationary conditions prevailed. The curves show average results, but it should be stated that the test wires were found to be remarkably uniform. The breaking loads in the mechanical-strength/temperature tests never varied by more than ½ lb. This shows that great care is already taken in the manufacture of heating-conductors.

It will be noticed that all the curves in Fig. 1 are S-shaped. This is seen even better by plotting the resistance/temperature curves shown in Fig. 2. The S shape is now clearly defined. It will be obvious from these curves that the calculation of the temperature of

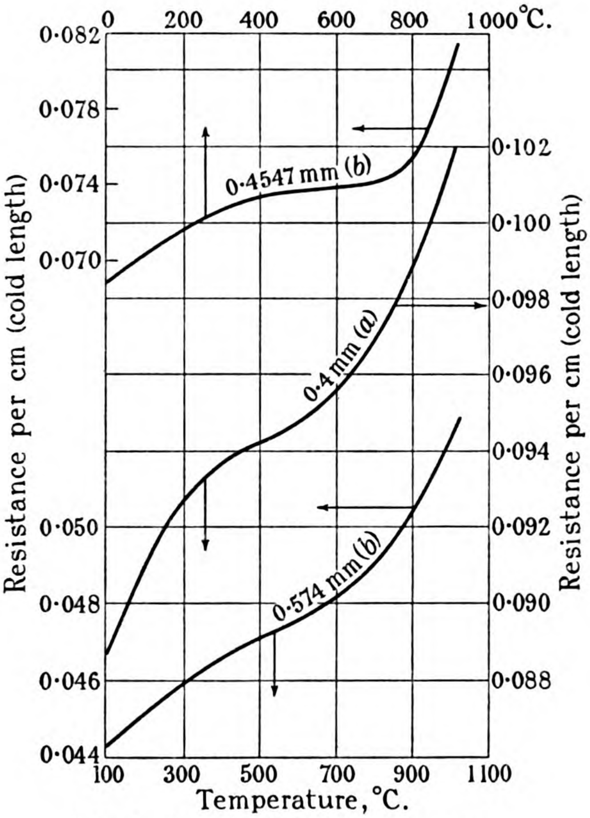

FIG. 2.—Resistance/temperature curves.

heating conductors when employing a constant temperature coefficient will yield unreliable results.

At the lower temperatures the tests were carried out in a Gallenkamp electric furnace with a suitable thermocouple, whereas at the higher temperatures an optical pyrometer was employed.

(3) MECHANICAL STRENGTH.

The mechanical strength of heating-wires as a function of the temperature (or current density) is the most important item from the standpoint of the life of an element. The results are shown in Figs. 3 and 4. The conductors had been subjected to the stated temperatures for 4 hours, and in some cases for 24 hours. It

will be noticed that the additional 20 hours have little effect on the mechanical strength for temperatures up to about 700° C., but beyond this temperature materials (*a*) and (*b*) deteriorate rapidly. This is more clearly shown in Fig. 5. For a working temperature of 700° C., material (*b*) retains its mechanical strength, whereas at 1 000° C. the wire oxidizes very rapidly and loses its

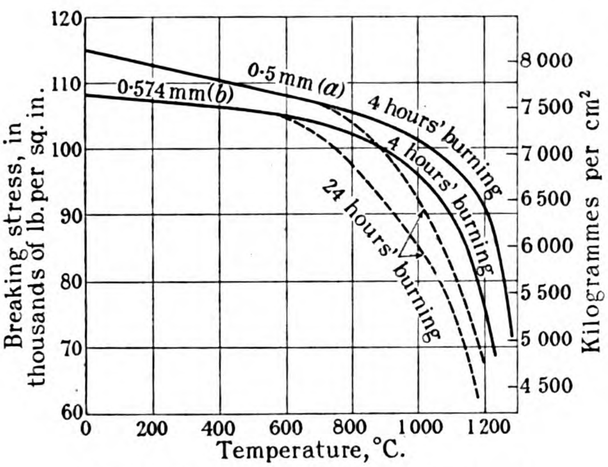

FIG. 3.—Temperature/breaking-stress curves.

mechanical strength. The best material is (*d*), which contains little iron but a large proportion of nickel. Its mechanical strength remains almost constant throughout the life test.

Of interest is the result of the test on material (*e*). This material contains a great deal of iron, yet it does not lose its mechanical strength as much as one would expect. This is due to the fact that the wire is considerably thicker than the others tested, so that proportionally less surface comes into contact with the oxygen of the air.

From the tests it is obvious that the maximum

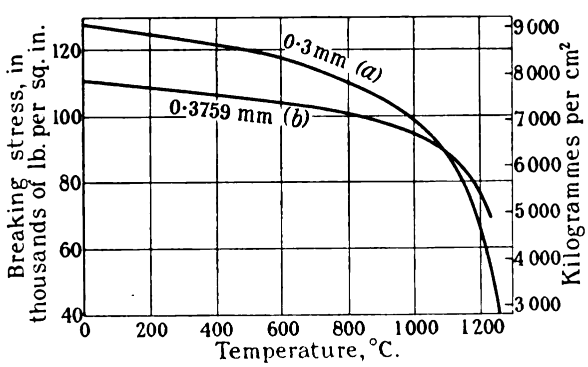

FIG. 4.—Temperature/breaking-stress curves.

temperature of wires (*a*), (*b*), (*c*) and (*e*) should not exceed 700–800° C. unless heavy conductors are used. Material (*d*) can be constantly worked at 1 000° C. This should, however, be the limit, as an increase in the voltage, even if temporary, might do lasting damage to the material. Once nichrome conductors have been subjected to an abnormally high temperature their mechanical strength has disappeared for ever, as there is no recuperation.

The oxidation of heating wires may be prevented by surrounding them with a suitable cement. Such cements should be good insulators, good heat conductors, non-hygroscopic and should not shed water on cooling. The author has been unable to find a cement possessing all these qualities. A special type of alundum was found fairly satisfactory. It has a heat conductivity about

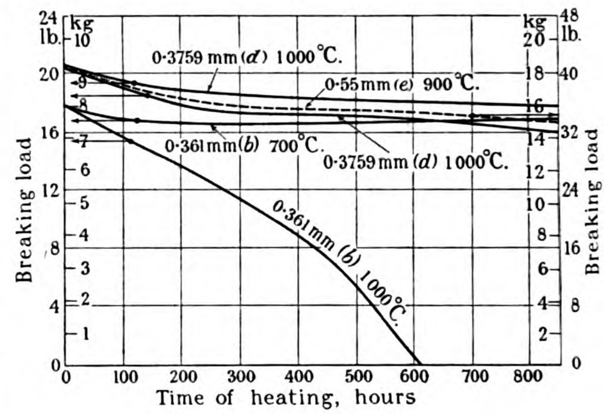

FIG. 5.—Life tests on heating-wires.

3 times greater than that of porcelain; it remains a good insulator even at very high temperatures; it is easily applied, does not crack after drying and does not shed water on cooling. It is, however, somewhat hygroscopic. For water-heating elements which are always in use the cement is excellent.

The mechanical-strength curves have been repeated

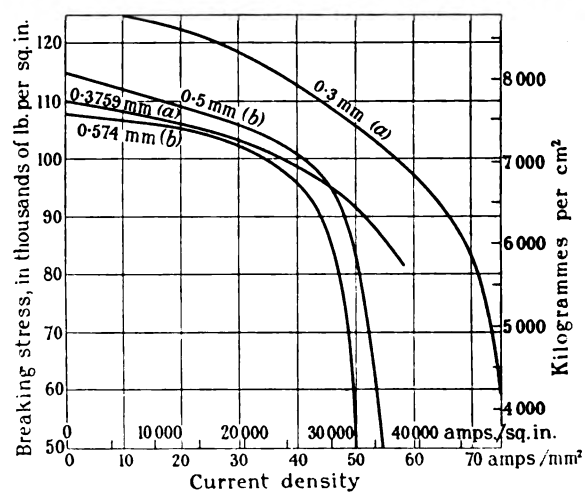

FIG. 6.—Mechanical-strength/current-density curves.

with current densities as abscissæ. The thinner the wire, the greater is the relative radiating surface and consequently the greater is the current density for a given temperature (see Fig. 6).

The fact that crystallization and an alteration in the structure of the wire occurs seems proved by Fig. 7, in which the resistance (after cooling down) has been

plotted as a function of the average temperature of the test, when the heating occurred for 4 hours. It will be seen that the resistance decreases at first until a temperature of about 800° C. is reached, when a rapid increase in the resistance sets in, due to oxidation and crystallization. This temperature should therefore not be materially exceeded.

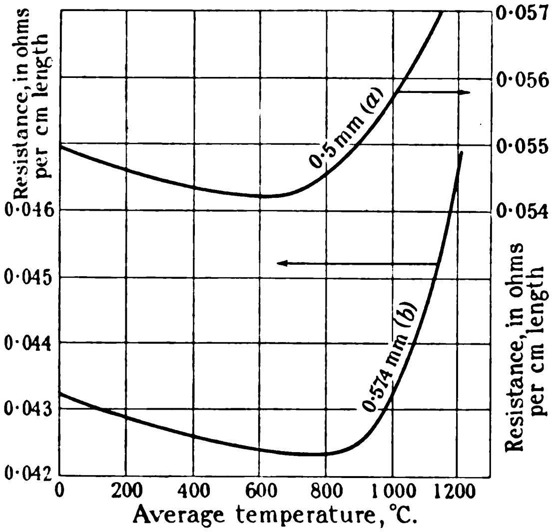

FIG. 7.—Resistance (cold)/temperature curves.

Further interesting results are shown in Fig. 8, which illustrates the change in resistance (hot) as a function of the time. After 40 hours there is an almost instantaneous alteration, but later on the resistance once more increases steadily. Obviously some unstable condition occurs during the life of a heating wire consisting of nichrome.

The conclusions which may be drawn from the results

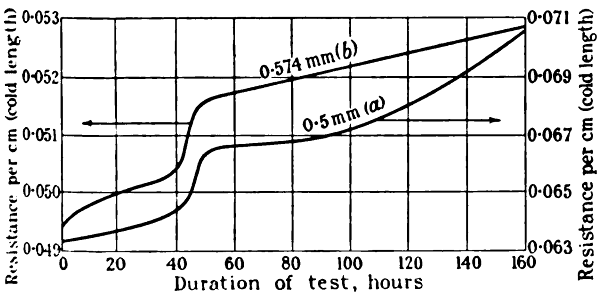

FIG. 8.—Resistance/time curves.

of these tests are obvious. The maximum working temperatures should not exceed values at which the material commences to deteriorate. This temperature should allow for all voltage variations, and in this connection it must not be forgotten that the temperature variation is practically proportional to the square of the voltage variation. To prescribe tests which allow the number of watts to be 40 per cent in excess of the normal, without stating the maximum working temperature, is detrimental to the life of the heating element. It would be far better to give the maximum working temperature, which, however, depends not only upon the current density but also upon the manner of fixing the element and the specific size of the heated surface.

(4) Heating-wires Under Normal Working Conditions.

When a heating element is placed in a cooking utensil, the conditions of working are entirely different from those which obtain when a wire is heated in free air. Radiation has now practically disappeared and is replaced by conduction, and the quality and reliability of a utensil depend mainly upon the quality of the heat conduction. The fall of temperature between the heating wire and the metal surface to be heated is expressed by

$$\theta_r = \frac{\text{watts per cm}^2 \times \text{thickness of insulation}}{\text{heat conductivity of insulation}}$$

This equation tells us that the thickness of the insulating material should be as small as possible and that the heat conductivity of the insulator should be high. The most suitable material is clear mica, not micanite. It withstands great heat, is mechanically strong so that very thin sheets may be used, and it does not fall to pieces when heated to a high temperature. Micanite, which has been frequently employed, always falls to pieces when subjected to great heat; its thickness has to be 3 to 4 times greater than that of pure mica, and its heat conductivity is about 3 times smaller. For a sheet of pure mica 0·025 cm thick the fall of temperature for 1 watt per cm^2 is given by

$$\frac{0 \cdot 025}{3 \cdot 76 \times 10^{-3}} \doteqdot 7 \text{ deg. C.}$$

which is very low. It is, however, essential that no air pockets can form anywhere. Still air is about the best heat insulator which we have, so that the fall of temperature across an air pocket will always be high. The heat conductivity of air, or the amount of heat in watts conducted in 1 second through an area of 1 cm^2 across a gap of 1 cm length for a difference in temperature of 1 degree C., is expressed by $0 \cdot 00022\,(1 + 0 \cdot 00228\theta)$, where $0 \cdot 00022$ is the conductivity at 0° C. and θ is the temperature in degrees C. From this it will be seen that for a gap of only 1 mm length the drop may reach dangerous values. Let us suppose that the average temperature in the gap is 600° C.; then the drop across a 1-mm gap for a specific load of 1 watt per cm^2 is nearly 200 deg. C. With a high loading the melting point of nichrome is soon reached. This shows the danger of loose fitting. In fact, too much emphasis cannot be placed on the necessity of making sure that every inch of the heating wire is firmly pressed against the surface which is to be heated. Moreover, this applies not only to the heating wire proper but also to the connection from the element to the terminals.

The usual practice consists in winding nichrome ribbon around strips of mica. This possesses the disadvantage that the under-surface of the element becomes considerably hotter than the one pressed against the surface to be heated. Moreover, the turns are liable to become short-circuited. To ensure good mechanical

contact with the surface to be heated the element is fixed with a number of screws, which increases the difficulty of replacing an element.

The author has constructed an element, shown in Fig. 9, which has no under-surface. It consists of a sheet of pure mica to which is fixed a helical spiral of nichrome wire. The various convolutions of the spiral are separated from one another by means of magnesia or similar tubes slightly less in diameter than the helix. When now the element is firmly pressed against the bottom of the vessel, which is accomplished by means of a single screw and a suitably sprung steel plate, the helix is reduced to the diameter of the magnesia tubes so that the whole element forms practically a solid plate. This ensures good heat conductivity and the

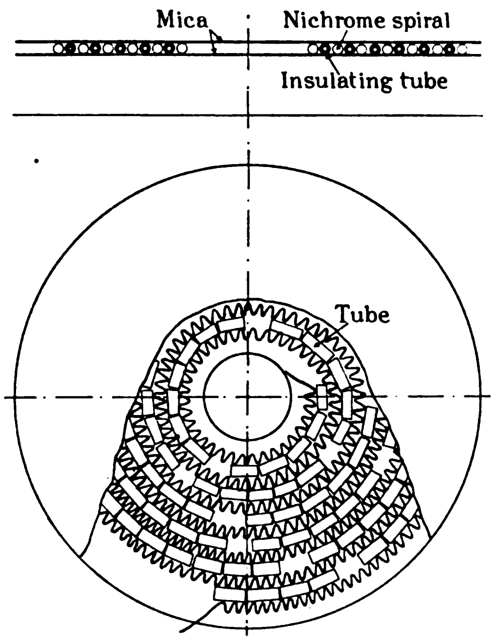

FIG. 9.—Heating element for cooking utensils.

specific load may be as high as 6 watts per cm² without raising the temperature of the heating wire beyond the safe limit.

(5) JOINTS.

It is rarely advisable to join the heating wire directly to the terminals of the utensil. It is frequently mechanically too weak and it may become too hot as well. Whereas the conduction of heat from the element proper may be good, from the connection it may be poor. A larger radiating surface will then be required for the connection, and this can be obtained by joining to the heating wire a stout conductor. A copper flexible cable is unsuitable, as the thin wires soon oxidize and after a short time the flexible cable is burnt through. Even a solid copper conductor does not last long. Constantan, if consisting of fairly thick wires, will give fairly satisfactory results, but pure nickel is best. Care must, however, be taken when making the joint. As only hard soldering can be applied, it may happen that during the heating of the joint the thin heating wire may be raised to a high temperature, somewhat near the melting point, in which case the element would be irreparably damaged before it was completed. Tests were carried out with 24 different types of joints. Copper flexible cables failed after less than 200 hours' burning. Hard sheet brass pressed firmly around heating wire and heavy connecting copper flexible cables gave satisfactory results, so long as the flexible did not become hotter than about 200° C. A very good joint is formed by making the heating wire long enough to be made in a 3-wire strand, the wires being firmly twisted together, the flexible cable thus formed reaching into the heating spiral. Whenever a hard soldered joint is employed, the joint must be well fixed mechanically so that vibration is avoided and the heat can get away. The connection from the element to the terminals may be insulated by means of glass beads if the temperature is not very high, or with a porcelain or silica tube.

On the whole it must be stated that the joints are the weakest parts in an element. On a 220-volt circuit the thickness of the wire rarely exceeds ½ mm, and if strip be used it is very much thinner still. To join heavy conductors to such thin wires will naturally make the system weak mechanically. If joints can therefore be avoided altogether, one of the main weaknesses in an element will disappear.

(6) COOKING UTENSILS.

The construction should be such that any intelligent person can replace an element, simply by removing a nut, or otherwise. A saucepan which has given every satisfaction is shown in Fig. 10.* It is fitted with the type of element illustrated in Fig. 9. Replacement is very easy. The saucepan may also be dipped into a bucket of water without endangering the element, in spite of the fact that the lower portion is not soldered to the upper one. There are two spirals fixed to a sheet of mica, for 600 and 400 watts respectively, which may be used separately or in parallel and in series, so that 1 000 watts, 600, 400 and 250 watts may be obtained. A suitable loading of such a vessel is about 4 watts per cm² of surface, though it may be raised to 5 watts. Aluminium or tinned copper will be found satisfactory for such saucepans. Pure nickel is now coming into fashion and gives excellent results, but is expensive.

Pure nickel is undoubtedly the best material that can be employed, as it has a very high melting point and is easily kept clean. It has also a high scrap value.

Aluminium possesses the disadvantage of a low melting point, and results have usually been very unsatisfactory. With the element shown in Fig. 9, aluminium vessels may be used with complete satisfaction. Between the heating wire proper and the metal of the saucepan there lies only a thin sheet of natural mica, so that the heat is conducted away very rapidly, and the temperature-drop between the heating wire and the metal of the saucepan is small. There is thus no necessity for employing very high temperatures, and 600–700° C. for the heating wire will suffice. The author has used in his own house aluminium saucepans for over 3 years, and they are still being used daily.

* British Patent No. 215539.

It is also a curious fact that heat preserves aluminium, and a saucepan with an element will last much longer than one without an element, care of course being taken that there is always something in the vessel when the current is on; otherwise the element shown in Fig. 9 will melt the saucepan. Even this, however, will not destroy the element. The action of heat counterbalances that of chlorine contained in the water.

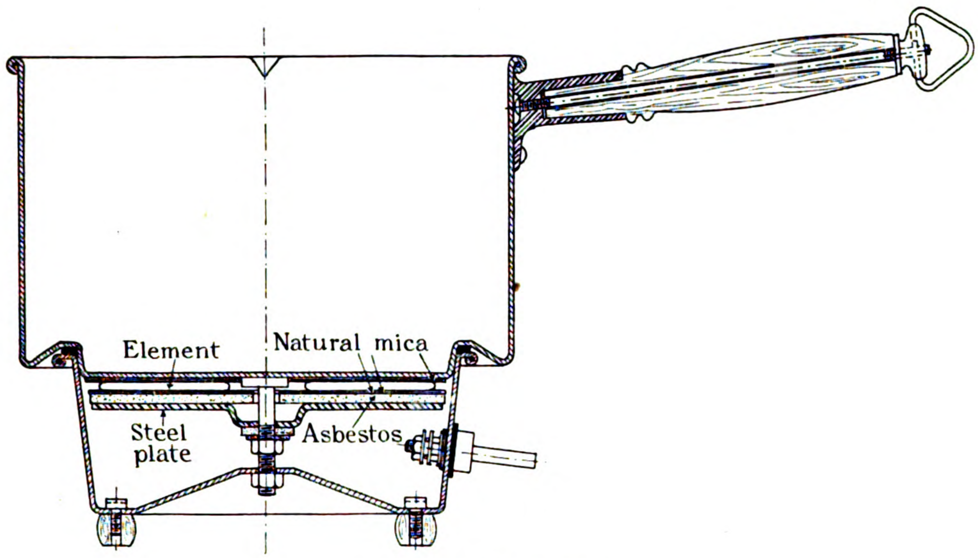

FIG. 10.—Saucepan.

Tinned copper possesses the disadvantage of requiring retinning fairly frequently. For large saucepans, tinned iron has also been used.

Large vessels should always be lagged to reduce the loss of heat.

The efficiency of the $2\frac{1}{2}$ litre saucepan shown in Fig. 10 was 88 per cent when bringing cold water to the boiling point for the first time. This shows the great advantage of the saucepan with an element, over the use of hot-plates.

In the tests given below for hot-plates the experiments were carried out with great care, all the vessels being a close fit. In an ordinary kitchen the efficiencies would be much lower.

(7) HOT-PLATES.

The author does not advocate the use of hot-plates. They are slow and inefficient, especially if ordinary ill-fitting cooking utensils are placed thereon. In an ordinary household the hot-plate is usually employed for one operation only, when the efficiency will rarely be more than 40 per cent, even if the greatest care is taken, and it may be as low as 30 per cent. Yet in spite of this fact, large electric ranges with numerous hot-plates are still being manufactured, with the result that those who buy them, mostly at a high price, soon find out that they cannot afford the bills for current at the end of the month. This has been proved over and over again in this country. Properly constructed cooking saucepans are preferable in every case.

There are two types of hot-plates on the market, the open spiral type and the enclosed plate type. The former has the advantage of cheapness but is often easily damaged by liquids boiling over.

The efficiency depends largely upon the weight of the plate and whether it is used for one operation only or for continuous work. The burning out of an enclosed hot-plate if left standing idle under current may be prevented by supplying the plate with corrugations. Such a plate is shown in Fig. 11. Even if made of aluminium it can be left idle under full load for $\frac{1}{2}$ hour or more, whilst if made of cast iron it can be used as a radiator.*

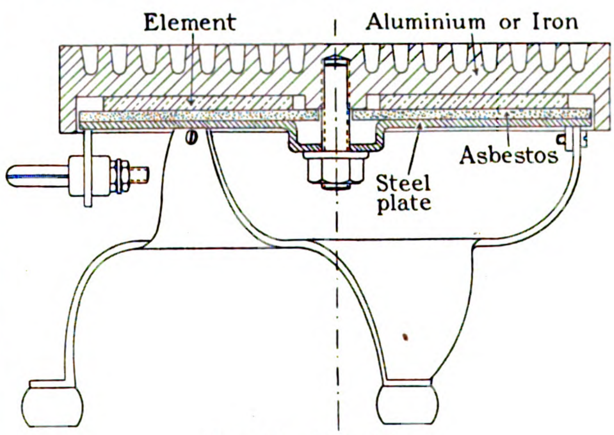

FIG. 11.—Hot-plate.

It may also be used as an element for a baking oven, for which it has proved very satisfactory.

Comparative tests were carried out with two different types of hot-plates, one of which was very light † whilst the other one was heavy. In both cases the same

* British Patent No. 219497.
† The light plate used would not be substantial enough for household purposes.

cooking utensil was employed and the same quantity of water was brought to the boiling point. The results of the tests are shown in Fig. 12, which is for 2 250 grammes of water in a vessel with a total content of about 6 litres. The tests show conclusively that a heavy hot-plate is a very inefficient article if the operation is to be performed once only and if the quantity of water or food is small.

When the quantity of water was increased to 4 000 grammes the efficiency of the lighter plate fell from 71 to 66·4 per cent, whilst that of plate B was increased from 31 to 44·3 per cent. When the plates were used a second time immediately after the first operation, the efficiency of the light plate increased by only 4 per cent (from 71 to 75) whilst that of plate B rose to 66·8 per cent. This shows that a heavy plate is suitable for continuous work and large quantities, a light plate for single operations, and that the light plate, which absorbs only 850 watts against the 1 766 watts of the heavy plate, is too small for large quantities. For every 1 000 grammes of water to be boiled the power taken should be at least 400 watts. In fact, it generally pays, at least from the standpoint of current consumption, to employ large powers and do the work quickly, rather than to use little power and much time.

After the cooking operation has been completed the energy stored in a heavy plate may be usefully employed for heating washing-up water. With the heavy plate 14 per cent was recovered in this way.

The experiments were repeated with an open grill type of hot-plate. For 2 250 grammes of water and a reflector below the heating wire the efficiency which resulted was 55·7 per cent when the bottom of the aluminium saucepan was highly polished. After painting this surface a dead black the efficiency rose to 66·9 per cent. The dead-black surface stops most reflection. When a highly polished "whistling" can was used the efficiency of the open grill without reflector was only 31 per cent; when the bottom was painted a dead black the efficiency rose to 62 per cent.

These simple tests indicate in what direction the efficiencies of hot-plates may be considerably raised.

A hot-plate in which the heating element consisted of rods of "silit" was also tested. The efficiency which resulted with 2 250 grammes of water was 54 per cent, the under-surface of the vessel being black.

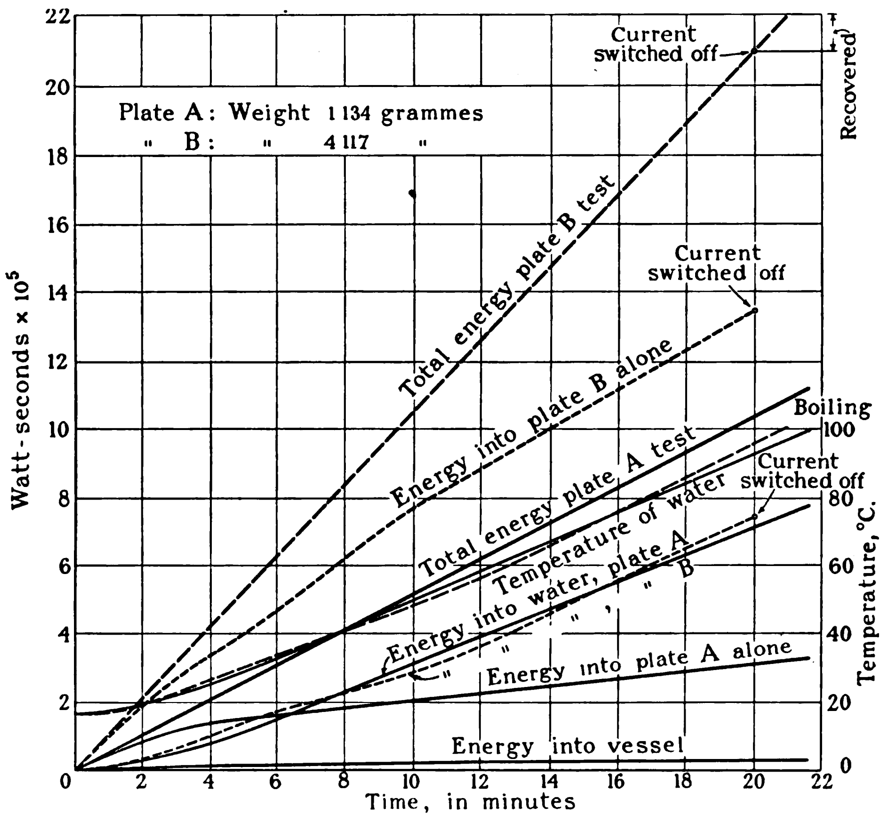

FIG. 12.—Tests on hot-plates.

A NEW SYSTEM OF CONTROL FOR ELECTRICALLY DRIVEN WINCHES AND CRANES.*

By J. Bentley, Associate Member.

(*Paper first received* 28*th August, and in final form* 10*th November,* 1925.)

Summary.

In the first part of the paper the author reviews the conditions which an electric winch or crane should fulfil, and discusses the different ways in which these can be met and the difficulties and disadvantages entailed.

An arrangement of contactors, resistances, etc., together with a patent speed-load device, is described as applied to an electric winch, and its method of working and performance under various conditions of hoisting and lowering loads are detailed.

A simpler, more compact and less costly system, obtained as the result of experiment, is developed, with curves giving the various speeds obtained at different loads and a description of the safety devices, etc., incorporated.

In providing an electric drive for a winch or crane to raise and lower loads, the following requirements must be arranged for :—

(1) To lift the load at suitable speeds.
(2) To hold the load from running back.
(3) To allow the load to be lowered under control.
(4) To prevent the load from being lowered at a speed beyond that at which the centrifugal forces set up in the armature reach a safe limit.
(5) To take up the slack in the cable without undue strains upon the gear when the slings tighten on the load.
(6) To drop the load carefully and without damage.
(7) To drop the load smartly when on the swing, and to make it respond to the operator's will as promptly as possible.
(8) To prevent the motor and gear from being overloaded.
(9) To prevent the motor from running back or re-starting if the power should fail without the operator's knowledge.
(10) To obtain good acceleration and retardation, thus enabling the cycle of operations to be completed as speedily as possible.

These requirements will now be considered in order.

(1) *To lift the load at suitable speeds.*—A series-wound motor with a suitable starting resistance, connected to a winding barrel through suitable gearing, is the prevailing practice, the diagram of connections being given at A (Fig. 2).

The relation between loads and lifting speeds is shown in Fig. 1 (curve A). This curve shows speeds varying as $1/\sqrt{T}$, where T is the torque, lower speeds being obtained by regulating the resistance. The speeds given by this arrangement compare unfavourably with those obtained from a steam or hydraulic winch or crane, since where the loads to be handled vary in weight the speeds at the light loads are too low. This curve can be improved by using a motor with an arrangement for field adjustment. The ideal amount of field regulation is that which causes the motor to take full current at any load and gives speeds as shown by

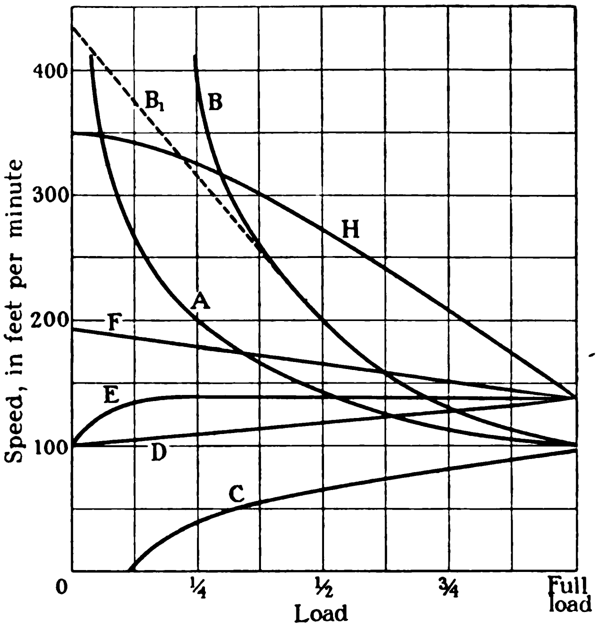

Fig. 1.

curve B in Fig. 1. Here the speed varies as $1/T$, T being the torque. This is only desirable for those loads above, say, ¼ full load, and it is not practicable so to arrange the design of the motor. This result can, however, be attained to all practical purposes by designing a motor to give twice full-load speed at one-half full load.

With a series motor the best way to arrange for field adjustment is by diverting current from the series winding, the amount diverted being arranged according to the load. This changes curve B (Fig. 1) to the dotted curve B_1. The connections are given in diagram B (Fig. 2).

Provision has to be made for the starting resistance

* The Papers Committee invite written communications (with a view to publication in the *Journal* if approved by the Committee) on papers published in the *Journal* without being read at a meeting. Communications should reach the Secretary of the Institution not later than one month after publication of the paper to which they relate.

to be cut out in proper increments, and time must be given for each surge of current to return to normal before the next step of resistance is cut out. This is done either by training the operator to start up gradually or by fitting some timing arrangement to prevent him from starting up too quickly. It is standard practice to divert the series winding after all the starting resistance is cut out. This keeps the current-kicks down when starting up. In practice it is found to be unnecessary to time the rate of diversion as the inductive effect of the field winding does this automatically.

The question of field diversion also arises in connection with acceleration. It is difficult for the operator to judge how much diversion to use in order to attain the requisite speed for a load of which he does not divert the series field to give a predetermined speed for a given deflection, i.e. a given torque.

The contacts R are connected to the coil of a circuit breaker and are arranged to open the latter when the load exceeds a prearranged value.

(2) *To hold the load from running back.*—The usual method of doing this is to fit a magnetic brake, i.e. a brake which comes into operation when the supply is disconnected from the motor.

Another arrangement is to hold the load by short-circuiting the motor across its own series winding, connection being made so that the motor acts as a generator. To obtain this braking effect, the series winding must be connected so that the current passes through it in the opposite direction to that in which it does when hoisting.

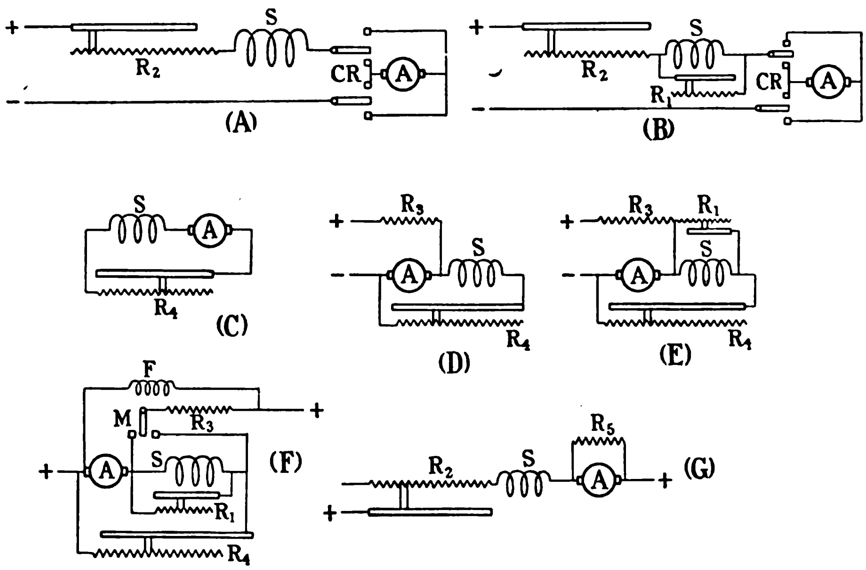

FIG. 2.

A = armature
S = series winding
R_1 = series diverter rheostat
R_2 = starting resistance
R_3 = lowering starting resistance
R_4 = variable resistance
F = shunt winding
CR = reversing switch
R_5 = armature diverting resistance

know the weight. The steps can be marked for various weights, but, unless the weight of a particular load is known, the operator cannot take advantage of this.

To be really advantageous the field diversion must be done automatically. One method of bringing this about is given in Patent No. 218461, the description of which is as follows :—

The motor is connected to the winding barrel through gearing of the sun and planet type (see Fig. 3). The centre sun wheel 22 is connected to the armature, and the three planet gears, 20, to the load. The internal gear 19 is arranged to float and is anchored through the spring 18. This spring balances the reaction tending to revolve the gear 19, the deflection being in direct proportion to the torque being transmitted.

The motion of the gear 19 is transmitted to a sliding rheostat 13, the stepping of which is graded so as to

If the motor is hoisting the load and the controller is brought to the "off" position, it is only necessary to short-circuit the armature across the series winding to obtain the braking effect, since when the armature reverses its rotation the current changes in direction, the armature passing current through the series winding in the same direction as for hoisting.

The objection to this method is that the motor must be in motion to obtain the required effect.

The load creeps slowly under these conditions, and if it is required to be held a foot brake must be fitted.

The advantages of this method of braking are dealt with under heading (7).

(3) *To allow the load to be lowered under control.*—There are several mechanical devices in use to prevent the load from taking charge, but the majority of them do not permit its control at a definite speed. A foot brake will do this, but due to the constant readjust-

ment required this method is found in practice to be unreliable. The load can be controlled quite simply electrically by using what is known as rheostatic braking, that is, arranging the motor to act as a dynamo, supplying power to a variable resistance.

Diagram C (Fig. 2) gives the connections and the speeds are as shown by curve C (Fig. 1). This arrangement is very simple and reliable so long as the load will overhaul the motor and is sufficiently heavy to overcome the mechanical and electrical losses.

When lowering lighter loads it is necessary to use power. The operator must be trained not to switch over to the power steps for heavy loads, and to come back on to the braking steps gradually, otherwise the voltage generated will be sufficiently large to cause the motor to flash over. This system is often used, but it is usual to fit a mechanical device to prevent excessive speeds should the operator apply power when lowering a heavy load, and also to install a timing arrangement to prevent the braking steps from being put into operation too quickly.

In order to overcome these difficulties a system of electrical braking known as potentiometer lowering can be used. The connections used are shown in diagram D (Fig. 2). This system consists of rheostatic braking, with the addition of current from the line. While the load is overhauling the motor the latter acts as a brake, but should the load be too light to do this the power supplied from the line rotates the motor, the series winding acting as a very inefficient shunt field.

Unfortunately, the system is very inefficient and the lowering speeds are limited, the speed with the hook light being approximately the same as the full-load hoisting speed (see curve D, Fig. 1). These lowering speeds can be improved for the lighter loads by having a series diverter as for the hoisting side, using the device described in connection with requirement (1) (see diagram E, Fig. 2). This diverter is variable according to the load being lowered. It was found, when fitting it, that the diverter must be disconnected before short-circuiting the resistance R_4 in series with the motor. The load falls and then pulls up with a jerk when the current-surges die down, and the motor has a tendency to flash over, this being caused by the machine ceasing to generate due to the self-induction of the field, the current passing through the diverter instead of through the field winding.

It will be seen from curve E, Fig. 1, that this arrangement only improves the speeds of loads which will drive the motor, the light-load speeds being still very low. These can be improved by adding a shunt winding to the motor and automatically changing over the current from the line to the other end of the series winding after the motor has got up to speed (see diagram F, Fig. 2). This addition weakens the field, since the series winding opposes the shunt, and gives the speed curve F, Fig. 1, but if the load is one which drives the motor the series winding helps the shunt winding and the load is still controlled.

The change-over of the connection from one end of the series to the other must be made automatically when the voltage on the armature has reached a certain value and the starting current has fallen to that required for light running, or when the load is sufficient to drive the motor; and the contactor must change back again if the current is too high, otherwise the motor will reverse and race due to the series winding overpowering the shunt. Under these conditions the motor is running with a weak field, and to supply the required torque the armature takes more current. As the field gets weaker the current taken by the armature rises, torque being proportional to the armature current and field flux, therefore the effect is cumulative.

Higher light-load speeds, as shown by curve H (Fig. 1), can be obtained with this arrangement of connections if provision is made for the insertion of a comparatively high resistance. The load is now controlled by the motor generating to the line. One precaution that must be taken is that the braking resistance must be automatically reduced if the power fails, otherwise the load will be out of control. An excess-voltage relay must operate to prevent the no-voltage device from being energized by the motor acting as a generator. The most critical period for this tendency to energize the no-volt circuit is when lowering medium loads, the heavier loads taking some time to attain generating speeds and allowing the no-voltage release to act first.

In dealing with this it was arranged to break this circuit altogether instead of inserting a high resistance in series with the braking resistance, but it was found that the rush of current from the line through the series winding in opposition to the shunt demagnetized the field and prevented the generating condition from coming into action. It is very probable that if the load had been allowed to drop far enough the motor would have started to generate, but it was not possible to test this because the speed attained would have been unsafe.

(4) *To prevent the load from being lowered at a speed beyond that at which the centrifugal forces set up in the armature reach a safe limit.*—To prevent the motor from attaining an excessive speed when lifting "light hook" a shunt winding to limit the speed to any required amount can be fitted. This shunt will not, however, limit the speed when lowering heavy loads, the reason being that the motor will tend to generate back on to the line, exciting the series winding in the opposite direction to the shunt.

A very common method of preventing excessive speed under any condition is to fit a centrifugal brake, i.e. a governor which applies a mechanical load when the speed reaches a definite value.

When using ordinary rheostatic control there is always one critical load which will cause the motor to race, even if the gearing is inefficient. This occurs when the load just balances the losses in the gearing and the motor, and the only reason that this trouble is not met with in practice is that the torque required to overcome the losses increases as the speed rises, while the torque exerted by the load remains constant.

Rheostatic braking and potentiometer lowering overcome the trouble of excessive speed when they are used in conjunction with a series motor, always provided that a power step without the braking resistance is not used. This means that the motor must be always

connected so as to be capable of generating across the resistance should the load be heavy enough to drive it. If, however, the gearing is very efficient a limiting shunt winding or centrifugal brake must be fitted for hoisting "light hook."

Mechanical devices which apply a brake when the load is driving the motor are sometimes used, but

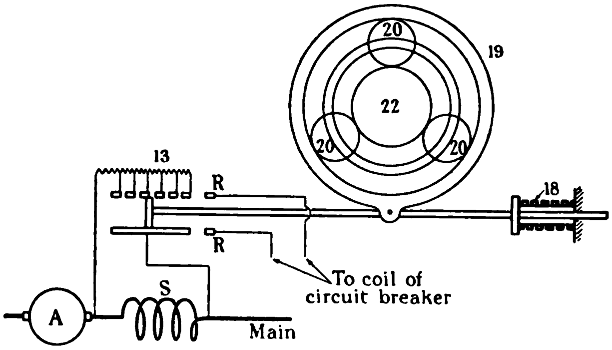

FIG. 3.

these do not prevent the latter from racing when the load just balances the mechanical and electrical losses, or when hoisting "light hook."

(5) *To take up the slack in the cable without undue strains upon the gear when the slings tighten on the load.*—To take up the slack in the rope steadily is only possible with ordinary rheostatic control by "teasing" the controller off and on, and is very difficult to perform satisfactorily.

The resistance in series with the motor does not absorb the voltage necessary to bring about the required reduction in speed until the machine is loaded.

To obtain a creeping speed a foot brake can be fitted to load the motor and reduce the voltage upon it, but it must be so interlocked with the controller that it cannot be used on any step of the latter which will pass sufficient current to overload the motor. It is best to arrange to use the foot brake on that controller step on which it can stall the motor with the power on, without passing an excessive current.

Another method of reducing the voltage on the motor armature is to insert a resistance across it, as in diagram G, Fig. 2. This arrangement passes current through the resistance and the series winding, increasing the field and reducing the voltage to the required value.

(6) *To drop the load carefully and without damage.*—The load can be lowered by hand-releasing the magnetic brake, if fitted, or by means of a foot brake, but this is liable to cause the load to drop in jerks.

Where potentiometer lowering or rheostatic braking is fitted, loads can be lowered at very low speeds which give very steady and easy landing.

The amount of resistance inserted in the generating circuit limits the speed to the desired value.

(7) *To drop the load smartly when on the swing, and to make it respond to the operator's will as promptly as possible.*—The operator should be given every facility for dropping the load smartly to enable him to clear obstructions. One disadvantage of fitting a magnetic brake is that the time taken by the brake to release prevents the load answering the controller quickly.

Where potentiometer lowering or rheostatic braking is fitted, the load is always alive and, provided it is heavy enough to overhaul the gearing, or the current from the line is sufficient to supply ample torque to the motor, the load will answer instantly.

For comparison between the accelerations given by the two methods, see the speed/time curves given in Fig. 4. The delay caused by the magnetic brake is at once apparent.

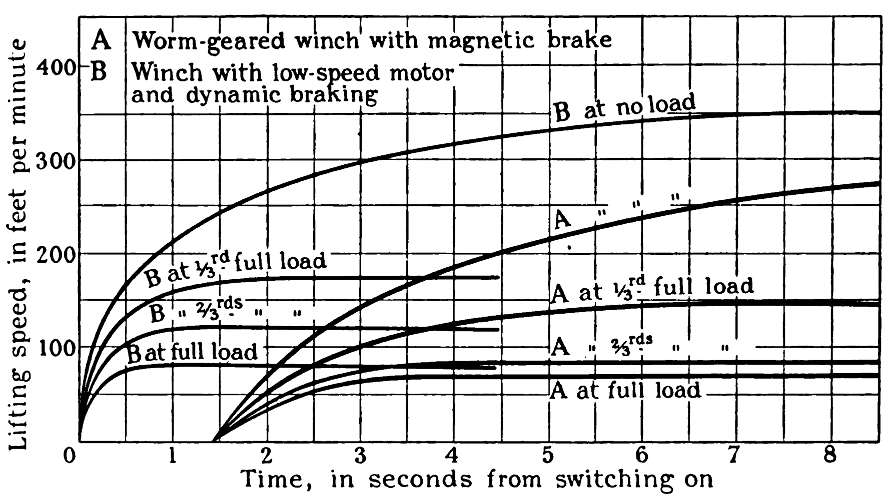

FIG. 4.

(8) *To prevent the motor and gear from being overloaded.*—The motor can easily be protected from overload by fitting fuses or an overload circuit breaker, but it is very difficult to provide against excessive stresses in the gearing and rope. Should an overload occur, the fuses or circuit breaker will act, but, whilst this protects the electrical equipment, the gearing and rope are strained due to the flywheel action of the

motor armature. This trouble can be avoided to some extent by measuring the load on the gearing side as described under heading (1), and arranging for this device to open the circuit breaker. By this means the duration of the overload is made as short as possible.

The time-lag of the current rising in the motor being obviated, the fitting of time-delay fuses or a time-element overload circuit breaker only aggravates the matter by lengthening the period of overload.

The circuit breaker, which is operated by the measuring device, should be self-replacing when the overload is removed, so that the operator can be independent of outside help.

Fuses and circuit breakers should be used only for a lifting motion as a protection against earths or defective electrical circuits, a sufficient time-delay action being arranged so that they may function after the mechanically operated circuit breaker. These should only be replaced by members of the skilled staff.

Strains on the mechanical gear and rope should be reduced by keeping down the angular momentum of the moving parts as much as possible.

addition, the motor must be prevented from running back if the power fails. This is dealt with under requirement (2).

(10) *To obtain good acceleration and retardation.*—The best results as regards acceleration and retardation are obtained by fitting an armature of low speed and as low a moment of inertia as possible and by the use of efficient gearing, the problem being not so much to accelerate the load as to accelerate the armature and other rotating parts. For instance, in the case of a winch fitted with a high-speed armature to lift 4 tons at 80 ft. per min. with a gear ratio of 26·5 to 1, the additional torque required at the armature to accelerate the load up to full lifting speed from rest in 1 second is about 120 lb.-in.

To accelerate the rotating parts up to this lifting speed from rest in the same time, the torque required at the armature is about 9 300 lb.-in.

With a low-speed armature of correspondingly larger size and with a small gear ratio, the rotating parts can be accelerated more quickly, as will be seen from the figures in Table 1.

TABLE 1.

Type of motor	Gear ratio	Moment of inertia of armature	Torque to accelerate armature	Torque to accelerate load	Normal torque to lift full load
			lb.-in.	lb.-in.	lb.-in.
High-speed (500 r.p.m.)	26·5 : 1	180 inch-lb. units	9 300	120	2 700
Low-speed (75 r.p.m.) ..	4 : 1	3 800 inch-lb. units	30 000	750	18 000

If the overload device has operated due to dead weight, the stresses in the rope and gearing are limited to this excessive load.

With the ordinary type of motor fitted to a crane or winch, the tension in the lifting rope to pull up the armature to rest from its normal lifting speed is about 80 times the required pull in the rope to bring the load to rest from the corresponding hoisting speed in the same time.

If the hook catches in some obstacle the stress in the rope is very great, due to the revolving parts, and can only be limited by making the angular momentum of these parts as low as possible and by fitting a powerful brake to pull up the revolving armature and gearing.

If the momentum is high the braking power must act quickly, and this in itself puts excessive stresses on the mechanical parts. A slipping clutch can be fitted to slip at a given load, to prevent excessive strains.

(9) *To prevent the motor from running back or re-starting if the power should fail without the operator's knowledge.*—If the power fails it should not be possible for the motor to start up again when the power is restored, if the controller has been left in the running position. The usual method of ensuring this is to make it necessary for the operator to come back to the "off" position before re-starting, by fitting a mechanical or electrically operated circuit breaker. In

In each case the winch is rated to lift 4 tons at 80 ft. per min.

The last column gives the normal full-load output expected from the motor, and it is apparent that the quick acceleration of the armature causes a heavy overload on the motor. In the case of the high-speed motor this overload is 3½ times full load, but with the low-speed armature the overload is only 1·7 times normal full load. Thus better acceleration can be obtained by fitting a motor of the low-speed type.

To run a motor up to speed quickly the difference between the applied voltage and the back E.M.F. must be kept as great as possible consistent with the overload which the motor will stand.

It is very difficult to obtain good acceleration at light loads, the reason being that the back E.M.F. rises quickly, whilst the field is slow in dying down.

Best acceleration is obtained under these conditions by weakening the series field by diversion at the start, an automatic diverter setting the field strength at the normal value for any particular load. The field strength is kept low and the armature current high.

It was found that by fitting a very low-speed armature that the motor could be started up without the use of timing arrangements on the contactors, the self-induction of the field windings being sufficient to limit the current to prevent sparking.

With the foregoing in view, the author considers that the best way of meeting these requirements and coping with the difficulties mentioned, is as follows :—

(1) To obtain the required lifting speeds the motor should have a field range of at least 2 to 1 by automatic field diversion, giving a speed curve as shown at B_1, Fig. 1.

The rushes of current should be kept down by having a highly inductive series field winding.

(2) The motor to be short-circuited across itself so as to generate should the load tend to lower.

(3) In order to keep the load under control, a form of rheostatic braking, with power from the line to lower light loads, should be fitted. A series diverter and shunt winding should also be fitted so as to get high light-load lowering speeds, the speeds suggested being as shown in curve H, Fig. 1.

(4) To prevent excessive speeds the rheostatic braking, and those arrangements for returning power to the line, must always be in operation even if the operator switches over to the light-load steps when lowering a heavy load.

(5) To obtain low-speed control on the hoisting motion an armature diverter should be fitted to reduce the effective voltage on the armature, or a foot brake should be applied to absorb the voltage in the main resistance.

This foot brake should be so interlocked that it cannot be operated without returning the controller to a step that will not overload the motor.

(6) "Dead slow" lowering speeds to be obtained by fitting rheostatic braking.

(7) In order that the load may answer quickly, rheostatic braking with sufficient power from the line to give good acceleration should be provided.

(8) Overloads to be prevented by measuring the load on the gearing side of the motor and arranging this device to open a circuit breaker when an overload occurs.

In addition, the angular momentum of the revolving parts should be limited, as far as possible, so that they can be arrested without the rope and gearing being unreasonably stressed.

Fuses or circuit breakers to be fitted only for electrical faults and to be supplied with timing arrangements to prevent them from operating before the mechanically operated circuit breaker, the former to be replaced only by the skilled staff.

(9) To provide protection against the effects of restoration of the power after failure, a no-volt circuit breaker to be fitted which can only be replaced when the master controller is in the "off" position.

(10) The rates of acceleration and retardation to be made as high as possible by fitting a low-speed armature with small moment of inertia, giving low angular momentum.

The starting gear should be so arranged that the current-kicks applied to the motor are as high as possible until the motor is up to speed, the machine being designed to stand these heavy rushes of current.

The series winding should be diverted before the starting resistance is cut out in order that the field strength can be kept down, thus avoiding the slow change of field due to self-induction.

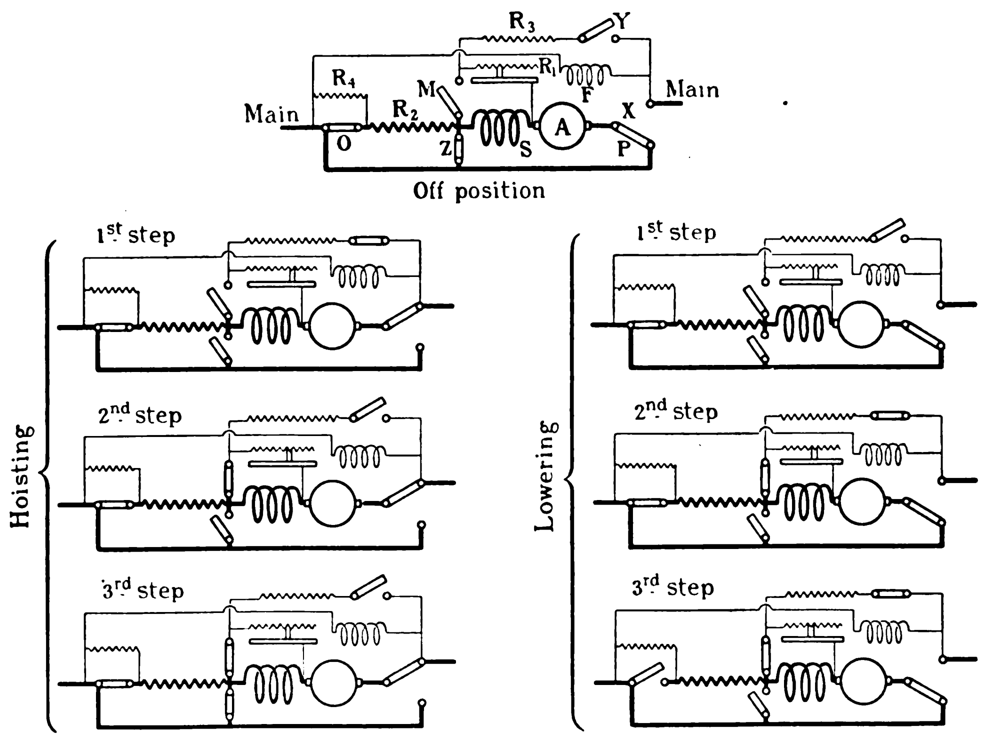

FIG. 5.

The connections which collectively provide for these conditions are shown in Fig. 5. The armature is denoted by A; S denotes a series field winding of value 90 per cent of the required field ampere-turns; F denotes a separately-excited shunt field winding of value 25 per cent of the total ampere-turns for lowering and 10 per cent for hoisting; R_1 is an automatically operated series diverter rheostat as in Fig. 3; R_2 is a starting and regulating resistance of such ohmic value as to give half speed with full-load current; R_3 is a starting resistance for lowering light loads; and R_4 is a resistance to be inserted to obtain high light-load lowering speeds. This resistance was found necessary as an alternative to breaking the circuit to ensure the excitation of the motor when lowering heavy loads. It is of such ohmic value as to pass 15 per cent of the full-load current with the series field, armature, and R_2 in series across the mains.

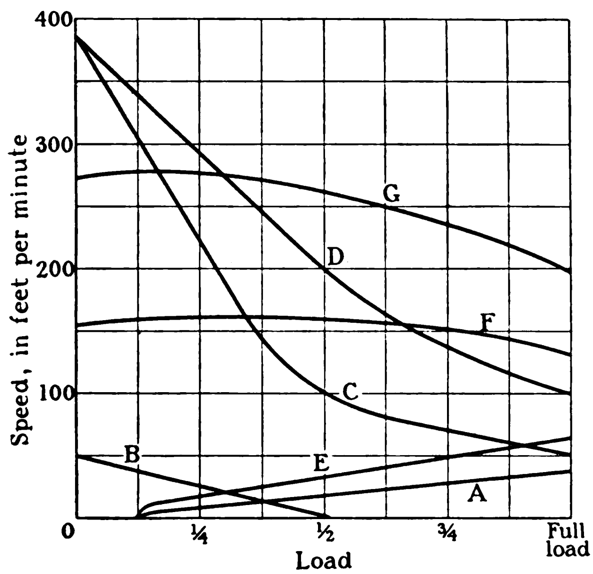

FIG. 6.

XP denotes a change-over contactor operated by a coil which, when energized, closes the side X, the contactor normally remaining in position P when the controller is placed in the off position or when the voltage fails.

O and Y are contactors which close when their operating coils are energized from the line voltage.

M denotes a contactor which closes when its operating coil is energized by the armature voltage.

Z denotes a contactor which opens when its operating coil is energized by the line voltage, and closes when the power fails.

It is preferable that these contactors be electrically operated, as the change-over connections are then more easily arranged. With mechanically operated contactors difficulties arise in the no-volt condition.

With the master controller in the " off " position the change-over contactor XP is closed in position P and contactors Z and O are also closed, the motor armature being connected across its own series winding. If the load is sufficient to drive the machine, the latter acts as a dynamo, the speed of lowering being dependent on its internal resistance.

Suppose the voltage-drop in the armature and series winding with full-load current to be X volts, and the line voltage to be Y volts, then the ratio of normal speed to lowering speed is given by $(Y - X)/X$.

For loads below full load the speeds must be adjusted for alteration in field strength due to the shape of the magnetization curve. If the field strength were directly proportional to the ampere-turns the speed would be the same for all loads (see curve A, Fig. 6).

Three hoisting and three lowering steps, in addition to the " off " position, are provided on the controller, and these act as follows :—

1st hoisting step.—The change-over contactor XP moves from position P to position X. Contactor Z opens and contactor Y closes. This connects the armature and series winding in series with the starting resistance across the mains and with a resistance in parallel with the armature. The speeds obtained are shown by curve B, Fig. 6.

2nd hoisting step.—Contactor Y opens and disconnects the resistance in parallel with the armature.

Contactor M closes and connects the automatically operated diverter rheostat across the series winding.

The amount of current diverted depends upon the load. If the motor is fully loaded, the diverter is cut out. Half full speed is obtained for any load above half full load with a certain value of starting resistance. The speed can be varied by varying the value of this resistance. For lower loads the speeds are proportionally lower. Curve C, Fig. 6, gives the speeds obtained.

3rd hoisting step.—Contactor Z closes and short-circuits the starting resistance. The motor is now connected across the mains with its series winding diverted for any load below full load (see curve D, Fig. 6).

1st lowering step.—The change-over contactor XP remains in position P as for the " off " position. Z opens and the armature and series winding are now connected across the starting resistance R_2. The load must be sufficient to drive the motor on this step (see curve E, Fig. 6).

2nd lowering step.—Contactor Y closes, connecting the motor to the line as a shunt motor with the series winding acting as an inefficient shunt winding.

When the voltage across the armature rises, contactor M closes, connecting the diverter across the series winding and connecting the main so as to supply current to the other end of the series winding.

If the load is not driving the armature, part of the current passes through the series winding so as to oppose the effect of the shunt winding, giving a weak field to keep up the speed for light loads.

If the load is already driving the motor the series winding helps the shunt winding and so keeps the load under control by generating across the resistance R_2 (see curve F, Fig. 6.)

3rd lowering step.—Contactor O opens, inserting the resistance R_4 in the dynamic braking circuit.

If the load is driving, the motor increases in speed

until the voltage is such as to cause it to generate back to the line.

While the motor is accelerating in order to attain a voltage to overcome that of the line, a small current is passing through R_4 to help the excitation (see curve G, Fig. 6).

When lowering light loads the value of the diverter must be such that the current in the series winding does not increase sufficiently to overpower the shunt. As the speed rises due to the weakened field, the current required to drive the armature increases and if the diverter does not take enough current the motor will reverse. Since the operating coil of contactor M is connected across the armature, if the motor tends to stop and reverse, this contactor will keep dropping in and out and the motor will hunt.

It should be noted that if the resistance of R_3 is of such a value as to allow rushes of current through the series winding heavy enough to overpower the shunt winding, the same conditions hold good (see curve G, Fig. 6).

It was found when using a winch fitted as described above that the master controller could be put over to any step without pausing on intermediate steps. For example, the operator could pass from full hoist to full lowering steps without the current exceeding about twice full-load value or causing any sparking on the commutator. Thus the control may be said to be perfectly foolproof.

When the connections in Fig. 4 are used for a deck winch on board ship a difficulty arises in that the winch may be required to lift or warp for either direction of rotation of the winch end. This difficulty can be overcome by fitting a reverser for the armature connections which remains locked unless the master controller is in the " off " position.

After experimenting with this arrangement of connections the author came to the conclusion that it could be simplified and the cost reduced on the following lines :—

(i) It is of very little use to have a motor with a series-wound characteristic, since the automatically operated diverter can be arranged to regulate a resistance to adjust the value of a shunt winding to give the required speed/load curve.

(ii) The motor would start up without resistances if the series winding could be arranged to give an inductive effect equivalent to that of the winding of a motor with a series characteristic, only a few ampere-turns being used for normal running, the rest of the current being diverted after starting.

(iii) The resistances being only necessary for speed regulation, these could be dispensed with if the shunt regulating resistance were short-circuited to give full field on the regulating step.

(iv) All the braking required for lowering can be done by regenerating back on to the line, provided an excess voltage relay is fitted to short-circuit the motor across its own series winding should the power fail.

(v) The required speeds with light loads, including no load, can be attained by arranging an electrically operated reverser which discriminates automatically as to whether the machine is motoring or braking.

To obtain the desired conditions a motor of low-speed type is used, with a field winding of high enough resistance and sufficiently inductive to keep the starting current within the sparking limits of the motor without the use of starting resistances being necessary.

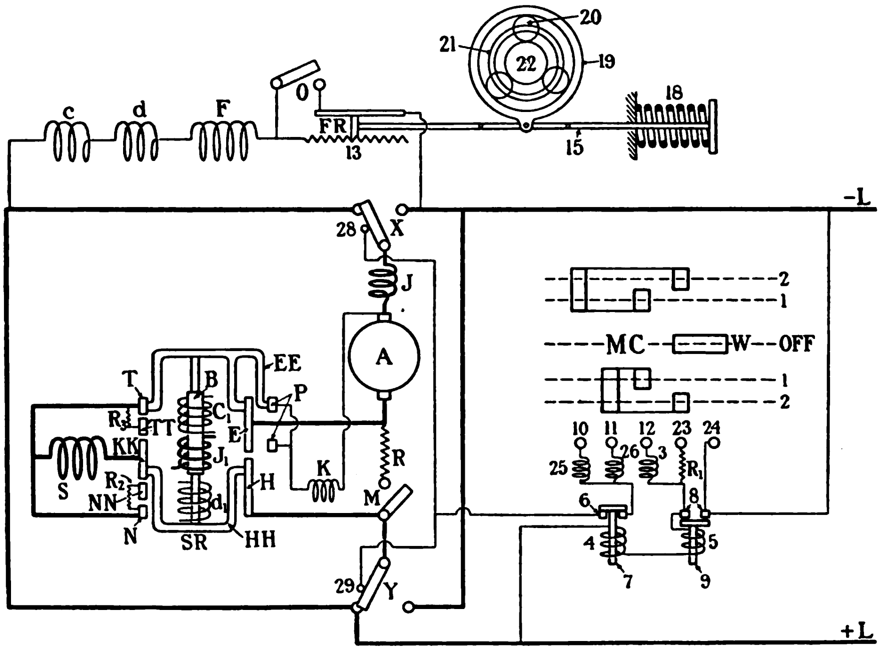

FIG. 7.

In Fig. 7 the armature is denoted by A. S denotes the series winding which has sufficient turns to give the required field, when carrying a current within the limits of the motor, to supply sufficient torque to resist the full load when the machine acts as a series generator. This series winding has to carry full current only for a short time when starting up, so need only be of small current-carrying capacity.

F is a shunt winding with sufficient ampere-turns to supply the principal part of the field flux.

FR is a variable rheostat operated mechanically as previously described, but in this instance the rheostat movable contact 13 inserts a resistance in series with the shunt winding F, the maximum resistance being inserted when hoisting or lowering "light hook" and the whole of the resistance being cut out for full load.

O is an electrically operated contactor which, when its operating coil 3 is energized, makes circuit and cuts out the resistance in the variable rheostat "FR."

X and Y are electrically operated change-over contactors which connect to the main (+ L) when their operating coils 25 and 26 are not energized, either being able to connect to the main (— L) when its operating coil is energized.

M denotes an electrically operated contactor which makes circuit when its operating coil K is energized by the voltage across the armature A.

R denotes a diverter resistance which shunts sufficient current out of the series winding S, when contactor M closes, to keep the current within the carrying capacity of the winding.

SR is an electrically operated reverser which acts in the following manner :—

The fixed contacts E and H are connected, one to the armature A and the other through the contactor Y to the main (+ L or — L).

The fixed contacts T and N are both connected to one end of the series winding S, and contact KK to the other.

Coils c and d are connected in series with the shunt winding F and are arranged to oppose each other. Coil J is connected in series with the armature A. These coils are indicated in position on the reverser SR, coil c as C_1, coil d as d_1 and coil J as J_1.

B is an iron core which is mechanically connected to, but insulated from, movable contacts EE and HH.

R_3 and R_2 are resistances connected to the fixed contacts T and TT, and N and NN, respectively.

When the coils C_1 and d_1 only are excited, the iron core B takes up a central position ; the movable contacts EE and HH, being attached thereto, connect contacts E to TT and H to NN.

The current will then pass from the armature (A) through the resistances R_3 and R_2 back to the main (+ L or — L) through contactor Y.

If coil J_1 is excited to help coil C_1 and oppose coil d_1, the iron core B will take up a position between coils C_1 and J_1. The movable contacts EE will then connect contacts E and T, and the contacts HH will connect contacts H and KK, passing the current in the series winding in a prearranged direction so as to help the shunt winding F.

If coil J_1 is excited to help coil d_1 and oppose coil C_1, the iron core B will take up a position between coils d_1 and J_1, and the movable contacts EE will then connect E and KK and contacts HH will connect H and N, passing the current through the series winding S in the opposite direction.

A relay 4 breaks contacts 6 when the line voltage is exceeded by a predetermined amount. The relay 5 breaks contacts 8 when the line voltage fails.

The operating coils of 4 and 5 are connected across the mains (+ L and — L) through contacts 8 or 23 and 24.

The operating coils 25, 26 and 3 are connected across the mains through contacts 28 and 29 when the master controller drum MC is in one of the running positions, each of the coils being energized in turn according to the position of the master-controller contacts.

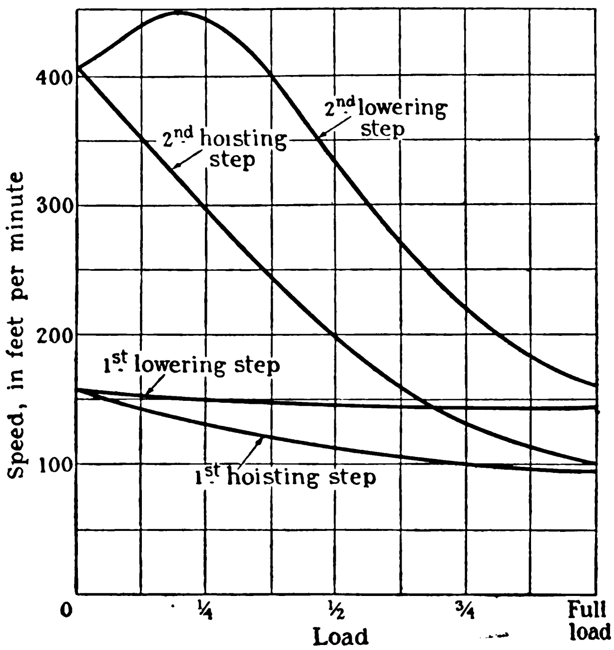

FIG. 8.

R_1 is a resistance having an ohmic value equal to that of coil 3.

MC denotes a master-controller drum fitted with connector pieces so that the connections through the finger contacts 10, 11, 12, 23, 24 can be altered in a prearranged manner at will.

The motor is controlled in the following manner : The master-controller drum MC, when in the "off" position W, connects contacts 23 and 24. This makes the connection through the relay-operating coils 4 and 5, lifting the relay plunger 9 and connecting contacts 8, enabling relay 5 to maintain its own operating circuit. Relay 4 is energized, but its contacts 6 remain connected unless the voltage on the motor exceeds the normal line voltage by a prearranged amount.

The operating coils 25 and 26 are not energized and the reversing contactors X and Y remain connecting both ends of the motor leads to the same main (+ L), leaving the armature (A) connected across the series

winding S, acting as a generator should the load tend to revolve the armature.

The shunt F and coils C and d are separately excited across the mains (+ L and — L) and decide the direction of rotation of the armature (A).

If the master-controller drum MC is moved to step 1, contacts 11 and 12 are connected and coils 26 and 3 are energized, changing over contactor X to connect to winding S always excites the magnetic circuit of the motor to help the shunt winding.

If the load requires to be driven the motor takes current from the mains, but if the load is driving the motor the back E.M.F. rises above the supply voltage and current is returned. If the master controller is moved to step 2, contacts 11 and 23 are connected, the current passing from main (+ L) through coil 26

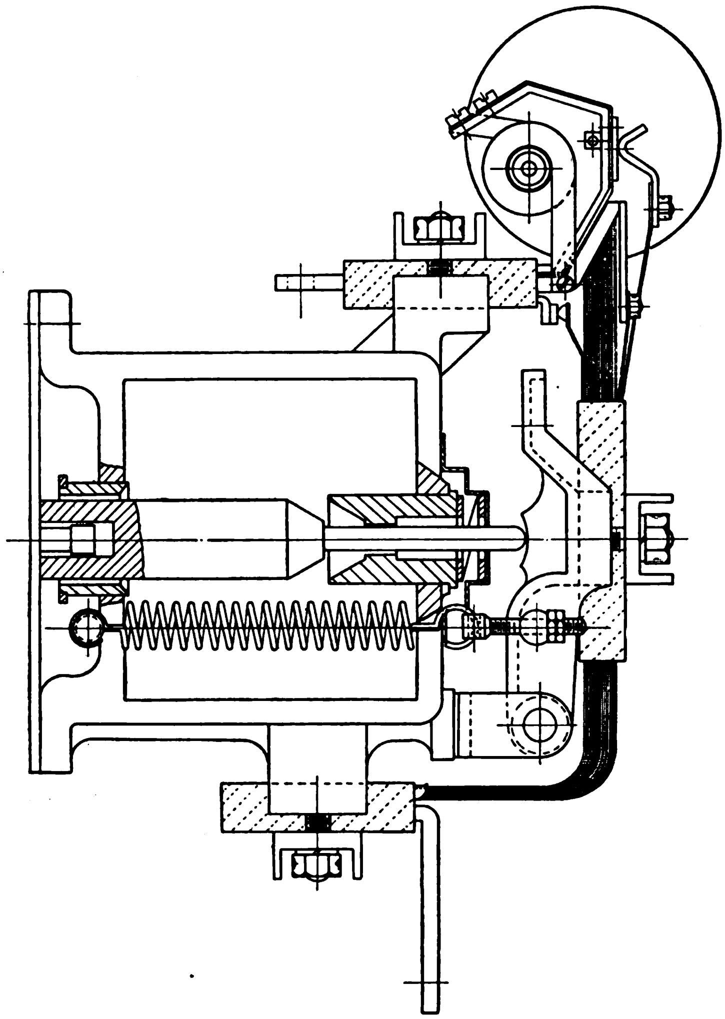

Fig. 9.

the main (— L). The motor is now connected across the mains and the variable rheostat FR is short-circuited by contactor O. The armature starts to rotate and, when the voltage across it reaches a predetermined value, the operating coil K being energized, contactor M makes circuit to diverter resistance R, dividing the current between this diverter and the series winding S.

From the description of the reverser SR it will be seen that the current passing through coil J in the same direction as through the armature decides which way current passes through the series winding.

The connections are so arranged that the series to the other main (— L), passing through resistance R_1 instead of coil 3.

Coil 3 not being energized, contactor O open-circuits any resistance that may be inserted by the variable rheostat FR. This weakens the shunt winding F for any load less than full load and an increased speed is obtained.

If the master-controller drum MC is moved in the opposite direction contact 10 is connected instead of contact 11, the reversing contact Y being operated instead of contactor X, Y connecting the motor to the main (+ L). The current passes through the

armature in the opposite direction and reverses the rotation.

To prevent an excessive rush of current due to the controller drum being rapidly brought from the full-on position for one direction of rotation of the motor to the reverse rotation, resistances R_3 and R_2 and contacts P are fitted to the reverser and contacts 28 and 29 are fitted to the change-over contactors X and Y and act in the following manner :—

If the motor is running light the reverser SR remains in the mid-position, there being insufficient current in coil J to be effective. The current through the armature must therefore pass through resistances R_3 and R_2 instead of through the series winding.

These latter are adjusted to limit the rush of current to a particular value when starting up the motor without the series winding.

Contacts P are disconnected, so that the operating coil K of contactor M does not function and the circuit through the diverter resistance R is broken.

If the motor is loaded, the reverser is in one of the extreme positions and one of the contacts P makes circuit to the operating coil K of contactor M, but when the reverser changes over, these contacts are broken and M opens during the change-over.

The coils 25 and 26 of change-over contactors X and Y are connected to the main (+ L) through contacts 18 and 19 so that the circuit to these coils is broken if both X and Y are operating together. Therefore the contactor which is breaking circuit from main (— L) must connect to main (+ L) before the other contactor can operate to make circuit to main (— L). This gives a delay action during the change-over.

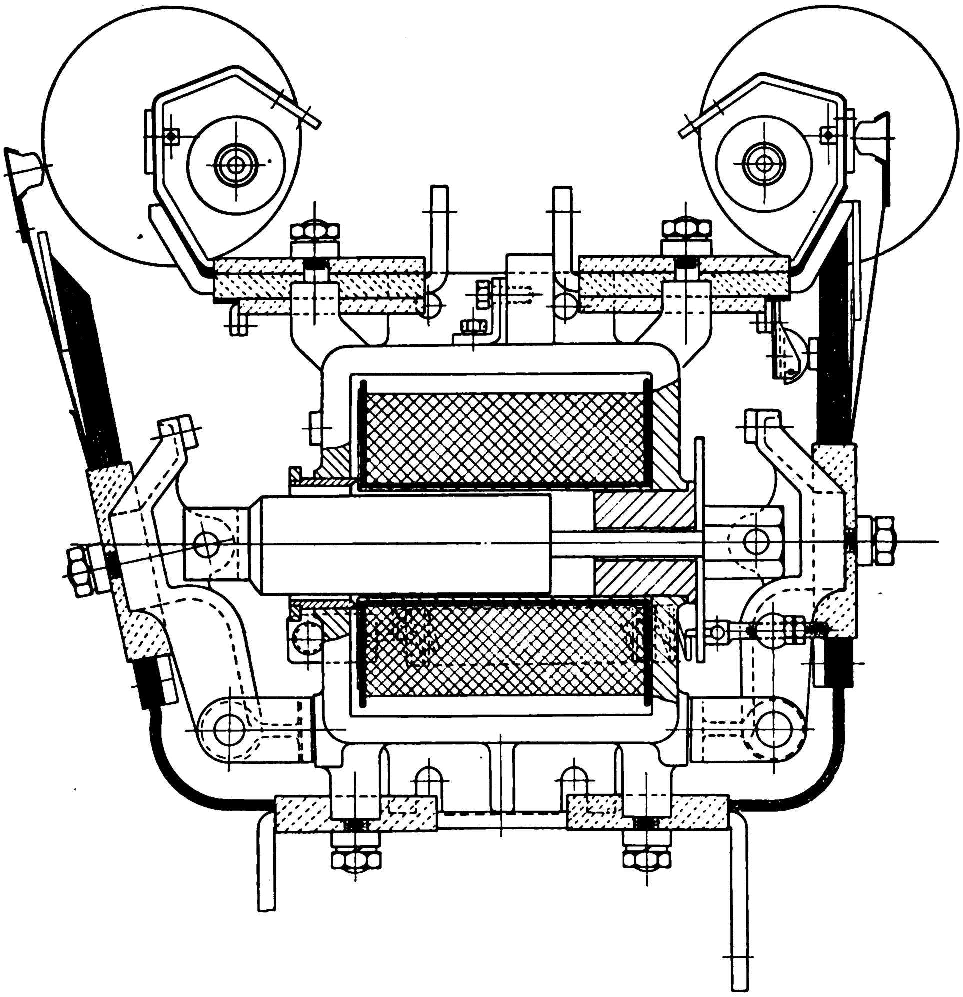

Fig. 10.

Excess voltage.—If the voltage fails and the motor is generating, through being driven by the load, then when the voltage across it rises above the line voltage by a prearranged amount the relay core 7 lifts and breaks contacts 6, disconnecting the circuit to the operating coils 25 and 26, and contactors X and Y make connection to the same main (+ L). The armature is now connected across the series winding and acts as a generator, keeping the load under control.

If the voltage fails under any conditions, relay coil S is de-energized and the core 9 disconnects and breaks its own circuit. This circuit is made again only by returning the master-controller drum to the "off" position W, making contacts 23 and 24.

The speed curves obtained from this arrangement are given in Fig. 8.

The difference between the hoisting and the lowering speeds is due to the difference between the voltages while generating and motoring, caused by the copper losses in the machine.

The advantages of the method of control here described may be recapitulated as follows :—

The efficiency of the system is high, since power is returned to the line when lowering the load, and the small gear reduction employed decreases the mechanical losses.

Low speed for taking up slack in the cable is obtained without losses in resistances.

In tests made upon a winch designed to lift 4 tons at 80 ft. per min., using this system, an overall efficiency of 65 per cent at full load was obtained. The efficiency remains comparatively high down to about one-quarter full load.

Stresses in the mechanical parts are reduced to a minimum since the angular momentum of the rotating armature is comparatively low, and the duration of an overload is made shorter by the insertion of an overload device in the mechanical, instead of the electrical, side of the machine.

The load is lowered under full control at predetermined speeds, without the wear and tear of a mechanical brake, and, when hoisting, the use of such a brake to prevent the load from running back is avoided.

The speeds obtained at light and medium loads are higher with a given size of motor, and the speed range is not limited by the characteristic of the machine.

The rates of acceleration and retardation are unusually high, full lowering speed being quickly attained by the application of power, until regenerative speed is reached, while the load is promptly checked and landed carefully and without damage.

The copper losses in the motor being heavy, the current is low when the machine is stalled.

The figures and curves given in the paper were obtained during tests made upon ships' deck winches designed to lift 4 tons at 80 ft. per min., the gear ratio employed between the armature and the lifting barrel being 4 to 1. The motor was without interpoles, 12 main poles being fitted, and was designed to run at 52 r.p.m. when lifting 4 tons at full speed.

The apparatus used in obtaining the curves shown in Fig. 8 was purely of an experimental nature. This particularly applies to the reverser then employed.

The special contactors used are shown in Figs. 9 and 10.

With regard to the comparative costs of the high- and low-speed types of motor, it must be considered that although that of the low-speed motor taken alone is excessive, the fact that the motor is embodied in the winch, the absence of magnetic brake, etc., and the reduction in the cost of mechanical parts and protective appliances, make the arrangement competitive for a given duty and rating. It is also open to question whether the low-speed machine for intermittent duty cannot be more highly rated for equal reliability since, for instance, the short-circuit current is lower and the motor is thus less likely to be stressed through ill-usage.

The author has found that the duty of a crane or winch seldom bears any relation to the rating specified for the motor, and he suggests that the specification should give the required temperature-rise for a duty of so many tons to be transhipped a given distance in a stated number of hours.

As the reliability of a low-speed motor is only limited by the permissible temperature-rise, the duty it has to perform should be more closely considered and the limit of temperature-rise more closely approached under working conditions.

THE PROPAGATION OF RADIO WAVES.

By J. HOLLINGWORTH, M.A., B.Sc., Associate Member.

[From the National Physical Laboratory; communicated by permission of the Radio Research Board.]

(*Paper first received* 23*rd October, and in final form* 24*th December*, 1925; *read before the* WIRELESS SECTION 3*rd February*, 1926.)

SUMMARY.

The paper gives the results obtained from a systematic study of the received intensities of various long-wave transmitting stations at four receiving stations over a period of nearly two years.

The weekly averages of the results are studied, and it is shown that they are inconsistent with any law of steady decay. The results also show very marked periodic variations.

It is suggested that all the observed effects can most easily be explained on the assumption of an upper refracting layer. This is supported by the results obtained from plotting an intensity distance curve in detail by means of a portable set, and by the study of the systematic changes which take place daily during the sunset period.

Various conclusions are drawn from these results, but it is pointed out that considerable further experimental investigation of many of the observed phenomena is necessary.

INTRODUCTION.

The study of the propagation of radio waves through the space between the transmitting and receiving aerials is one that has attracted many workers, as it is of fundamental importance. Ever since the early days the discrepancies between actual and expected results have demanded explanation. The problem has often been attacked from the theoretical side; but in those days, largely owing to the limitations of experimental technique, the underlying physical data were indefinite, and consequently very varying results were obtained. With the development of the thermionic valve and the resulting more accurate measuring apparatus, however, it has become possible to put the experimental side on a firmer basis and so provide more definite information for the theoretical solution.

Even from the experimental side there are two ways of approaching the subject, though the line of demarcation is not always sharply defined.

The first is primarily concerned with obtaining data for reception and transmission purposes; and so is most concerned with long-distance transmission under working conditions. Valuable theoretical results may, and do, follow from this, but they still remain a secondary factor. On the other hand immediate practical results may be subordinated, the measurements being viewed chiefly as a convenient means of examining the electrical state of the intervening medium, in which case it often happens that the actual figures obtained have no direct practical application. In the following work the second of these two alternatives has always been given most consideration, and consequently, after the first preliminary trials, all experiments have been chosen with a view to illustrating some particular feature to the best possible advantage.

APPARATUS.

The apparatus is substantially the same as that described in a previous paper,* the only considerable alteration being the substitution of a Dye transformer † for the calibrated mutual inductance. Actual experience has, of course, resulted in a certain number of detail modifications both in design and in operation, the chief one being the addition of a string galvanometer so that readings can be taken on the ordinary routine of a station; but the fundamental principle remains unchanged.

GENERAL PRINCIPLES.

This series of experiments differs from the majority of those which have already been made on this subject in several important particulars. The chief of these are:—

(*a*) Distances are comparatively short.
(*b*) Simultaneous observations have been taken whenever possible.
(*c*) Only daylight transmissions have been considered.

As these are not accidental, but part of a settled policy, they require a short consideration.

Experiments of this nature differ from many others in containing an excessive number of unknown and uncontrollable factors. In the first case, many of the causes of variations are at present altogether unknown, and the experimenter has practically no power of controlling them, or even of being able to repeat an experiment under reasonably similar conditions. Secondly, although on ideal grounds the transmitting station should be under his control or, as in the case of the special "URSI" signals, be working under carefully observed conditions, it is in practice impossible to extend this to all the observations which become necessary; so that, even in the case of the known possible causes of variation, the control is still incomplete.

Scientifically, this means that the number of independent variables is unusually large; so that unless the routine of observation is controlled as rigidly as possible, masses of results are obtained under such indeterminate conditions that, except on a purely statistical basis, no attempt can be made to sort out the various causes. In the early days of the work this rule was, of course, less rigidly applied, but as soon as an inkling into possible causes had been obtained, subsequent experiments were planned to illustrate that particular point under the most favourable conditions.

* *Journal I.E.E.*, 1923, vol. 61, p. 501.
† *Ibid.*, 1925, vol. 63, p. 597.

It is not denied that the results of long-distance work are in practice the most important and yield the most surprising results. They are also the ones to which most attention has been given by other experimenters, so that a considerable amount of information is already available about them. If, however, the matter be considered in the same light as any other physical experiment, the natural method is to take the simplest cases first, and to work up from them to the more complex. After all, the mechanism of propagation must always be the same, though it may exhibit its effects differently at different distances.

Comparatively short-distance work appears to offer an opportunity for reducing the uncertainty with regard to some of these independent variables, as it seems reasonable to suppose that there is a chance of natural phenomena being more constant over small areas than over large ones. In particular, it removes the special cause of difficulty in long-distance transmission in which the path contains both day and night sections. It also tends to higher accuracy of measurement, owing to the more powerful signals in relation to disturbances.

It appears very doubtful whether any satisfactory generalizations can be drawn from measurements of a single transmitting station at a single receiving station. Such a process assumes that the situation of the receiver is ideal and unaffected by local conditions, and also that the law of propagation is perfectly regular and uniform, and it offers no verification of either of these facts. Consequently, in these experiments four receiving stations have been used, at Slough, Manchester, Glasgow and Aberdeen. These sites had to be chosen more with a view to the facilities available than on scientific grounds, but the results obtained seem to justify their choice.

Experimental Results.

The basis of all the earlier work has been the "URSI" signals. These are special transmissions arranged under the auspices of the Union Radio Scientifique Internationale, and consist of a preliminary call—URSI de . . . .—then a statement of the exact wave-length and aerial current of the previous day's transmission, followed by a steady dash lasting two minutes. Those of which most use has been made are :—

(i) From GBL (Leafield) daily except Sundays and public holidays at 1400 G.M.T.; $\lambda = 12\,350$ m; $I = 200\ a$ (nominal).

(ii) From UA (Nantes) daily at 1415 G.M.T.; $\lambda = 9\,000$ m; $I = 180\ a$.

(iii) From LCM (Stavanger) daily at 1000 G.M.T.; $\lambda = 12\,140$ m; $I = 200\ a$. (In this case the signal consists of a series of 20-second dashes.)

A signal is also sent from LY (Bordeaux) at 1955 G.M.T.; $\lambda = 18\,900$ m; $I = 480$; but this has not been much used up to the present, owing to its proximity to the sunset period.

Routine observations have been kept on these stations since June or July 1924 and, in the case of Nantes, at Manchester since March 1924. Slight interruptions have been caused at times owing to the fact that to obtain trustworthy results it is vital to employ competent experimenters, who, in general, could only give part of their time to the work.

These results have been sent to Teddington, where they are reduced to a fixed aerial current and then each set is averaged weekly. The system of weekly averages, each involving, as it does, from two to six readings only, was adopted after some consideration, as it was felt that they were rather small groups to average.

The plotting of daily results was soon found to be too cumbrous, whereas monthly averages would have enormously lengthened the work, and might possibly have hidden interesting transient results of shorter period. On the whole, the study of the curves seems to show that the system of weekly averages has been fairly justified.

The results require analysis on both a time and a space basis, i.e. a study of the week-by-week variations at each receiving station of each transmitter, and also of its simultaneous distribution at all four receiving stations. In view of the number of graphs involved, and the widely different scales to which they have to be plotted, it is necessary at times to plot selections from them in various fashions, but for the present all results will be derived from the weekly figures referred to above.

Seasonal Intensity Graphs.

Fig. 1 gives the weekly averages of the observations on Nantes and Leafield at the four receiving stations over the period June 1924–December 1925.

Considering first the early months, the most striking feature is that Manchester recorded, on Nantes, signals equal to and even greater than those at Slough, although the distances are 695 km and 485 km. It was also noticed that, on the few individual days when variations did occur, they usually appeared at all stations, but not necessarily in the same direction. An unusually high value at one station was generally accompanied by a low value elsewhere.

During September 1924, although the change in weekly averages was mostly small, day-to-day variations became much larger; and at the same time it was noticed at Slough, where simultaneous readings of direction were taken on another set, that the bearings were becoming unsteady and the minima poor. In October, however, big changes began to occur, culminating in the sudden and enormous variations in the week 25th October–1st November. Consideration of the daily logs shows that actually the majority of the changes occurred between the 27th and 30th October, and, as it was really this which gave the first suggestion of a possible cause, it requires discussion in detail.

The first, and most striking, characteristic was the simultaneity of the changes. In these few days signals from stations as far apart as Nantes and Stavanger, at receivers as far apart as Aberdeen and Meudon, showed abrupt changes, amounting in some cases to over 100 per cent, and the figures published by Prof. Mesny in *L'Onde Electrique* of readings on Bordeaux at Meudon show the same variation (see Fig. 2), even though at this time of year this signal is sent several hours after dark. Traces of the effect are also visible in Dr. Austin's

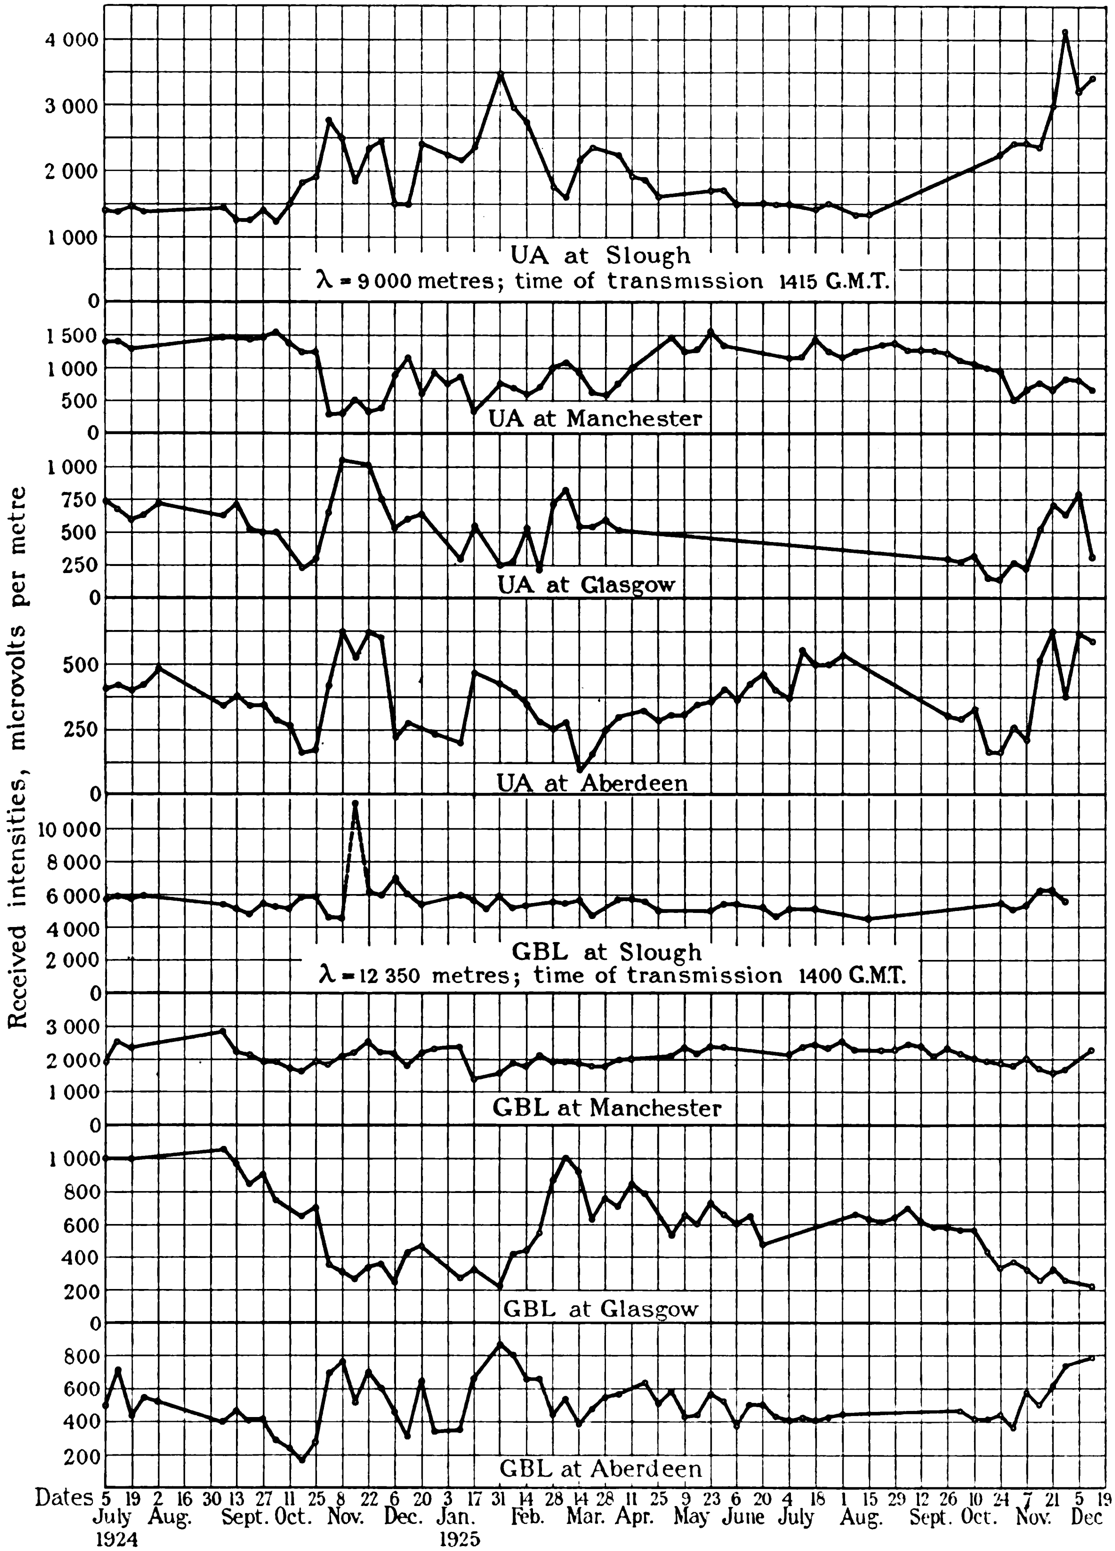

FIG. 1.—Diagram showing weekly average intensities of "URSI" signals from UA (Nantes) and GBL (Leafield) at the four fixed receiving stations.

figures for observations on some of the European stations at Washington,* and in a recent paper by Captain Round and Mr. T. L. Eckersley † Fig. 14 seems to indicate a similar phenomenon in previous years, though the exact time of its occurrence is not so definitely marked. The effects were not merely transient, as in most cases, although the day-to-day unsteadiness was very marked; there was in the following weeks no definite reversion to the summer values.

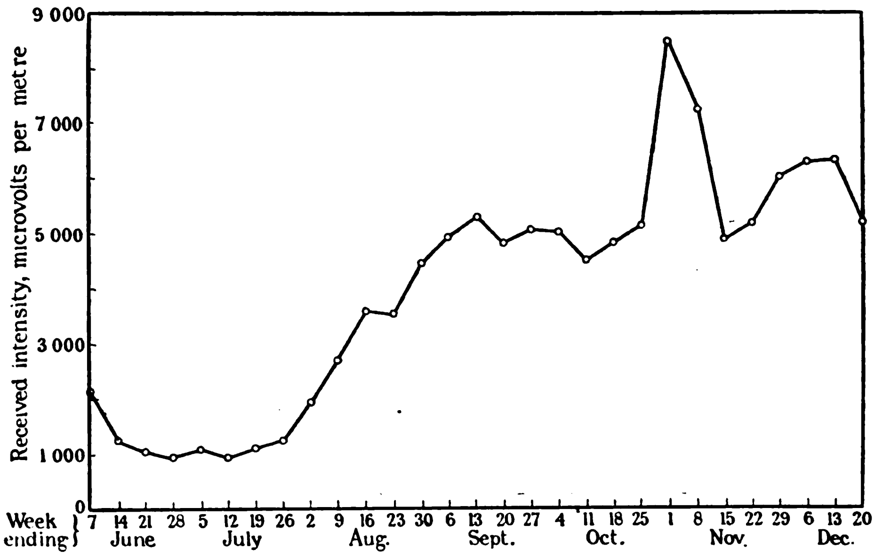

FIG. 2.—Weekly average of "URSI" signal from Bordeaux (LY) received at Meudon by Prof. Mesny. $\lambda = 1\,920$ m; time 1955 G.M.T.; distance, 520 km.

In 1925 the results were very closely similar, in that, during the spring, signals gradually steadied down again to practically the same values as those during the previous summer. In the autumn the same feature

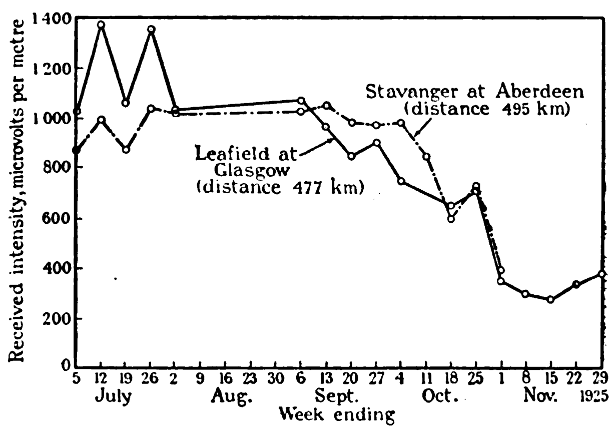

FIG. 3.

of the abrupt October change again occurred on practically the same days. Another fact, perhaps equally striking, is that after this date the day-to-day variations were enormously greater than before it.

* *Journal of the Washington Academy of Sciences*, vol. 15, p. 227.
† *Journal I.E.E.*, 1925, vol. 63, p. 943.

For instance, in the week ending 29th November, 1925, the daily readings of Nantes at Manchester were 1 320, 1 390, 50, 209, 550; and at Aberdeen 560, 500, 241, 115, so that with results like this a weekly average figure has not much meaning. This will be referred to later.

It is hardly possible to avoid the conclusion that these changes were not due to local variations, but to some main cause operative over a large area, and the possibility is also suggested that all signal-strength variations might be due to this cause, differing in degree rather than in kind. Also, in view of the fact that the signals from Leafield at Glasgow and from Stavanger at Aberdeen (see Fig. 3) were practically equal, although the

TABLE 1.

Distances between Transmitters and Receivers.

	Slough	Manchester	Glasgow	Aberdeen
	km	km	km	km
Nantes (UA) ..	485	695	973	1 100
Leafield (GBL) ..	78	184	477	590
Stavanger (LCM) ..	911	775	680	495
Northolt (GKC) ..	13	243	540	630
St. Assise (FT) ..	396	635	930	1 000

former path is entirely over land and the latter entirely over sea, it does not seem possible to admit the conductivity of the ground as a major controlling factor. It seems most unlikely that this conductivity should remain constant for over four months, and then change suddenly and completely in two days, especially as it will be remembered that 1924 was an extremely wet year, and there are no signs of permanent weather change about this date. Also, Smith-Rose and Barfield

have shown * that in the British Isles, at any rate, the conductivity of the soil for long wave-lengths is of a high order.

Further, it will be noticed that at times during the 1924 winter period the intensity of the signals from Nantes at Manchester is actually less than that at Glasgow and Aberdeen, whereas in the case of Leafield the Aberdeen figures are above the Glasgow figures. The various distances are given in Table 1.

For medium distances, therefore, it seems that there is no justification for holding to any law of steady decay except for purely practical average purposes, because to explain the above figures on such a basis, modified by purely local conditions at each station, would involve a large number of simultaneous and elaborate but totally independent coincidences.

It remains to be seen if all these effects can be approximately accounted for by a single cause.

Intensity/Distance Distribution.

To discuss this it is necessary to make use of space-distribution curves, i.e. to plot intensity against distance and not against time. Such a curve is given

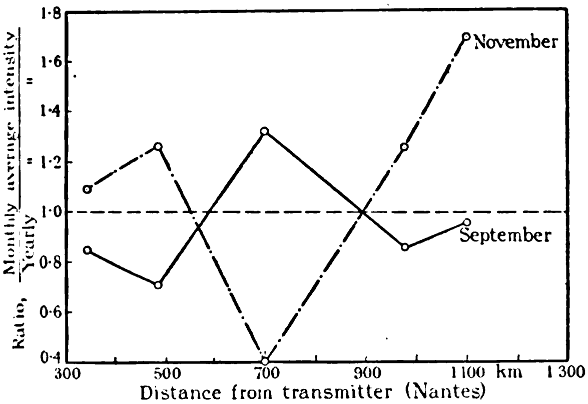

Fig. 4.

in Fig. 4, but the ordinate scale is unlike the previous ones owing to the fact that, due to the ordinary attenuation, the actual intensities at the various stations are widely different. For the moment we are more interested in the relative variations than in the absolute values, consequently the ordinates in Fig. 4 are the ratio of the monthly average intensity at any point to the mean annual intensity at that point. By this means the relative changes at each station can be studied on a common scale. As at the moment it is the change during October which is under consideration, the two curves in Fig. 4 are derived from the monthly averages in September and November. The September curve is closely similar to those of the preceding months and may be taken to represent the average summer distribution ; October is deliberately omitted, being treated as a transition period. The characteristic features of these curves are clearly the alternation of high and low values, and also the complete reversal of form between the two months.

Curves of this nature at once suggest something in the nature of an interference phenomenon, so that from this point the primary object of subsequent experiments has been to study this effect under the most favourable conditions.

Now if, as suggested by this and previous results, the intensity/distance distribution is not a smooth curve, it follows immediately that a very much larger number of points on it are required than can possibly be obtained from the four fixed stations ; so it was decided to proceed immediately with the construction of a portable measuring set, and meanwhile to carry on with the steady routine of " URSI " signals with a view to their future interpretation.

A study of Fig. 1, and more especially of the daily logs, shows that for an experiment of this nature, which would inevitably occupy some weeks, the work could only be done at a period of the year at which the day-to-day consistency was highest. This limits the possible period to from the middle of May until the middle of September, and consequently the early months of 1925 were occupied in the development and construction of the portable set. The work gained added interest about this time from the publication of an article by Prof. Appleton and Mr. Barnett,* suggesting the existence of a similar phenomenon on shorter waves ; but unfortunately their experimental method was not practicable in the case of long-wave high-power stations. Various delays intervened, and finally it was impossible to start work with the portable set before the middle of June.

Although the original ideas had been derived from measurements of the signals from Leafield and Nantes, neither of these stations was quite suitable for the purpose of this later experiment. In the case of Nantes, its working hours are short and irregular, and for this sort of work it is vital to have a station working practically continuously, as when on tour it is impossible to guarantee arrival at a fixed spot at a fixed time. The geographical situation of Leafield is also not altogether satisfactory, as an inspection of the figures already obtained suggested that the phenomenon would not in this case become strongly marked until the north of Scotland was reached, which would involve an excessive amount of travelling, together with a possibility of not being able to extend the tour far enough away from the station to obtain the required result. Choice finally fell on St. Assise (FT ; $\lambda = 14\,350$ m). This station appears to work almost continuously during the most suitable observing hours (10 a.m. to 4 p.m.) and it gives a powerful signal, which is most convenient since the limitations involved in making a set portable lead to a slight sacrifice of sensitivity and accuracy. Preliminary tests also showed that the signal usually maintained a very steady value throughout each period of working.

Moreover, reports from the fixed observing stations during May showed that, whilst it was well received at Glasgow and Aberdeen, considerable difficulty was experienced with it in Manchester, where signals were, on an average, only about one-third of the strength of those at Aberdeen. It was thought that either this was a very marked case of interference, or that

* *Proceedings of the Royal Society*, A, 1925, vol. 107, p. 587.

* *Nature*, 1925, vol. 115, p. 333.

Manchester conditions were abnormal, so that a tour on this station might enable a definite decision to be reached.

Five tours were therefore made, four being confined to working as nearly as geographical conditions would permit on the great circle from FT to Aberdeen, and one with the definite object of getting as far away from this great circle as possible, in order to see whether the effects were confined to any particular direction. During these tours control observations were kept at one, at least, of the fixed stations.

In an experiment of this nature, besides the question of day-to-day consistency, there is also the factor of suitable sites, as, especially in hilly country, the choice of what appears to be an ideal position for a site is not always available. Of the actual sites on which the readings were obtained, some did certainly appear to be very good, being situated in open country free from steep hills, heavily wooded country, or long-distance telegraph lines. Such good sites were obtained, in particular, on Salisbury Plain, on Dartmoor, and in the neighbourhood of Nottingham. Examination of the curve shows, however, that the readings obtained on these sites are not appreciably nearer to the mean curve than some taken in what at first sight appeared to be far less satisfactory positions.

In one particular case a reading was taken just at the top of a steep drop, in what was practically a Devonshire lane, the hedges on the side banks being above the level of the top of the coil and the lower wires below the surrounding ground level, but the reading was quite normal. The question of long-distance telegraph wires is a more open one, as it is conceivable that their effect may be dependent on the constants of the circuits, in which case immunity from trouble is merely a matter of luck.

All readings were taken at a distance of not less than 200 yards from such wires.

The results are shown in Fig. 5, and the small sketch map (Fig. 6) gives an indication of the points at which observations were taken, the difference in the bearing of FT at the extreme points being 42°. After allowing for all the factors mentioned above, the curves appear to be very definite and to be entirely free from anything in the nature of a steady decay, the dotted line being the theoretical value as calculated from the Austin-Cohen formula. This curve is given, as there is reason to think that, whilst the authors of it fully appreciate the limitations under which it is applicable, some subsequent writers have invested it with an accuracy and validity which were never originally claimed for it and seem entirely unjustified. The curves seem to justify very definitely the claim for the existence of an interference phenomenon and, owing to the greater number of points on them, allow conclusions to be drawn with a much higher degree of certainty than when observations were confined to the fixed stations.

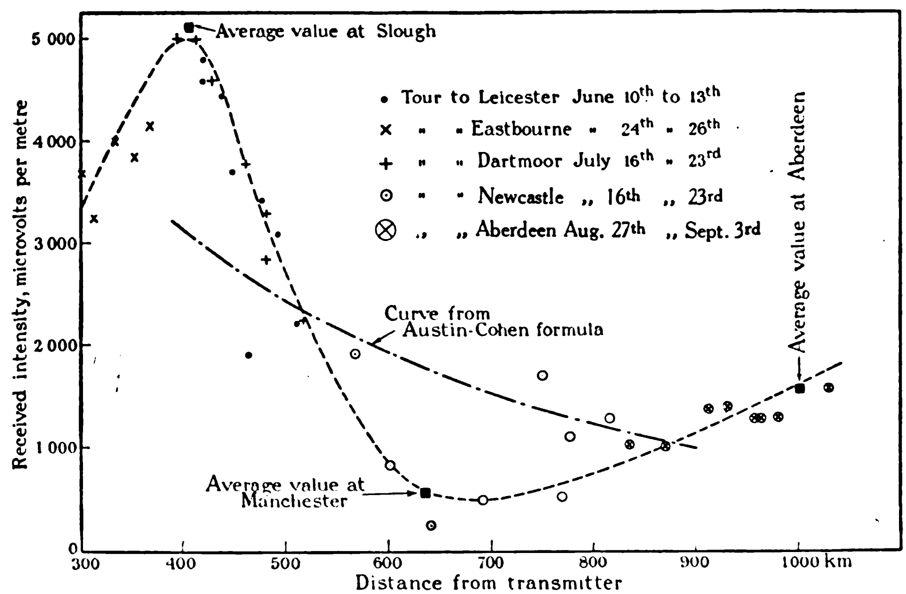

FIG. 5.—Intensity/distance curve during summer months taken on St. Assise (FT; 14 350 m) in 1925 with a portable set.

General Inferences from these Results.

In view of the fact that hardly any two of the points at which readings were taken lay exactly on the same great circle through the transmitter, it seems unlikely that these effects are confined to any particular direction. Also, the various paths contained very different proportions of sea and land, which again goes to confirm the view expressed earlier in the paper, that for these wave-lengths the nature of the path is of minor importance.

An interference phenomenon demands two waves, so that it is necessary to give a short discussion of the means by which such two waves could arise. In some of Sommerfeld's original work it is shown that the

velocity of propagation of a "surface" wave over a semi-conductive layer is slightly different from that of a "free" wave in space. At first sight this suggests a possible explanation of the phase-changes necessary to produce an interference effect, but calculation shows that by the time a sufficient phase-change had occurred due to this cause, the "surface" wave would have been attenuated to a negligible intensity. It seems, therefore, that the explanation must be found rather in difference of path length than in velocity of propagation, and this leads at once to the idea of the upper layer. The existence of such a layer has been suggested from the earliest times, and forms the basis of most of the mathematical work on the subject; but opinion on this point is by no means unanimous, and it has been claimed that all observed phenomena can be accounted for without its assistance.

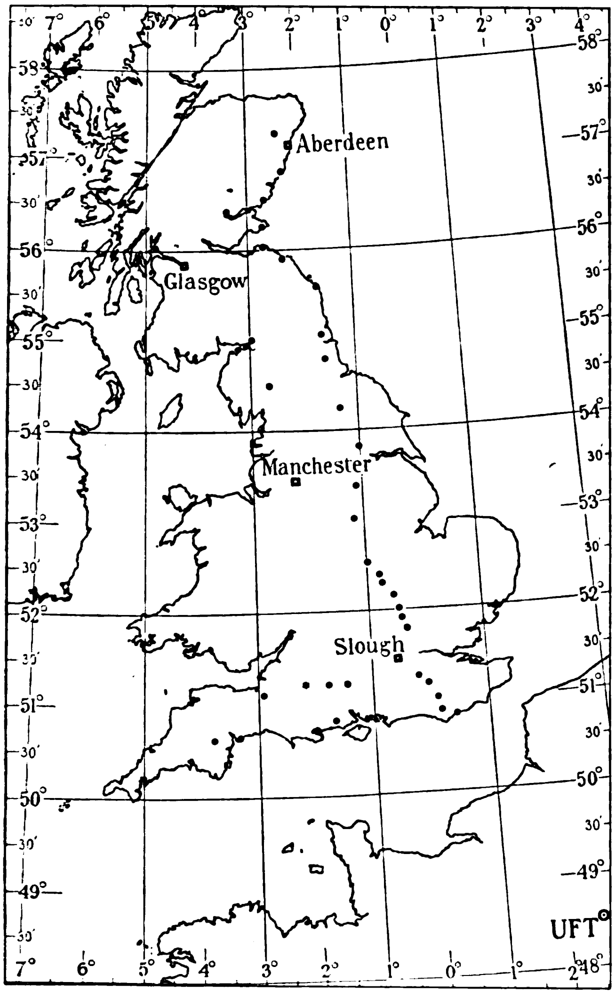

FIG. 6.

It is therefore proposed to assume as a starting point the existence of such a layer, but with its characteristics unspecified, and then to show that all the results obtained in the paper can be accounted for if certain definite constants are attributed to it. The question, by its very nature, does not permit of direct experiment, but can only be settled by the accumulation of evidence.

Now if on the surface of the earth (Fig. 7) one wave follows the arc A B between the two stations, whilst another is reflected at a point C on the upper surface, it is easy to calculate the phase-change due to the difference of the paths A B and A C B. At this stage of the work it is impossible to give a decision as to the actual physical nature of the layer, its constitution, or its sharpness of definition, the layer in Fig. 7 being treated as the imaginary sharp layer required to produce the same effect. Consequently, it cannot be said definitely whether the effect is strictly one of refraction or reflection, or, as seems likely, something of an intermediate nature. In all that follows, the word "refraction" is used in this indeterminate sense and must not be more strictly interpreted. Many more experiments under varying conditions are required before this further question can be answered in detail.

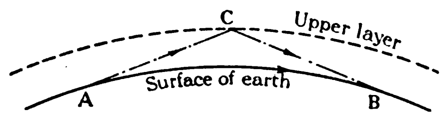

FIG. 7.—Diagram illustrating wave paths.

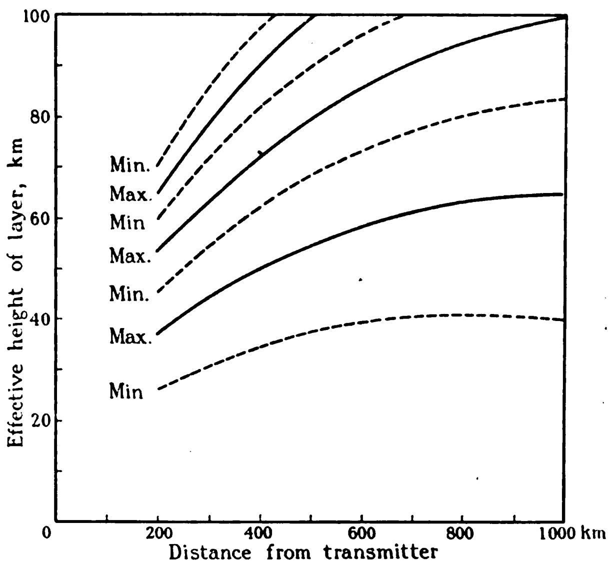

FIG. 8.—Chart of position of interference phenomena for $\lambda = 14{\cdot}35$ km.

Returning, however, to Fig. 7, the distances at which maxima and minima should occur for various heights of layer have been calculated for the wave-length of FT ($\lambda = 14\,350$ m) and are plotted in Fig. 8. The full lines give the positions of the maxima, and the dotted lines the minima.

With regard to these curves, it is very important to note that the actual positions of the maxima and minima are independent of the attenuation of either of the waves, a fact which is of great value, as it eliminates some of the most uncertain of the unknown factors. The actual intensities at these points are, however,

entirely dependent on the attenuations, so that the interference phenomena will exhibit all degrees of intensity. At short distances, where the surface wave is strong and the refracted wave weak due to the small angle of incidence, the maxima and minima will follow in rapid succession as the distance varies; but their actual excursions will probably be so small as not to be definitely separable from the irregular momentary and daily variations. As the distance from the transmitter increases, the effects will become more and more marked and, as appears from Fig. 5, an almost total extinction may be obtained; whilst at greater distances, due to the large attenuation of the surface wave, the effect will again diminish, if by this time it has not totally disappeared, as the last minimum will of course be at the point at which the two paths differ by half a wave-length. Thus, to exhibit this effect to the best possible advantage, the distances from the transmitter must be carefully chosen or it may be overlooked.

Now, if Fig. 5 be compared with Fig. 8, it will be seen that the conditions are fairly well satisfied if the equivalent height of the layer be taken as 75 km, which should give a maximum at 430 km, and a minimum at 640 km, with no intermediate value.

Returning for the moment to Fig. 4, if its figures are compared with graphs of the same type as Fig. 8 but drawn for the appropriate wave-length it will be found that, for the September reading, a layer at a height of 72 km should give a minimum at a distance of 450 km and a maximum at 800 km. These correspond very fairly to Fig. 4, after making allowance for the fact that with only four points of observation the position of the maxima and minima cannot be determined to any high degree of accuracy. The November reading in Fig. 4, on the other hand, suggests a height of the order of 85 km. It thus appears that, at any rate up to this date, all the major elaborate variations observed are explicable on the assumption of a refracting layer at a height of about 75 km during the summer months, rising somewhat abruptly during October to a height of about 90 km.

This does not, of course, definitely prove the existence of such a layer, as any other theory which could account for the observed results would be equally acceptable; and all that can be said at present is that it offers what appears to be the simplest explanation, which, at the same time, covers all the most marked observed phenomena.

Of the actual physical nature of the layer, present results are not sufficient to give any details. General conceptions are somewhat adverse to the idea of a sharply defined surface of separation, though it must be remembered that sharpness would only be a relative term, being in fact a function of the wave-length; so that the degree of sharpness may be entirely different for long and short waves, with a resulting difference of observed phenomena. If, however, the suggestions put forward by Dr. Eccles * or Prof. Larmor † are accepted, the practical result is that the "effective height" would be different for different wave-lengths. The range of wave-lengths used in this paper is not sufficient to settle this point without special experiments designed to illustrate it, but it is hoped to undertake these in the future.

* *Proceedings of the Royal Society*, A, 1912, vol. 87, p. 79.
† *Philosophical Magazine*, 1924, vol. 48, p. 1025.

Seasonal Variations.

So far, results have been chiefly confined to the summer period. The next points arising are :—

(i) Comparison of results obtained during the summer and winter months.
(ii) Comparison of results during the same period in successive years.

The abrupt transition at the end of October appears to mark a distinct line between these two periods, and in this connection also the curve given in Fig. 2 is of special importance. It is obtained from the results published periodically by Prof. Mesny in *L'Onde Electrique*, and its significance lies in the fact that the time of transmission (1955 G.M.T.) is close to the sunset period. Actually it is about the time of sunset at Bordeaux on the longest day, and at Paris in the middle of July. The first rise in the curve evidently corresponds to the normal sunset change, which is discussed in more detail below, but the striking point is that, after a comparatively steady period following this, another abrupt change occurs at exactly the same time as on the stations whose transmissions are in daylight throughout the year. As by this time of year sunset has occurred, both at Meudon and Bordeaux, several hours before the reading is taken, it seems impossible to argue that the winter change is merely a reversion to normal night conditions. The two may be related, and probably are, but they do not seem to be identical.

For the daylight stations the results appear to group themselves into two sections, that from May to September being marked by its relative stability, and that from October to May both by average values differing largely from the summer ones, and also by a very pronounced day-to-day instability.

Also, it has been shown that the marked change at the end of October is consistent with a rise in height of the layer from 75 to 90 km, so that it seems natural to suggest that some, at any rate, of the winter variations are due to the same cause. Unfortunately, the large day-to-day variations referred to above cause great difficulty in applying the system of weekly averages, which under these circumstances do not appear to possess much physical value. For this purpose a daily analysis of the results has been undertaken, in order to see if even the daily variations will allow of quantitative explanation, but the preliminary arithmetical work is very heavy and it is not possible to say yet whether the analysis will be successful.

One point in connection with the layer appears to be very striking. It is clear from Fig. 8 that a change in height of only about 10 km may be sufficient to convert the signal at a given point from a maximum to a minimum. Now the readings during the summer show that the day-to-day variations at any given point are often only a few per cent, and that even the weekly average for the same week in successive years may not differ by more than this amount. Consequently, although it appears that the layer undergoes a nightly change, it must go through a cyclic change of extraordinary

constancy over periods measured by weeks if not by months. It may be added that it is admittedly somewhat premature to draw conclusions as to yearly variations from observations extending over so short a period.

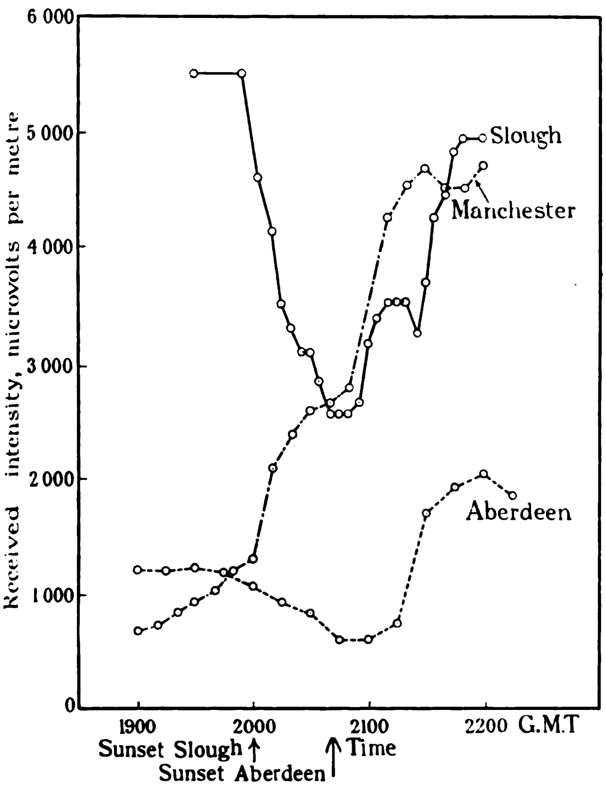

FIG. 9.—Sunset run on St. Assise (FT ; 14 350 m), 21 July, 1925.

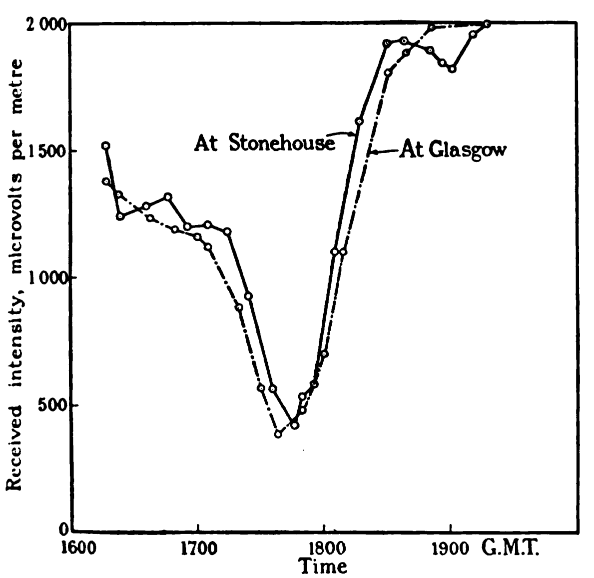

FIG. 10.—Sunset run on FT (St. Assise) on 12 October, 1925. Stations 24 km apart.

Time alone can settle this question, but it is certainly striking that, as far as results go at present, there appear to be very marked signs of an annual repetition.

SUNSET EFFECTS.

A completely separate series of experiments suggested by my assistant Mr. Naismith have also been made. Continuous watch kept at Slough during the summer months on St. Assise from about one hour before sunset until two hours after, showed that during the summer period the intensity went through a very marked cycle of change, which was repeated daily with only very minor modifications. Similar observations were therefore organized at the other three permanent stations, and the results showed that whilst the same

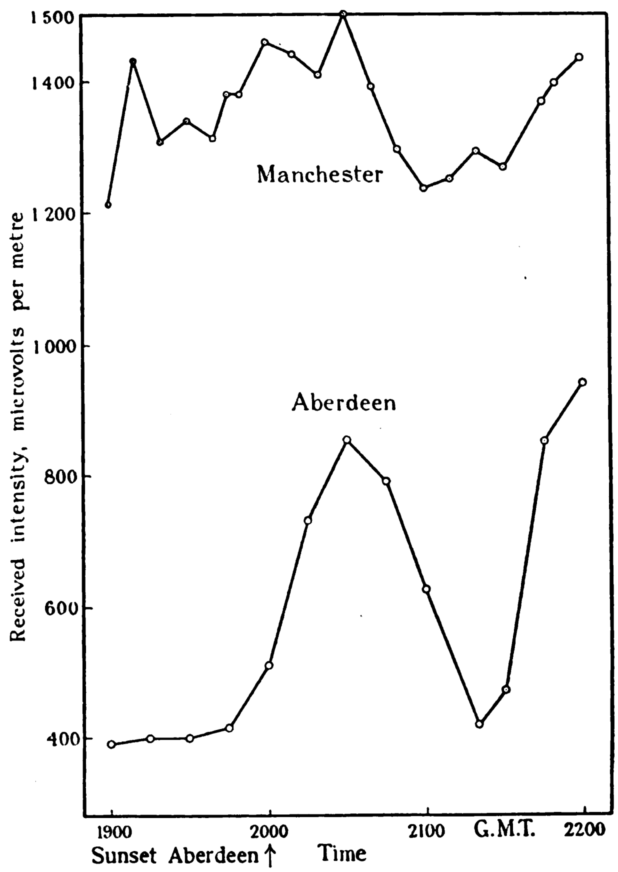

FIG. 11.—Sunset run on Northolt (GKC ; 6 950 m), 30 July, 1925.

thing was true at every station, the actual curves obtained had entirely distinctive and different shapes. These are given in Fig. 9 for FT at Slough, Manchester and Aberdeen, and in Fig. 11 for GKC (Northolt) at Manchester and Aberdeen. Fig. 10 is also interesting, as showing the curves obtained at the same time by two independent stations 24 km apart. Neither of the observers knew that the other was working, and the results obtained have been plotted without correction, so that it would appear that the agreement between the various sets of apparatus is good. It will be seen at once from these curves that the effect can no longer be classed under the general heading of "night increase," but that it must be, although perfectly systematic, of a much more complex nature. Now it is generally

held by the supporters of an upper-layer theory that, with the removal of sunlight, the effective height of the layer increases.

Following out this idea, if the curves in Fig. 9 are compared with the graphs in Fig. 8 the variations at all stations are explicable on the basis of a rise in effective height from 75 km to 90 km, bearing in mind the fact which has been referred to above, that a minimum is not necessarily a zero.

Another interesting, though tentative, calculation can be made from these results. From Fig. 9 it is possible to determine the actual values of the maximum or minimum attained at each station, and sometimes both, depending on the range of the curves.

The intensity of the diffracted wave can also be calculated from the formula given by Watson ‡ and by Van der Pol,§ and hence the intensity of the reflected wave is known.

From this the equivalent reflecting power of the layer can be deduced, on the assumption that the intervening air is a perfect dielectric.

The figures actually obtained are shown in Table 2.

Table 2.

	St. Assise (FT ; λ = 14 350 m)			
	At Slough	At Manchester	At Glasgow	At Aberdeen
(i) Maximum value from curve	*	*	*	2 000
(ii) Minimum value from curve	2 500	600	400	600
(iii) Calculated surface wave..	4 000	1 980	1 000	900
(iv) Reflected wave	750	1 300	700	750
(v) Calculated maximum value	5 500	4 600	2 800	2 100
(vi) Reflection coefficient†	0·16	0·42	0·37	0·42
(vii) Angle of incidence on upper layer	68·5°	75·5°	78·5°	79·5°

A corresponding figure derived from the Northolt results is 0·6 for the reflection coefficient, but it must be remembered that the idea of working out these results only occurred some time later. It has consequently been necessary to assume the nominal value of aerial current, and if this was not the actual value when the observation was taken the reflection coefficient would be correspondingly different; in fact, further work suggests that this figure should also be of the order of 0·4.

These results are interesting, especially as showing the rapid falling off of reflecting power for larger angles of incidence, which is not altogether unexpected, but like many other figures in the paper they must only be taken as provisional and subject to further verification, by the method of daily analysis referred to previously.

Conclusions from the Results.

Whilst many of the ideas suggested in this paper cannot at present be regarded as much more than guesses at a possible state of affairs, it may be as well to collect and re-state some of the definite facts that rest on experimental evidence and must form a basis for any theory which can cover them.

(1) Long-wave signal intensities over medium distances (< 1 200 km) remain extremely steady over the period May to September, during daylight hours.

(2) Their distribution does not correspond to the Austin-Cohen formula for anything less than yearly averages, in which case the distance is not large (see Table 3) and the law of decay is not uniform.

Table 3.

	UA		GBL	
	Yearly average	Austin-Cohen value	Yearly average	Austin-Cohen value
Slough ..	1 880	1 660	5 560	5 650
Manchester ..	1 070	1 040	2 100	2 260
Glasgow ..	690	650	820	770
Aberdeen ..	370	530	510	590

(3) During the sunset period each station goes through a distinct and individual cycle of change, which is repeated daily.

(4) Towards the end of October all observed stations showed simultaneous and large departures from their summer values. This is the beginning of a period of marked day-to-day instability, which persists until the following May, by which time all stations have settled down to their normal summer values.

* It is not always possible to determine these values reliably from the curves. For instance, in the case of a V-shaped curve such as that for Slough (Fig. 9) there is no definite evidence of a point of inflexion having been reached either at the beginning or end. The missing values have therefore been calculated in (v) in order to see whether they are of the right order, and they appear to be in most cases very close to figures which have at times been obtained (cf. Fig. 5 for the maximum value at Slough).

† The reflecting power of the ground has been taken as unity, as Dr. Smith-Rose's results (in course of publication) have shown that this is not far from the actual figure.

‡ *Proceedings of the Royal Society*, A, 1919, vol. 95, p. 83.

§ *Philosophical Magazine*, 1919, vol. 38, p. 365.

(5) Careful plotting of a day-time intensity/distance graph gave an undulating curve, showing, under certain conditions, practical extinction at a definite distance.

(6) In addition to the slow periodic changes, there appear to be more rapid fluctuations superimposed. During the summer months they are comparatively small, but assume big intensities during the winter. There is not yet evidence to decide whether these are due to fluctuations of layer height too small and rapid to be definitely detected by present methods, or whether they are due to some totally separate cause.

Extension to Long Distances and Short Waves.

The actual results in this paper are definitely confined to medium distances and long waves, as the deliberate idea throughout has been to investigate phenomena rather than results ; but at the same time it is interesting to inquire how the ideas can be applied to these other cases.

(*a*) *Long distances.*—The interference phenomena discussed above have a definite upper limit of distance for two reasons. The first is that, on the assumption that they are caused between a refracted and a diffracted wave, the attenuation of the latter is so large that at great distances its effect is negligible. Secondly, these effects cease when the difference in path length for the two waves becomes less than half a wave-length ; and this, together with the curvature of the earth, places a definite geometrical limit on the possible distance, there being also a maximum range for a first reflection with a given height of layer.

The idea of multiple reflection cannot, however, be excluded (cf. Captain Round and Mr. Eckersley *) and it is conceivable that some effect of the following nature may take place.

The signal from a distant station would consist of the vector sum of a series of multiple reflections. The least number of reflections possible is given by dividing the total distance by the maximum range of a single reflection leaving the earth tangentially (in the case of a layer 75 km high this figure is 1 950) and taking the next integer above this.

* *Journal I.E.E.*, 1925, vol. 63, p. 995.

Theoretically all multiple refractions of a higher order than this would be present, forming an infinite series, but actually, owing to the loss at each refraction and the gradually increasing angle of incidence, their relative attenuations would be rapid and probably only two or three would survive to a measurable extent. These might even show interference phenomena among themselves, though at large distances the effect would be so sensitive to variations in the layer too small to produce any effect at short distances that it would for practical purposes be incalculable.

(*b*) *Short waves.*—There is danger in applying these results directly to wave-lengths below 1 000 metres, for, whilst the presence of such a suggested upper layer would be a very important factor in short-wave propagation, the difference in frequency is so great that there is no doubt but that the actual observed phenomena would be entirely different.

Conclusion.

In conclusion, it is again well to lay emphasis on the fact that, whilst the results given in the paper are reasonably definite, the conclusions drawn from them must not be treated as more than suggestions with varying degrees of validity. The primary object has been to deduce from somewhat general observations definite systematic points requiring further investigation, and it is not until confirmation, or the reverse, is obtained that any opinion can be expressed as to the degree of actuality of the suggested phenomena.

This work was carried out for the Radio Research Board under the Department of Scientific and Industrial Research, and I am indebted to the Committee on Propagation of Waves for their helpful criticism. Finally, I must express my gratitude to the observers at my out-stations, Dr. Fyvie at Aberdeen, Mr. Hoyle at Manchester, and Messrs. Dalgleish and Naismith at Glasgow, the latter of whom is now working with me at Slough since the departure of my previous assistant Mr. Reading. To them has fallen the part of taking the routine, and somewhat monotonous, observations, without which none of the results could have been obtained.

Discussion before the Wireless Section, 3 February, 1926.

Prof. E. W. Marchant: The variations that the author has observed in the winter months are just about the same as those we observed in Liverpool on (UA) and Nauen during the winter months of 1924. I feel considerable doubt, as indeed the author himself does, as to the value of the weekly averages which one obtains by taking means with results of that kind. The suggestion that the author makes—that these variations are all explained by interference phenomena—is, I think, open to criticism. There are some days in the winter when nearly all stations seem to come in very much more strongly than they do on other days. I should like to ask whether it is possible to get any evidence of interference bands from those who have made observations of signal strength on board ship. Austin has done a good deal of work on that subject, and other workers in this country have also made many observations. It would be interesting to find out whether these observers, when they made accurate measurement of signal strength, have observed variations of the same kind as those the author has noticed. The most interesting figure in the paper is Fig. 5, which shows the up-and-down variation in strength as the distance from the transmitting station increases. It appears to give very clear evidence of the existence of interference bands and thus provides further proof of the existence of the Heaviside layer. It would have been of value if the author had included in this paper, besides

the weekly averages, the daily figures that were obtained at the various stations—Manchester, Glasgow, Slough and Aberdeen—so as to make it possible to estimate roughly the height of the Heaviside layer and the variations in height from day to day. In one respect our observations have differed from those which the author has described. We have found, in the relatively small number of observations we have taken, that there is not a constant effect from day to day at sunset. These results were described in a paper read before the Institution in 1915.* These experiments give clear evidence of interference and mark a definite advance in our knowledge of the causes of the variations which have been observed in signal strength.

Dr. E. H. Rayner : It will be seen from the account of the observations given in the paper that the sensitivity of measurement is not unlikely to be better than the sensitivity or accuracy of some types of ammeter by which the current is measured in transmitting antennæ. Absolute accuracy of indication of such instruments is of comparatively little importance at present, from the point of view of measurements described in the paper, but variation of accuracy is of real importance, whether it be a variation from hour to hour or month to month. There is also the difficulty as to what is the effective transmitting current when observations are made on traffic transmission by observing the amplitude of the excursion of a string galvanometer. It may be the same as is indicated by an ammeter, when a 2-second or 2-minute signal is sent, but it is also possibly somewhat different. Experiments have now reached a stage in which the performance of particular instruments, of a type the verification of which is a matter of considerable difficulty, has become one of the uncertain factors in work of this character. The difficulties are increased by their being situated in foreign countries in several cases. Prof. Marchant mentioned the subject of transmission to or from a ship at sea. This has seriously been considered by the Committee of the Radio Board. The suggestion was made that certain ships, on the Atlantic for instance, might be asked to send suitable signals for measurement on shore, or that shore signals should be sent for measurement on ships. The difficulties in connection with measurements of a physical character would, however, be very considerable. The effect of the ship itself, its rigging and the difficulty of assigning a reasonably accurate value to the effective height of its antenna, complicated by probable directional effects, seemed to make the numerical value of any observations obtainable so doubtful that it was decided not to carry the suggestion any further. Measurements made on a substantially metal-free ship offer a very attractive method of working, and it is hoped that some day an opportunity may arise of carrying out observations in such a manner. Since the subject of carrying out systematic observations at sea was considered, the land journeys have been made by the author, and have resulted in much of the information which it was the aim of the proposed sea observations to provide.

Mr. T. L. Eckersley : Particular interest seems to be associated with the November effect which was noticed by Capt. Round over long-distance transmissions as early as 1911. It seems to be a fairly universal effect. It was measured by us * and is shown in Fig. 142 (page 943 of vol. 63) and it was suggested on page 983 that this effect over great distances was partly due to an increase in height of the layer, but chiefly to an increase in attenuation. The author, by confining his attention to relatively short-distance transmissions, has been able in my opinion to separate these two effects, since attenuation has very little effect at such short distances and the major part of the changes must be attributed to variations in height. I am glad to note that he agrees with us in supposing an increase in height in the winter months. The fact that at short distances the November period does not show up as a sharp drop, but may be accompanied by a rise, suggests that the main cause in the drop in signals over long distances is increased attenuation. In confirmation of this we have a very distinctive evidence in the case of very short waves which indicate a *decrease* of attenuation in winter, thus implying an increase of attenuation in the winter daytime on the long wave. The chief interest in the paper seems to centre round the experiments, the results of which are exhibited in Fig. 5 and which seem to show up beyond doubt an interference pattern near the transmitter which we may very reasonably attribute to the interference of the ray reflected from the Heaviside layer with that diffracted round the earth's surface. The results are very remarkable as showing how far from a gradual decrease of signal strength with distance the actual signals are. Traces of the same effect are exhibited in Fig. 89 of our paper, showing the ratio of calculated to observed values of the signal E.M.F. over distances as great as 4 000 to 5 000 km, and were noted in our original measurement of signals from the American stations in England. Sine-wave deviations from the exponential decrease showed up in practically all our plots of the attenuation curves. The chief difference is that at the shorter distances examined by the author the maxima and minima are much more pronounced than those at greater distances. He has interpreted this result—I think quite rightly—as being caused by the interference of the direct and reflected ray from the Heaviside layer, and has used the observed results to obtain a tentative value for the height of the layer. I am not sure, however, that I quite agree with his numerical interpretation of Fig. 5. The estimated height is given as about 72 km, on the strength of the agreement of the maxima and minima with those shown in his theoretical diagram. I am inclined to think that the absolute positions of the maximum and minima are not so important as their distance apart. The absolute positions will be modified by any change of phase in reflection or refraction, which may amount to a considerable fraction of 180°, but the relative position should be independent of this to the first approximation. To obtain the best estimate the values at the shortest distances should be used where complications due to multiple reflection are least likely to occur. Taking these effects all into account I should estimate from the rapidity with which the maxima

* *Journal I.E.E.*, 1915 vol. 53, p. 334.

* "Report on Measurements made on Signal Strength at Great Distances during 1922 and 1923 by an Expedition sent to Australia," *Journal I.E.E.*, 1925, vol. 63, p. 933.

and minima alternate in the neighbourhood of 300 to 500 km that the height was not above 50 km, which is more in agreement with the results previously obtained by me by an independent method. These were approximately 40 to 48 km in the summer and 56 km in the winter. The discrepancy cannot be due to wave-length difference, as the results obtained by the author were on a 15-km wave, and mine in the range between 10 and 25 km.

Mr. J. E. Taylor: So far as the author's observations and the methods used in making them are concerned, there is little that can be fairly criticized. Such measurements are all to the good, though I fail to see how any prolonged scheme of observations can be planned out without having preconceived ideas of what is happening, and I imagine that is the case here. As far as the inferences drawn from the observations are concerned, qualified though they may be, I wish to express my entire disagreement with the author, and also to take special exception to the scanty treatment of what I call the guided-wave view. It is dismissed in a few words by reference to Sommerfield's surface-wave effects or theory. I look upon that part of the paper with some suspicion as an attempt to drag a red herring across the trail. Has the author ever heard of waves on wires; does he realize that those waves follow the wires with the strictest fidelity through all their bends and turns and twists? Does he realize that those waves do not necessarily decay to a negligible intensity after traversing hundreds and even thousands of miles? Would it make any difference to those waves if instead of a long wire we make them travel along a broad strip of metal, or if instead of along a broad strip of metal we make them travel along a sheet of metal? Will not they still follow the curvature of that metal without the assistance of any hypothetical upper reflecting layer? Very well. Suppose we cover the earth with that sheet of metal; surely the waves will still follow its curvature. Then remove the sheet of metal from the surface of the earth. Why will not the conducting surface of the earth still guide the waves? That is the robust proposition the author will have to face—not Sommerfeld's theory of surface waves. Now, on that view, how are we to explain this interference phenomenon? In my view the author is dealing with two sets of waves, one transmitted direct from the transmitting station to the receiver, wherever it may be, over the great circle of the earth, and the other set of waves going completely round the earth, which re-concentrates as it gets back again and interferes with the direct wave. The interference would, of course, depend simply on the arrival phase of the waves transmitted completely round the earth. That is my opinion, and I feel quite strongly on the matter. I cannot help suggesting that a good deal of time, money and energy is being wasted on the pursuit of this academic myth of a useful ionized layer.

Dr. R. L. Smith-Rose: The results shown in Fig. 5 give, I think, what is a new view as to the propagation of waves, namely that under stable daylight conditions the signal-strength/distance curve passes through a series of maximum and minimum values and does not show a steady decay as we have all hitherto thought was the case. In the latter portion of the paper the author deals with an explanation of these results on the basis of a reflected wave from the upper atmosphere interfering with the direct waves along the earth's surface. To some of us, before we heard Mr. Taylor speak, this evidence was convincing enough in itself, but I should like to draw attention to the fact that a much larger amount of evidence exists at the present time than has been given by the present author, and this, I think, affords adequate confirmation of the theory. Others beside Mr. Taylor have been sceptical about the existence of the Heaviside layer. If any excuse were needed for that scepticism I would say that it has provided the incentive for several years' experiments which have now brought quite fruitful results. Several investigators who have been associated with the Radio Research Board have obtained other evidence on this matter. In a paper read before the Royal Society last December, Dr. Appleton and Mr. Barnett described the measurement of interference effects between reflected waves and direct waves on the earth's surface, somewhat similar to the author's work but on shorter wave-lengths. In addition, another method was described there of which it is difficult to give any other explanation than that of a wave coming down on the earth's surface at an appreciable angle of incidence. Mr. Barfield and I have been engaged for two years in trying to convince ourselves whether this explanation of variations in signal strength and in bearings is correctly ascribed to waves reflected from the upper portions of the earth's atmosphere. We have now developed four different methods of determining that waves do at night come down on the earth's surface at an appreciable angle of incidence. Those four methods are absolutely independent of each other and can be worked independently by independent observers, yet they give very similar results. Three of those four methods enable us to measure the actual angle of incidence at which the wave comes down on the earth's surface, and also the relative intensity of the direct and down-coming waves. It is well known from fundamental classical theory that if an electromagnetic wave is sent through space the wave is constituted by an electric force and a magnetic force at right angles to each other and to the direction of propagation. It is also fundamental that these two forces are exactly equal to each other at all times anywhere in the line of propagation. If, therefore, waves are received at any part of the earth's surface horizontally, such as I understand is the case with the so-called guided-wave theory, those two forces must be equal at all times. Using methods by means of which the electric force and the magnetic force can be measured independently, it can be shown that at night under certain conditions where we get variations in signal strength and bearings the magnetic force is frequently greater than the electric force. That might appear to be a rather startling result, but there is a perfectly simple explanation of it. If a wave comes downwards and not horizontally, immediately it hits the earth's surface (the earth being a tolerably good conductor) a reflected wave will be set up. In such a case it can be shown that the ratio of the magnitude of the resultant vertical electric force to that of the resultant horizontal magnetic force is equal to the sine

of the angle of incidence of the arriving wave, and will thus be less than unity. The very fact that at times the resultant fields are not equal is considered to be a definite proof that a wave is coming down on the earth's surface at an angle of incidence which is not 90°, i.e. it is not arriving tangentially as it would be by the guided-wave theory. If the wave is travelling along horizontally at the earth's surface, the magnetic force is horizontal. By measuring the direction of the magnetic force it can be proved quite definitely that its direction can depart from the horizontal under suitable conditions of night phenomena. This is considered to be a second proof that waves are coming down from the upper atmosphere and not being transmitted horizontally along the earth's surface. With regard to phenomena associated with direction-finding observations, I thought it might be interesting to set up a direction-finder and take bearings on the "URSI" signals simultaneously with the measurement of signal strength the author was carrying out, and on the lantern slide are shown graphs of the daily bearings observed on these signals sent by Leafield and Nantes. The observations extend from October 1924 to December 1925, and were all taken in daylight, the signals in question being sent at 2 p.m. and 2.15 p.m. It is seen that in the winter months—from October to March—the bearing varies from day to day over a range of 10° to 15° on either side of the true bearing. About March the bearings settled down, and during the whole of the summer months it was moderately steady—a small variation of 1° or 2° only, which may be due to slight instrumental error of the apparatus. In October the variations start in a similar manner to the previous year. In the case of Nantes the variations are similar, but not quite so large. These effects resemble the signal-strength variations which the author obtained at the same time; he found erratic variations during the winter months and steady results during the summer months. The author has explained that during the summer months his results still necessitate a reflected wave as well as a direct wave. Since the bearings are quite steady during those summer months, that reflected wave must have come down in such a manner that it could cause no variation in bearings, since we got negligible variations in the summer. That is, the polarization of that wave was always such that the electric force was in the vertical plane and the magnetic force in the horizontal plane, whereas during the winter months and at night time the plane of polarization of that reflected wave must have been rotated so that the magnetic force was no longer horizontal. That indicates a possibility of having a downcoming wave which is normally polarized, as we term it, and which is not rotated in its path and thereby does not cause any variation in bearing although it may result in variations in signal strength being observed. If those summer conditions indicate that the reflecting layer is at a lower limit of its height, then there would appear to be some minimum height at which rotation of polarization of reflected waves takes place. I notice that the author gives all his ordinates in microvolts per metre. As he is using a frame coil measuring horizontally the magnetic field and as, as has been pointed out, the vertical electric field is not necessarily equal to the horizontal magnetic field, he would not appear to be justified in giving the signal strength in microvolts per metre.

Mr. E. B. Moullin: I think that the time is not very far distant when we shall be able to correlate all these records and understand the conditions in which wireless waves travel, and also how these conditions change with season and wave-length. I regard this paper as a fund of useful information the significance of which we are not fully able to appreciate at present, and I read it with less thoughts of the present discussion than of its bearing on the discussion of some future paper. I think that Fig. 3 is very important, for it shows that waves of 12 km wave-length travel with equal facility over land or water: this conclusion seems final and we may accept it gratefully as at least one definite decision. I await eagerly a corresponding curve for a wave-length of say 600 m and then I expect we shall find that waves are transmitted much more readily over sea than over land. The suddenness of the October change does not impress me with the same force as it appears to impress the author. This change seems to me to have been in progress at all stations for a full month before the 30th October and to have continued long after; in addition the peaks and hollows at this time are not more violent than those which occur at other times in the year. I think that if the author had given more daily readings round about this time we might have been able to judge whether we should regard the end of October as a time when the average value changes very rapidly or whether to regard it as a time of great daily variation superposed on a slow change of the mean. I think that metereological and kindred records over this time should be searched in the expectation of finding also violent daily fluctuations of some observed quantity. The paper contains much confirmation of the hypothesis of a Heaviside layer and I think the analysis I am about to suggest might yield interesting results. If the layer exists, as it surely does, we are prepared to expect it at the same height over all the British Isles on any particular day. If this layer rises and falls regularly from year to year we should expect the season of maximum signals at one station to be a season of minimum signals at some other nearer or more distant station. If the curves of Figs. 1 and 2 were analysed into a Fourier series we should find how the phase of the fundamental variations was related to the distance from the transmitter. We could then test whether this phase change was consistent with a uniform height of layer and, if it were, we could find its rate of rise and fall. Casual inspection of Figs. 1 and 2 will show that the fundamental sine curve has a large amplitude and that the phase differs with the station; for example, Slough and Manchester are almost in antiphase with one another. In spite of the violent daily and seasonal variations, this paper discloses that the yearly average can be predicted very closely by the Austin-Cohen formula. This is very noteworthy and remarkable. Let us hope that time will prove this simple formula correct for the yearly average and then in course of time we shall be able to add to it a harmonic factor which will make the necessary seasonal variation which

arises from wave interference. If the Austin-Cohen factor is proved to be appropriate it will tell us much about the mechanism of attenuation. Now that this chain of observing stations is established we could obtain very valuable information if the transmitting station would alter its wave-length slowly and continuously for a period of an hour or so. This would virtually repeat the experiments of Appleton and Barnett with the advantage of several observing points. I hope that the author will put on record such explanations as he is able to suggest of the multiple-value points recorded in Fig. 5 and also state definitely the extreme range of variation recorded at the three watch stations during the time the trips were in progress. I think that analysis of the sunset effects might yield interesting information about the rate of rise of the layer during the sunset period. I notice that a string galvanometer was used to record the St. Assise signals, and I should like to know whether the mean recorded values depended on the rate of signalling. Though I realize that it is impracticable to publish the whole set of daily records, yet it would surely be an advantage if these should be accessible. I suggest that the Institution Library might keep a typed copy of the complete records. Possibly I do not fully understand Mr. Taylor's views respecting the mechanism of propagation round the globe, but surely it is a matter of common experience that if a source of light is placed close to the surface of a large opaque sphere, then no light is visible even a quadrant away from the source, an experience which is not modified appreciably by polishing the sphere.

Mr. P. P. Eckersley (*communicated*) : Qualitatively, undoubtedly, all must agree with the author's conclusions reached, whilst, as he himself has partly admitted, one may be more sceptical of the quantitative deductions. It is, perhaps, a little surprising to find no mention made, first, of a paper * recently read before the Institution by Mr. T. L. Eckersley, nor, secondly, of his previous papers published immediately after the war in the *Radio Review* dealing with work done from 1916–1918. These papers, I venture to state, anticipate a great deal of work done by others in the same field. I, for one, was satisfied by him in 1916 that theories of electric wave propagation, which sought to explain observed variabilities, must be based upon a reflecting layer hypothesis. If further confirmation of his original deductions is required, it is undoubtedly found in the interesting catalogue of observations contained in the present paper, and also in certain experiments conducted by Mr. Appleton and the British Broadcasting Company. The British Broadcasting Company have, by their unique opportunity of studying mass observation, obtained some interesting qualitative data on wave-lengths shorter than those observed by the author and his co-workers. Without doubt the "come down" of a station (i.e. the point B in Fig. 7) is manifest in broadcast telephony reception. In parts of Scotland, for instance, the Bournemouth station is louder than either Glasgow or Aberdeen. In many cases Scandinavian stations are louder than British stations, which are geographically less distant, and observers under the "arch of radiation" (the line ACB of Fig. 7) have frequently noticed a complete lack of correlation between signal strength and distance. Undoubtedly, at short waves (300 to 500 m) the effect of shielding by hills and mountains introduces other variables. In the valleys around Cardiff, and more particularly in the mountains near Milan, conditions *can* be obtained where even a sensitive receiving set is unable to pick up powerful stations a few tens of miles distant. A case is known of a particular fjord in Norway where a 7-valve supersonic receiver is, with an adequate aerial, unable at 10 miles from a 200-watt transmitting station to pick up even a heterodyne interference beat. In Britain, on the other hand, several hundreds of miles distant, the station, which incidentally is also severely screened, is clearly audible. One would suspect an accepted theory that the indirect ray is largely responsible for the achievement of communication. In further corroboration of the shielding effects by uneven ground, I have observed signals from London on the London–Daventry road, while travelling into the country, to be far weaker when descending the hills. Curiously, at every town the signal strength appeared to increase. The effects noted by indirect reception of screened transmitters are also noticed by transmitters which are unscreened and receivers which are screened. As a practical indication of this, I know of a case where two of the short-wave B.B.C. stations could be received quite adequately in a Norwegian fjord while 5XX, the long-wave, high-powered station of the B.B.C., was quite inaudible. Just outside the fjord 5XX came through roughly at the correct strength as compared with the short-wave stations. This would seem to point to the facts that the short-wave stations were being received on their indirect waves, the longer wave being not affected, in the same way, whereas outside the fjord the direct rays manifested themselves and, naturally, 5XX was the stronger. Further observations at very short ranges have been taken, and it has been observed that, where very strong signals obtain, a rough application of the inverse square law does not introduce serious errors. In broadcasting, those responsible for a satisfactory service are more interested in those areas where the signal strength is large compared with extraneous interference. In some tests on the so-called "crystal range" of a station (a scientifically ambiguous term signifying any range at which the signal strength is large compared with extraneous interference) between a set at Chelmsford using a power of 10 kW and another of 3 kW in the heart of London, the point of equality of signal strength was found to obey, within the limits of the inaccuracies obviously present, the inverse law. The place was, approximately, 8 miles from Oxford-street and 22 miles from Chelmsford. Other corroborations were obtained. In conclusion, I must argue with others that the value of the author's observations and his clear statement of fact cannot be overestimated, but he will without doubt forgive a healthy scepticism of the quantitative estimates derived on the basis of somewhat unconfirmed assumptions.

Mr. J. Hollingworth (*in reply*) : I agree with Prof. Marchant that it is necessary to accept weekly averages with reserve. I have in fact, discontinued taking them out during the winter, but during the summer I

* *Journal I.E.E.*, 1925, vol. 63, p. 933.

am inclined to regard them with more confidence. The alternative—the consideration of individual figures—involves very considerable reliance on instrumental accuracy, and on the constancy of conditions at the transmitting end. In the narrow sense, the statement that all effects may be due to interference phenomena is probably going too far and I would amend it to say that at these wave-lengths the majority of observed variations (especially at medium distances) are due to changes in the upper air rather than to surface conditions.

A daily analysis of results is now in progress and it is hoped to publish tentative results shortly, but the process is one of considerable difficulty and uncertainty, as in order to reduce anything to calculable form it is necessary to make certain arbitrary assumptions which can only be justified by the results they yield.

The daily results were not given in the paper, purely from considerations of space. My experience with the sunset results, which during last October were taken daily and are now taken weekly, is that occasionally the effect is definitely and entirely absent but when it does occur it always possesses its characteristic features. For instance, on the 10th February, 1926, the sunset curves at all stations were practically straight lines, whereas on the 17th February (the next observation) they reappeared in such marked form that the intensity at Aberdeen actually fell to zero for about 5 minutes.

I agree with Dr. Rayner that the reliability of the transmitting end is a factor of considerable importance as, even if accurate instruments were available, it is impossible to organize detailed observation of them over the very varying routines of observation which become necessary.

I agree with Mr. T. L. Eckersley that the most important feature about the November change is its universality, though I think its comparative abruptness is also striking. My personal experience of long-distance work is so small that I did not feel justified in doing more than merely comment on it, and I am indebted to him for his more authoritative opinion. I also agree that these sine-wave deviations from the smooth curve have often been observed before; they are in fact visible in some of Dr. Austin's original curves. In those very early days it is probable that instrumental uncertainties may have overshadowed them, and I think they have been usually treated as somewhat secondary phenomena, but the prime object of the present paper was to obtain them under the most favourable conditions and to use them as the fundamental analytical weapon.

The problem of the phase-change at refraction is a very vital one. It cannot be calculated directly until more information is available about the layer, which information is again itself probably most easily obtained from observations of this type, so that here, as throughout the work, it seems only possible to progress by a method of successive approximation. In the paper the mere path difference was taken as being the simplest assumption, though it was appreciated that the resultant "height" would be very artificial and that relative values would be of more value than absolute ones. Prof. Macdonald has since published a paper* in which it is suggested that under these conditions of working a constant phase-change of $\pi/12$ might be assumed, and the results have been recalculated on this basis. The effect on the height of the layer is small, lowering it 2 to 3 km at the utmost, but it does appear to give slightly more consistency in the daily analyses. It may be taken as the second stage of approximation. But even allowing for all these I find some difficulty in reducing the height to 50 km, for the following reason. In Fig. 5 we have a maximum at a distance of 420 km, followed by a minimum at 650 km. Now with the layer at a height of 50 km the phase-change of one wave relative to the other between these two distances due to path difference only is 46°. The angles of incidence on a layer at this height are respectively 76° and 81°. Consequently, if the phase-change at the upper surface in the first case is $\theta°$, the change in the second must be $(\theta + 134°)(= 180° - 46°)$, i.e. a change of only 5° in the angle of incidence must cause a variation in the refractive phase-change of as much as 134°. This of course is not impossible, but it seems very large to be assumed.

* *Proceedings of the Royal Society*, A, 1925, vol. 108, p. 52.

I am afraid I am unable to follow Mr. Taylor's ideas on guided waves from a quantitative point of view. Even if one were to admit his contention that such waves could travel very large distances along a pair of wires without serious attenuation (incidentally I believe Mr. Taylor admits that if his wires were perfect conductors they would not guide the waves, so that there must be some loss on this basis), I fail to see how the effect can continue when the wires are replaced by a conducting surface covering the earth, in which case the same amount of energy must spread out over the whole earth instead of being strictly localized as before. Again, with regard to the interference effect being produced by the reconcentration of waves which have travelled round the earth, the components of such a concentration, having all travelled by different paths, would meet with every possible value of relative phase relation and so would, on the whole, neutralize one another. Moreover, it seems inevitable that under such conditions the appearance of interference maxima and minima would be entirely fortuitous, whereas the experimental evidence alone, apart from any theory, shows that they obey very definite sequential laws. Moreover, Round and Eckersley have definitely observed a phenomenon of this type under antipodal conditions, the special features of which do not occur elsewhere.

There is not much that I can add to Dr. Smith-Rose's survey of the subject except to emphasize the point that this paper is simply another link in the chain of evidence. As he points out, at the time this work was started there were still very strong differences of opinion on the subject and in view of its importance there was a real need of further evidence gathered from as many different points of approach as possible. I have never regarded it as anything but a slightly new method of attack on an old problem, which is perhaps a partial explanation of the lack of references to other work that has been remarked upon.

The October change referred to by Mr. Moullin is probably of the nature of a sudden change superposed on a slow mean change, but I am at present inclined

to think that in a Fourier analysis the fundamental would be small. The striking fact is the abrupt change in the nature of the readings about this time, as will be seen from the figures in Table A.

It will thus be seen that on the 12th October occurs the first drop below 1 000 for nearly 6 months, and that on the 30th October the readings again broke abruptly to an entirely different order with enormous day-to-day variations. It will also be obvious from figures of this nature that any average taken during November would have no physical meaning.

The daily analysis curves also show a very abrupt change of height of 10 to 15 km at this time, but the change from comparatively steady to violent daily oscillation is the most marked feature. Probably the explanation may be found in a rapid change of layer characteristics in the neighbourhood of this height, and information on this subject from other sources would be extremely welcome.

The work of Appleton and Barnett was not specifically referred to since it was not actually published until after the completion of this paper, but the application of their method was seriously considered and only turned down for practical reasons. In their method the percentage variation of wave-length necessary to produce a given number of interference bands for small changes of wave-length is proportional to the wave-length. Hence on a wave-length of 9 000 m, the number of maxima obtained for the same swing of wave-length would be 1/20th of that on 450 m and is consequently mechanically impracticable. During the tour in Fig. 5 the extreme range of variations was about 20 per cent. These variations were not momentary, as during each day the variations were not more than 10 per cent, and it is thought that they were partly due to the seasonal drift as the tour extended over several months, and possibly also to slight differences in aerial current. It must be remembered that not more than 5 per cent accuracy is claimed for individual readings and perhaps 10 per cent on high-speed automatic working when using the portable set where it is not practicable to take so many precautions as on the fixed set. Provided the set is not worked with an excessively small decrement, there is no appreciable difference in intensity for any frequency of sending for which it is possible to observe the string movement with the eye. The station used, FT, which alternates periods of slow and fast sending, provided many opportunities of verifying this.

The double points in Fig. 5 are readings taken at different times and in different localities which happened to be equidistant from the transmitter. Some of them lie within the limits of experimental error, but the large variations at distances of 750 to 850 km cannot be explained on this basis. It is striking that they were all taken in the Northumberland district where the country is very broken (so that choice of suitable sites was extremely difficult) and where there is an enormous quantity of overhead lines of various natures. On the other hand they may be purely experimental errors. As every reading taken on the tours is included, the graph is not merely a selection of the best. The neighbourhood requires more survey to settle this point and this was not possible last year, but I am hoping to obtain this year, curves on the same lines as Fig. 5 but on different wave-lengths, and while I am in that district I shall investigate the point further.

I cannot understand Mr. P. P. Eckersley's remarks as to the absence of reference to Mr. T. L. Eckersley's paper. It is definitely referred to twice, though in the advance proofs of the paper (for brevity's sake) it is mentioned by the name of the first author (Captain Round) only. Personally I was never of two minds as to the value of this work, but is Mr. Eckersley aware that as late as the end of 1924 the definite statement, "There is no Heaviside layer," was made and several times repeated in a paper, and that a similar opinion has been expressed this evening? In view of this it appeared that there was still further need of independent evidence on the subject, and this paper has attempted to supply it in part.

The results obtained by B.B.C. stations are most valuable on this subject and I hope they may be followed by quantitative figures. They show that there is no doubt that shorter waves are affected by the configuration of the ground, and also probably by the nature of the surface. From the point of view, however, of the study of the upper layer such results would merely introduce a further complication into a subject already bristling with indeterminate factors, and I feel that for this investigation long waves are preferable to begin with. The study of shorter waves is, of course, an essential future development.

THE DIRECTIONAL RECORDING OF ATMOSPHERICS.

By R. A. WATSON WATT, B.Sc. (Eng.), Associate Member.

[Communicated by permission of the Radio Research Board.]

(*Paper first received* 15*th September, and in final form* 14*th December*, 1925; *read before the* WIRELESS SECTION 3*rd March*, 1926.)

SUMMARY.

The paper describes a simple pen-writing instrument for the continuous recording of the apparent direction of arrival of atmospherics, and cites typical samples of the data obtainable from such recorders. The samples chosen show the diurnal variation of intensity of atmospheric disturbance, the diurnal variation of apparent direction of arrival, and the location of apparent sources of atmospherics by a group of recorders.

TABLE OF CONTENTS.

I. INTRODUCTION.

The data which have until recently been available as to the incidence of atmospherics have consisted almost entirely of relatively brief and isolated observations based on aural estimates. There does not yet exist a sufficient quantity of comparable data, from well-spaced observing stations, over an adequate period, to present anything beyond the barest outline of the world distribution of atmospherics. The purpose of the present paper is to describe an instrument which, despite many limitations and imperfections to be enumerated, does enable continuous records taken under comparable conditions at widely distributed stations to be obtained and compared without an excessive expenditure of effort. The description is followed by some data from a first group of such recorders, which are presented as typical of the minimal results to be expected from an international network of co-ordinated recording stations. Such a network seems to be called for at the present stage of research on atmospherics.

II. HISTORICAL.

The development of the recorder to be described arose from a limited investigation into the possibility of locating thunderstorms by observations on the apparent direction of arrival of atmospherics, which was initiated by the Meteorological Office in 1915.* This work was subsequently developed into a fundamental inquiry into the origin and nature of atmospherics, under the auspices of the Radio Research Board which was established under the Department of Scientific and Industrial Research in 1920.

The first observations were made aurally by means of the standard Bellini-Tosi radiogoniometer, and the results of observations at certain coastal direction-finding stations have been discussed elsewhere.*

As a matter of convenience, recourse was later had, at the experimental station set up at Aldershot by the Meteorological Office, to the frame-aerial direction-finder, and a statistical analysis † of a year's data from this instrument has been published. While these observations were in progress, and in the intervals of other meteorological duties, experiments were in progress with a view to the development of a simple and easily operated directional recorder, with the purpose of obtaining data throughout the 24 hours, and not merely at selected hours. The obstacles to the production of such an instrument were, at the period when the work was undertaken, the lack of a robust pen-writing galvanometer of short period with good damping, and the imperfections and inconstancy of the multi-stage triode amplifier.

Many schemes for recording were considered and tried. It was known that for application to everyday meteorology a recorder depending on photographic registration would be unsuitable, hence the otherwise clearly indicated Einthoven galvanometer was ruled out. Considerable success had been attained with a modified Duddell oscillograph arrangement, carrying a light siphon pen in place of the mirror, when details became available of the Abraham-Bloch moving-iron oscillograph. The published data showed that this instrument had a sensitivity comparable with that of the bifilar instrument tried at Aldershot, and was considerably more compact and economical. Samples were therefore procured, and the form of recorder developed depends on the use of the Abraham-Bloch instrument.

Concurrently, tests were made of a variety of triode amplifiers, with special reference to their suitability as amplifiers of atmospherics. The special features required were stability and constancy, freedom from internally generated disturbances simulating atmospherics, and absence of sharp selectivity. The resistance-capacity type proved itself by far the most suitable.

† WATSON WATT: *Proceedings of the Royal Society*, A, 1922, vol. 102, p. 464.

The first instrument resulting from these experiments came into operation at Aldershot in December 1921, and continued to run practically uninterruptedly until August 1924, when it was dismantled for removal to the new site at Ditton Park, near Slough, of the Radio Research Board's station for investigations on atmospherics.

Slight mechanical and electrical improvements, converting the instrument into a self-contained device ready for housing in an outer shell of the requisite size, were embodied in the pattern of recorder finally standardized, constructed at the Aldershot station and issued in 1924 to four stations at home and abroad. This standardized pattern of directional recorder for atmospherics will now be described in detail.

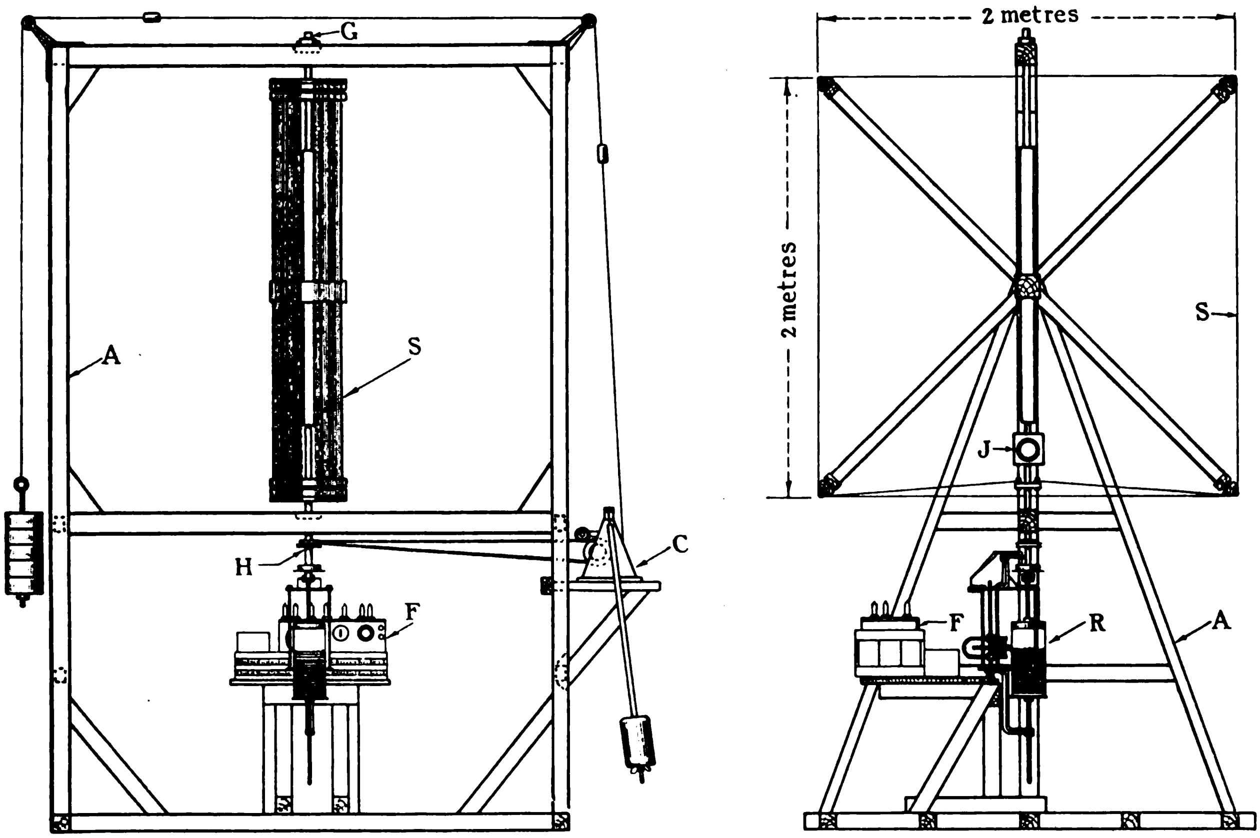

Fig. 1.—General arrangement of recorder.

III. The Directional Recorder.

The instrument, the general arrangement of which is indicated in Figs. 1 and 2, comprises a teak framing A, which supports a frame antenna S, belt-driven by a turret clock C, and carrying a recording drum R, on which is inscribed the trace of the oscillograph pen E, actuated by the output of the multi-stage amplifier F connected to the frame antenna.

The main teak framing is designed to give the rigidity required for smooth and uninterrupted running. Early experience showed that the reserve of driving power from a clock of moderate dimensions was so slight that rigid supports and careful maintenance of clean bearings were essential. The base measures approximately 2·5 by 2·2 metres, the overall height being just under 4 metres. The hut necessary to house the instrument, with the necessary clearances, measures 4·5 metres high by 3·75 metres square.

The driving clock, supported by a bracket on the outside of the main framing, is a small turret movement with a 15 cm (6 in.) main wheel and a robust escapement protected by a safety clutch. The driving barrel is exceptionally large; since daily winding at the time of chart changing is convenient a relatively small driving weight with a rapid rate of fall is permissible, and the weight of about 30 kg falls 7·5 cm per hour. The driving cable, broken by insulators, passes over pulleys which carry it over the main framework. This maintains the self-contained nature of the installation, and makes some slight contribution to the rigidity of the structure. The drive is taken by a 6 mm diameter leather belt from a stepped pulley on an intermediate shaft of the movement. The original recorder had a bevel gear drive on a silver-steel shaft, but the more elastic belt drive was substituted to reduce the stresses due to the application of essentially intermittent impulses from the escapement to the frame and drum system, the moment of inertia of which is considerable (of the order of 10^5 kg-cm^2).

The frame antenna measures 2 metres square and

0·4 metre deep. It is wound on a spider of paxolin tube, with teak centre and corner bearers, the weight of frame and winding being some 12 kg. The evolution of this light antenna is of some interest; the first frame antenna used in quantitative work at the station, having been wound in copper wire on solid timber, weighed about 75 kg. Later frames were wound in aluminium on hollow aeroplane spar spiders, and paxolin was finally substituted on account of its excellent mechanical and dielectric properties, coupled with the fact that it cost no more than hollow wood spar. The resulting 12 kg antenna has a higher value of area-turns and inductance than had the original 75 kg structure.

The winding of the antenna is in four sections, two of 20 turns each, and two of 10 turns, each of 1·2 mm diameter bare aluminium wire, with a winding pitch of 5 mm. The sections are separately terminalled for series or parallel groupings; normally they are connected in series. The taking up of sag due to initial stretching and to thermal expansion of the wire in varying climatic conditions is of considerable importance in closely wound frames of large size; it should be accomplished without increase of leakage paths such

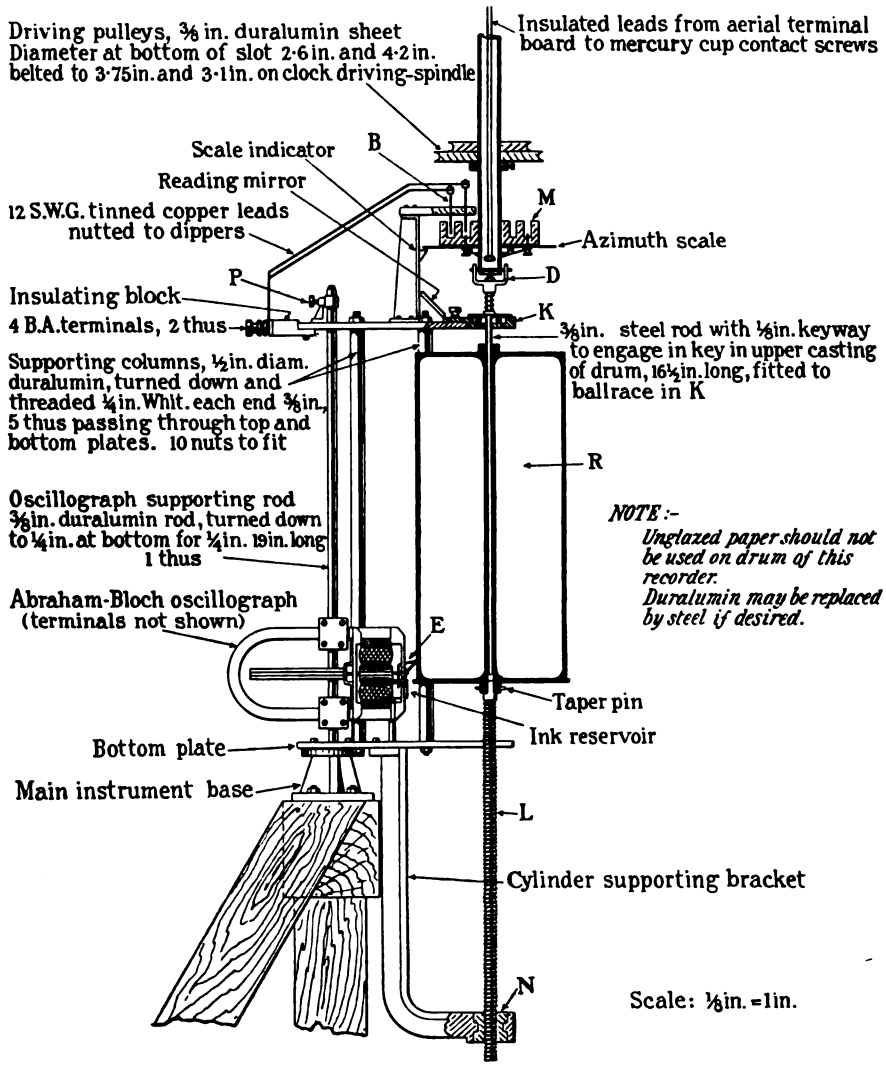

FIG. 2.—Details of recorder.

B = Two 14 S.W.G. copper dippers passing through ⅜ in. paxolin sheet, 3 in. × ¾ in., secured to pillar support with 4 No. 6 B.A. screws.
D = Forked brass casting.
E = Girder pen.
K = Ball-race housing.
L = ⅜ in. steel rod 15 in. long; 1 in. turned down to ¼ in. to fit bottom drum casting; bored for taper pin. Thread ⅛ in. pitch.
M = Mercury cup; 1 in. × 4 in. diam. bakelite-delecto, bored 1 in. in centre with 2 circular channels ½ in. × ⅜ in. deep, fitted steel contact screws. Secured to shaft by collar and pinching screw.
P = Pen-adjusting mechanism.
R = Recording drum, 6 in. outside diam. × 13½ in. long, in brazed copper tube, brass castings at ends bored for centre tube after assembly; centre tube internal diam. to clear ⅜ in. rod. To run true to 1/100 in. in passing pen point.

as was introduced by the first device of combs, in the middle of each span, connected by tension springs to the central boss. The final device, which has proved thoroughly satisfactory, was the introduction of four heavy volute springs in compression in each corner member of the spider. These springs compress 3·5 cm per 100 kg load, and the average compression in each paxolin member of the spider is about 150 kg at normal temperature.

The insulation and pitch of the winding are maintained by winding in locating grooves in paxolin rods carried on each corner member.

The frame antenna hangs freely, by means of a duralumin tube (G) of 2·5 cm diameter forming part of the composite main axis of the antenna frame, from a self-aligning ball race—nominally a radial bearing but employed as a thrust bearing in preference to the standard thrust bearing, which was found to have more friction—carried in the upper member of the main framework. A similar duralumin shaft (H) is carried through a radial bearing in the lower member of the framework 1·25 metres above ground, and carries driving pulleys, tuning condenser, mercury "slip-rings," and an azimuth scale. The shaft terminates in a pin which engages with a fork (D) for transmission of rotation to the recording drum. A variable condenser (J) of maximum capacity 0·01 μF is connected across the winding, and a pair of leads is brought through the lower duralumin shaft from the terminals of this condenser to the mercury slip-rings carried in a moulded insulating collar (M); into these slip-rings dip stout copper brushes connected to the input terminals of the amplifier.

The amplifier is fitted with five stages of resistance-capacity coupling, followed by a detector and two stages of transformer-coupled low-frequency amplification. Provision is made for the use of a varying number of the high-frequency stages, three such stages being normally used for recording atmospherics. The coupling resistances of 100 000 ohms each are wound from 0·04 mm diameter constantan, on slotted ebonite formers, the direction of winding being reversed in alternate slots to reduce the total inductance. The ordinary anti-inductive winding is objectionable on the grounds of self-capacity, whilst the special anti-inductive and anti-capacitative windings are too bulky and too costly to be justified in this application. The adoption of wire-wound resistances was found necessary on account of the very high temperature coefficients of resistance of the more usual forms of anode resistance. The residual temperature coefficient of constantan is actually slightly advantageous, since its sign is such as to assist in compensating the temperature coefficient of voltage of the plate circuit accumulator battery. Carbonized cellulose grid-leaks, although objectionable, were retained in the standard design, *faute de mieux*. A milliammeter is provided in the common plate circuit lead to the first seven stages, measuring the sum of the plate currents in these stages, whilst a second milliammeter measures the current in the output stage. A switch and series resistance are provided so that the former milliammeter can also be used as a voltmeter for the plate circuit battery. The coupling elements are well spaced to reduce stray couplings, and negative capacitative retroaction is provided for stabilization. The amplifier is contained in a teak case 50 × 28 × 28 cm, with ebonite front and top, the front carrying meters and controls, the top carrying triode sockets.

The triodes used are dull-emitters with 1·8 volt, 0·3 ampere filaments. All except the last stage are of the D.E.R. type with internal impedance of the order of 30 000 ohms, whilst the output stage contains a D.E.6 triode of 13 000 ohms impedance. Accumulators (90 ampere-hour), crated in groups of three, are used for filament lighting. They are charged in series and discharged in parallel, and no important fall in voltage takes place in 24 hours; thus with a slight adjustment each day a sensibly uniform current is maintained throughout four days at one charge. The plate batteries are 60-volt units of 1·25 ampere-hour capacity, with ribbed glass cases, so arranged that each individual cell is visible for maintenance. Similar cells are used in a 10-volt unit which maintains the normal grid potential of the output triode at − 10 volts. This gives rectification of the output current, eliminates interference by transmitting stations, and selects only the stronger atmospherics for recording.

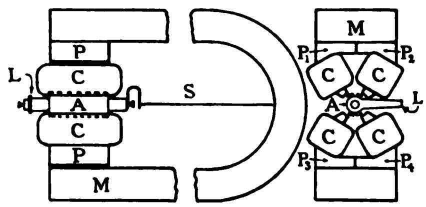

FIG. 3.—Abraham-Bloch oscillograph.

The oscillograph (Fig. 3) inserted in the plate circuit of the output triode is a tetrapolar moving-iron instrument, designed by Abraham and Bloch,* and made by the Carpentier workshops in Paris. It comprises a permanent magnet M with four laminated radial poles P_1 to P_4, each carrying a coil C, the coils being so connected that the passage of a current rotates the resultant magnetic field to a new direction. The solid soft-iron armature (A) in following this rotational displacement produces torsion of the steel-wire control spring (S). The coils have a total resistance of 10 000 ohms, the armature has a moment of inertia of 2·75 g-cm^2, whilst the restoring couple per unit displacement is of the order of 10^6 dyne-cm. The free period of the armature is about 0·01 sec., strong magnetic damping being obtained by the non-lamination of the armature.

A tongue on the armature shaft carries a pen girder (Fig. 4) in aluminium. The girder, cut from sheet 0·2 mm thick, is 9·5 cm long, and carries a siphon pen of silver tube of bore 0·12 mm and total length 3·5 cm. The total weight of girder and pen is 0·4 g. This pen dips into an inkwell of adjustable height; the pen will feed from a negative head of over 1 cm, but it is usually operated at a head between zero and 2 mm. The girder is designed to give considerable rigidity in its own plane, combined with flexibility in a plane at right angles, so that pen friction may not be

* *Revue Générale de l'Electricité*, 1920, vol. 7, p. 211.

unduly increased by slight irregularities in paper thickness, truth of drum, and such causes. Residual variations in pen friction are not important in view of the large working forces of the oscillograph.

The recording drum (R in Fig. 2) is a vertical brass or aluminium cylinder 34 cm long by 15·3 cm diameter, with a square-threaded steel lead-screw (L) of 3 mm pitch pinned to its lower end. This lead-screw works in a nut (N) clamped in the recorder stand.

No direct quantitative calibration of the response to atmospherics can, for the reasons given in Section IV (3) following, be made. For the purpose of determining a typical overall performance, however, recourse was had to measurement with a steady input at 15 kilocycles, with 100 per cent modulation at 1 kilocycle, and the results are shown in Fig. 5.

The oscillograph pen gives a deflection of 3 mm per milliampere for small deflections.

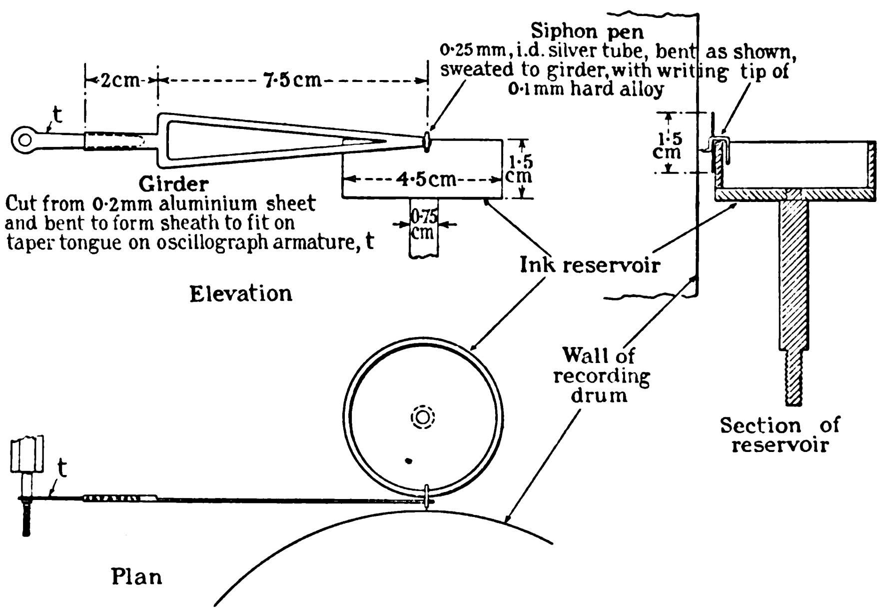

Fig. 4.—Girder siphon pen.

The fork (D) already mentioned turns, in a radial non-self-aligning bearing, a guide rod in which is cut a longitudinal (vertical) keyway; a feather on the bore of the drum engages in this keyway, carrying over the rotation of the frame antenna to the drum, which is simultaneously lowered by the lead-screw. The chart is a rectangle 49 cm × 34 cm wrapped around the drum, resting on the lower flange, and with a vertical 1 cm lap joint secured by photo mountant. The housing of the small radial bearing, and the lead-nut, are secured by clamping devices so that the system comprising guide rod and bearing, drum, lead-screw and nut can be lifted out as one unit for chart-changing and re-setting of the nut to the lower end of the lead-screw. On removal from the drum the helical trace is resolved into 96 approximately horizontal lines, each representing one revolution, or 360° in angle, and 15 minutes in time at the normal speed of rotation.

Electrical constants.—The frame antenna has a maximum inductance of 13·5 mH and is tuned to 15 000 cycles (20 000 m) by the variable condenser. The d.c. resistance of the four sections in series is 10·8 ohms, whilst the high-frequency resistance at the working frequency is 50 ohms. This comparatively high value might of course be reduced by sacrificing the wide band of wave-lengths for which the instrument is designed.

Operation.—It will be seen from the description that the method of operation of the recorder is as follows. The turret clock drives the frame continuously at a speed of 4 (or if desired 8) revolutions per hour. The fork connector and guide rod transmit this rotation to

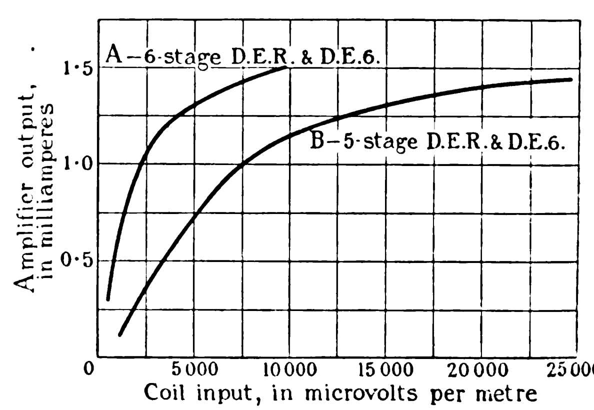

Fig. 5.—Calibration of recorder.

the drum carrying the chart, and the lead-screw feeds down through its stationary nut, so that the drum descends through 3 mm per revolution. The oscillograph pen will thus, in the absence of impulses from

the amplifier, describe a helical trace of 3 mm pitch on the chart. The arrival of an atmospheric producing a sufficient voltage release in the amplifier will be marked by a vertical excursion transverse to the helical base. The amplitude of this excursion will, within limits to be mentioned later, be a measure of the voltage produced across the tuning condenser, and its position on the trace will be a direct measure of (*a*) the time of arrival of the atmospheric and (*b*) the instantaneous azimuth of the plane of the frame antenna at that moment; since the drum is directly coupled to the frame, all impulses received when the frame is in a given azimuth will appear on the same generator of the cylinder formed by the chart.

If then we had a single sharply-directed stream of uniform atmospherics impinging on the antenna, a single revolution would give a trace in which the lengths of the transverse kicks due to atmospherics departed from a simple function of the cosine of the instantaneous angle between the plane of the frame and the axis of the " beam " of atmospherics, only on account of the non-linear response of the amplifier and the oscillograph. The envelope of the extremities of the deflections would, in any case, be a double-humped curve with two sharply-marked minima locating the plane perpendicular to the axis of the beam.

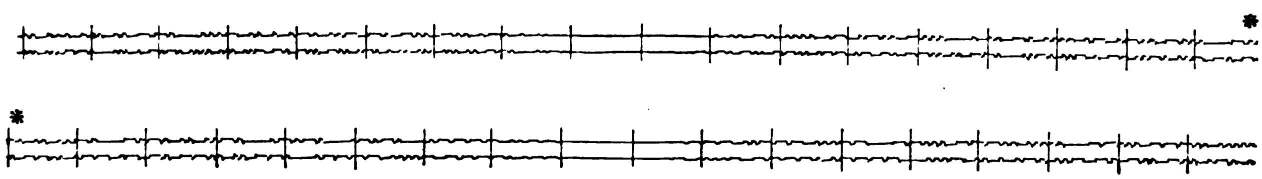

FIG. 6.—Signal trace from recorder.

The very wide range of variation in peak field strength, rate of change of field strength, duration and relative times of arrival of atmospherics, and of the position of their sources, precludes the possibility of obtaining an actual record corresponding to this ideal case, but the nature of the response is well shown in Fig. 6, which is a record of the deflections, over two whole revolutions, due to a received signal from Ongar (GLO) wireless telegraph station.

IV. DEFECTS AND LIMITATIONS.

The recorder is obviously a somewhat crude device, far short of the ideally quantitative, sharply directional and discriminating recorder which is desirable. But it was considered worth while to develop and run an instrument which has the very real merit of demanding practically no maintenance attention other than chart changing and accumulator charging, so that it might be providing preliminary data while more fundamental work, the progress of which was certain to be slow, was being carried out along with other lines of investigation on atmospherics.

The principal defects of the method are as follow :—

(1) The instrument is non-discriminating, in that it deals with the average direction of arrival of the whole distribution of atmospherics. The large area enclosed by the polar curve of reception, the cosine curve of the ordinary frame aerial, involves the superposition of effects from all azimuths, so that, for example, the appearance of a small disturbance at a position on the chart corresponding to azimuth ψ may correspond to the arrival of an atmospheric of small amplitude along the great circle of azimuth ψ or $\psi + 180°$, or of a moderate atmospheric from $\psi + 40°$, or of a strong atmospheric from $\psi + 80°$. Thus it is to be expected that at times the trace will be too much complicated by dispersed directions of arrival to give an intelligible record of the distribution; but, as will be seen later, these cases are comparatively rare, and a single predominant stream of atmospherics is generally traceable from the records.

(2) The instrument is only quantitative within somewhat narrow limits, the lower limit being set by the comparative insensitivity imposed by the use of a pen-writing oscillograph. This limit would, however, have appeared in any type of incompletely discriminating recorder, since the traces from an oversensitive instrument cannot be interpreted. The upper limit, imposed by saturation of the triodes in the final stages, and by the characteristic curve of the oscillograph, is a more objectionable factor, but again narrow limits must be imposed on any type of recorder if a 24-hour record is to be compressed in a reasonable area of paper. Were the limitation of deflections to the order of a few millimetres not imposed by the amplifier-oscillograph system, it would be necessary to impose it otherwise, unless a tape record of inordinate length were to be tolerated.

(3) The instrument gives a deflection the amplitude of which, for any one atmospheric, depends not simply on the peak field strength or on a simple function of that field strength, but on the wave-form and duration of the impulse, in relation to the characteristics of the tuned circuit and of the moving-iron oscillograph.

(4) The record becomes too sparse to be interpreted if the total amount of disturbance falls to a low value. This reduces the applicability of the instrument for the study of what might otherwise be the simplest distributions experienced.

(5) The sense of the direction of arrival is not determined, i.e. the normal radiogoniometric ambiguity of 180° remains.

V. ADVANTAGES.

These defects and limitations, formidable as they may be, are, after all, common in greater or less degree to all normal direction-finders, and the data supplied, though far short of the absolute standard, may on this account be expected to be comparable with that from aural directional observations. But whilst it is practically impossible to devote sufficient labour to aural recording to provide more than five test observations

daily, and whilst these observations are subject to errors of sampling and to large personal factors, the recorder gives fair sampling under relatively invariant observational conditions throughout the 24 hours, the total time devoted to maintenance and to reduction of records being less than would be required for the inadequate aural sampling. In particular, the instrument is ready at all times to record special phenomena, whilst the aural observer is, by the exigencies of everyday life, practically limited to fixed-hour observations if any protracted period is to be covered, and is seldom beside his apparatus when conditions of special interest arise suddenly.

The recorder has the further advantage that its trace is available for re-examination in case of doubt, or when a new line of investigation suggests itself.

Finally, the recorder enables data to be collected at widely scattered stations without the provision of specially trained and skilled observers.

A click recorder.—It is, however, to be kept clearly in mind that, partly by the inherent characteristics of its components and partly by deliberate choice and adjustment, the recorder is almost exclusively a "click" recorder, giving traces in which the strong, comparatively isolated, impulses, comparable in aural effect with those received in daylight from lightning within 1 000–2 000 km, predominate over the more continuous stream of relatively weak disturbances which may, on account of its continuity, be a more serious interferent agent in long-distance radio telegraphy. Thus it will be necessary, in comparing results with those of other methods, to remember that every method is selective as to the type of disturbance receiving most weight in the measurement, and the differences resulting from this selectivity, though confusing at first, may be expected to throw light on the origins of different elements in the general distribution of atmospherics.

Maintenance and reliability.—The average amount of time required for maintenance, accumulator changing and chart changing is somewhat under $\frac{1}{4}$ hour per day. The reliability of running may be inferred from the results of the first $2\frac{1}{2}$ years' experience, with the first instrument of its kind, at Aldershot. The total number of "lost hours," i.e. hours when no record, or a record marred by remediable instrumental faults, was obtained, averaged 8 per cent over the whole period, but fell to 3 per cent over the last $1\frac{1}{2}$ years. The higher percentage losses in the first year were due in part to lack of mechanical rigidity affecting the clock drive, and in part to considerable difficulties with early dull-emitter valves, now happily surmounted by the extreme reliability and constancy of the D.E.R. valve. It need hardly be pointed out that it was the advent of the dull-emitter which made the instrument practicable for general issue, since a recorder using 6 to 8 bright-emitters for 24 hours each day involves accumulator charging on an almost prohibitive scale.

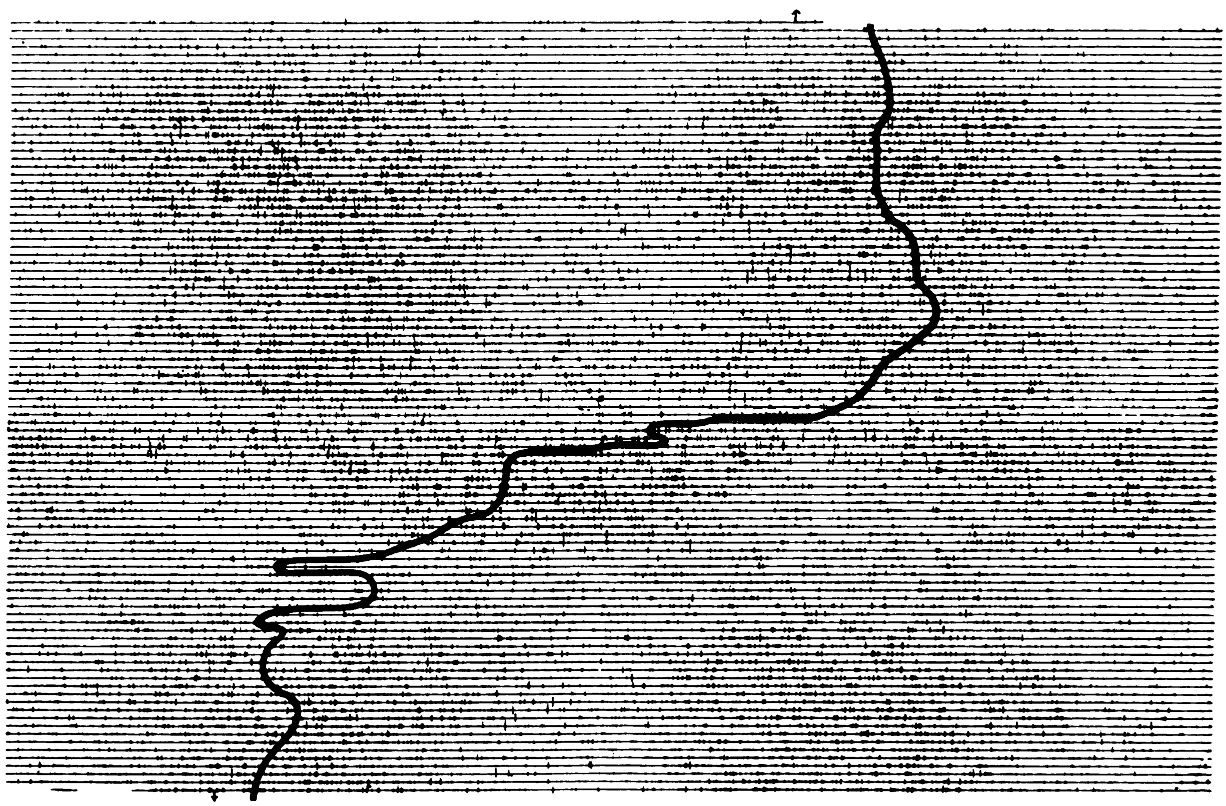

FIG. 7.—Typical daily chart.

VI. Reduction of Records.

The reduction of the resulting records may be carried to varying stages of completeness, according to the use to which the data are to be put. Mere visual inspection of the chart in situ is usually sufficient for a determination within 10 degrees of the apparent direction of arrival and for estimation of the relative intensity of disturbance. It is believed that a much smaller instrument could now be designed for used in an ordinary room, and that a number of such instruments would help to clear up many of the remaining obscurities in the problem of atmospherics.

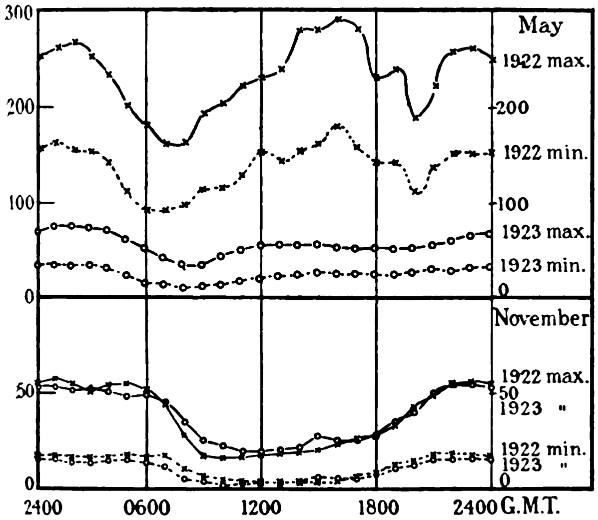

Fig. 8.—Diurnal variation of intensity.

For closer and more complete study of the direction of arrival, the charts are examined line by line, and the most probable direction of maximum disturbance is determined by location of the two maxima 180° apart and two minima approximately midway between these maxima. The points so found are joined by a more or less continuous line traversing the chart, from which can be read the mean azimuthal position of the frame antenna against which appear the greatest number of recorded atmospherics of large or moderate amplitude in each hour. This is accepted as the mean apparent direction of arrival of atmospherics for the hour. Fig. 7 is a typical chart, with the line of most disturbed azimuths drawn in. It is frequently possible to trace double distributions, and in many cases a "grinder maximum" marked by the occurrence of large numbers of disturbances of small amplitude can be located with some accuracy, in addition to the location of the "click-maximum."

The accuracy with which these azimuths can be determined is, of course, difficult to specify. There is no doubt that, regarding the mere reduction of the trace, discrimination to about 2° in azimuth is normal. How far this is from corresponding to a 2° accuracy in discriminating the great circle joining the source of atmospherics to the recording station can only be inferred from comparison of the resulting data with data otherwise obtained.

This directional reduction is a relatively simple and brief process. If, however, estimates of relative intensity are required a somewhat laborious process is involved. The charts are ruled with a graticule dividing them into blocks of which the width represents 10° in azimuth and depth 1 hour in time. The integrated departure from the base line in the blocks containing the maximum and minimum disturbance are then determined by an opisometer, and the "intensity at maximum" and "intensity at minimum" for each hour are tabulated, on the arbitrary scale resulting from the complex process of reception, amplification, rectification, magnification, limitation, re-rectification, recording and measurement.

It cannot be pretended that the sensitivity of the whole instrument can be kept nearly constant from day to day, but it is most probable that the relative disturbance from hour to hour of the same day, and the mean intensities measured over long periods, will be comparable. The first typical data to be presented will illustrate this point.

Table 1.

Interval (in hours) between times of the various stationary points and the times of the solar phenomena to which they are related.

Month	Jan.	Feb.	Mar.	Apr.	May	June	July	Aug.	Sept.	Oct.	Nov.	Dec.
M_1 after sunset	6	6	$5\frac{1}{2}$	$5\frac{1}{2}$	6	$6\frac{1}{2}$	$6\frac{3}{4}$	$7\frac{1}{2}$	7	7	$6\frac{1}{2}$	$6\frac{1}{2}$
M_2 before sunset	4	$4\frac{1}{4}$	5	5	4	5	6	$5\frac{1}{2}$	5	4	—	$4\frac{3}{4}$
M_3 before sunrise	2	2	$2\frac{1}{4}$	3	$2\frac{1}{2}$	$2\frac{3}{4}$	$2\frac{3}{4}$	$1\frac{3}{4}$	1	$1\frac{1}{4}$	—	1
M_4 before sunset	$\frac{1}{4}$	$2\frac{1}{4}$	1	—	1	$\frac{1}{4}$	1	$\frac{3}{4}$	$2\frac{1}{2}$	$2\frac{1}{4}$	1	$\frac{3}{4}$
N_1 after sunrise	$3\frac{1}{4}$	$2\frac{1}{2}$	$3\frac{1}{2}$	—	$3\frac{1}{2}$	—	5	$5\frac{1}{4}$	5	$4\frac{3}{4}$	4	—
N_2 after sunset	$\frac{1}{4}$	$-\frac{1}{2}$	0	0	$\frac{1}{4}$	—	$\frac{1}{4}$	$-\frac{1}{2}$	$-\frac{1}{2}$	$-\frac{1}{2}$	0	$-\frac{1}{2}$

Note :—M_1 and M_3 coalesce in August.
M_3 nearest sunrise save in June and July, when M_1 crosses.

VII. The Diurnal Variation in Intensity of Disturbance.

Data as to the monthly mean value of the intensity of disturbance at each hour of the day, for the hourly azimuths of greatest and least disturbance, are available from the Aldershot records from January 1922 to August 1924. The curves for the months of May and November are shown in Fig. 8 as illustrating the greatest and least diversity in intensity experienced for the same months in different years; they serve particularly to emphasize the close agreement between the trends plotted in Fig. 9. It will be noted that each monthly curve contains some 7 or 8 stationary points, and that of these there stand out prominently a principal maximum M_1 in the hours of darkness, a secondary maximum in the early afternoon, a principal minimum N_1 before noon, a secondary minimum in the early evening, and subsidiary maxima in the early morning and evening. The times of incidence of these stationary points are plotted in Fig. 10, in which are also shown the mean times of sunrise and sunset for each month. It is immediately obvious that a close correlation exists between the incidence of the

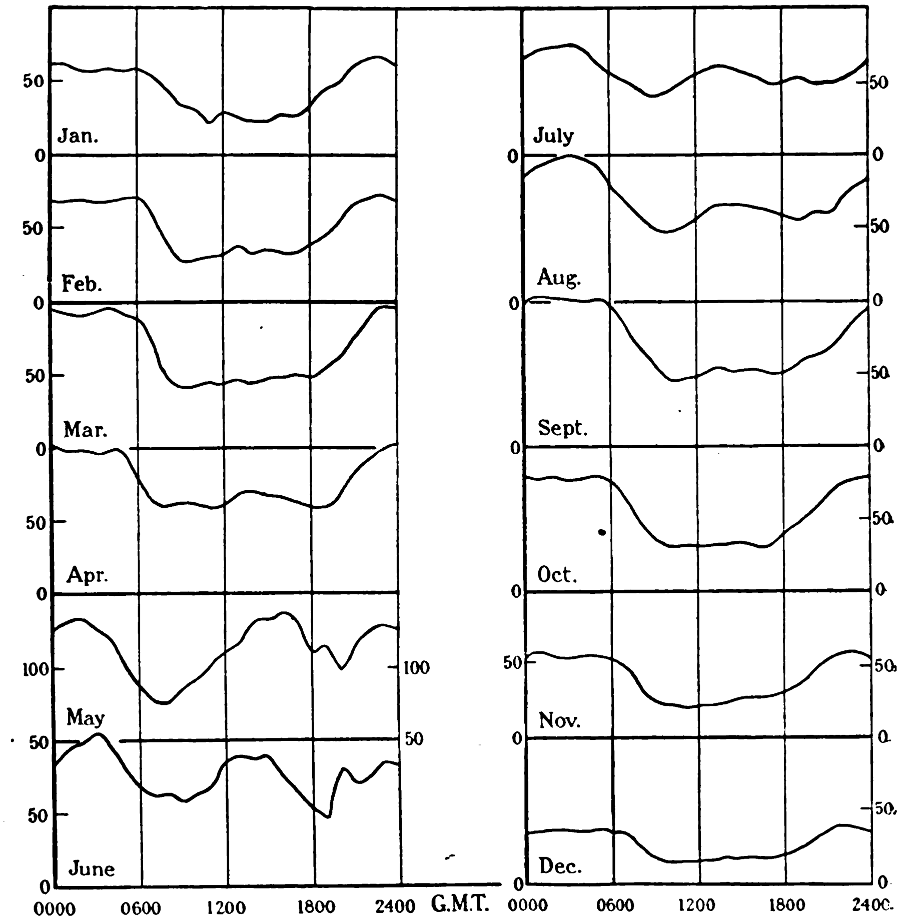

Fig. 9.—Diurnal variation of intensity.

of the intensity curves at the directions of maximum and minimum disturbance, and the constancy of form of the diurnal variation, even in years where the actual amplitudes differ considerably. The similarity of the curves of intensities at the directions of maximum and minimum disturbance is doubtless very largely due to the wide polar curve of the frame antenna and need not at the moment be examined further, since more refined methods will improve our discrimination in this respect. The form of the diurnal variation will therefore be discussed with reference to the values from the direction of maximum disturbance throughout. The mean monthly curves for the $2\frac{1}{2}$ years' data are maxima and minima of disturbance and the times of zero solar altitude at the receiving station. Table 1 shows the approximate constancy of the intervals between the times of the various stationary points and the times of the solar phenomena to which they are related. It may be added that similar relations hold for some of the still less prominent irregularities which appear in the curves of Fig. 10.

Speaking generally, then, the diurnal variation of atmospheric disturbance in a long-wave receiver in England may now be described, with much greater accuracy and confidence than has formerly been possible, as reaching a maximum 6 hours after sunset,

the fall from the maximum being temporarily interrupted by a slight increase 2½ hours before sunrise. (In May and August the maxima coalesce, whilst in June and July they are reversed in sequence, owing to the shortness of the sunset to sunrise period.) The minimum disturbance of the day is reached some 4 hours after sunrise. An increase, most marked in summer, then begins, and reaches a maximum 5 hours before sunset (this maximum is just detectable in winter, and in summer rises to the same order of amplitude as does the principal maximum). The fall to a secondary minimum at sunset is interrupted by a slight increase 1 hour before sunset.

arrival in the same general statistical fashion as has been used in the case of intensity values. The main difficulty, to which reference has already been made on page 599, is that due to the ambiguity of 180° in the determination of azimuth. This ambiguity renders difficult the selection of a direction which may be accepted as characteristic of a period. If, for example, a "mean direction of arrival" for a period is to be extracted, the mean will be widely displaced by the reversal of the sign attached to directions approximately 90° from the mean. In the former papers cited, the mean was extracted on the specific assumption that the distribution was approximately symmetrical about

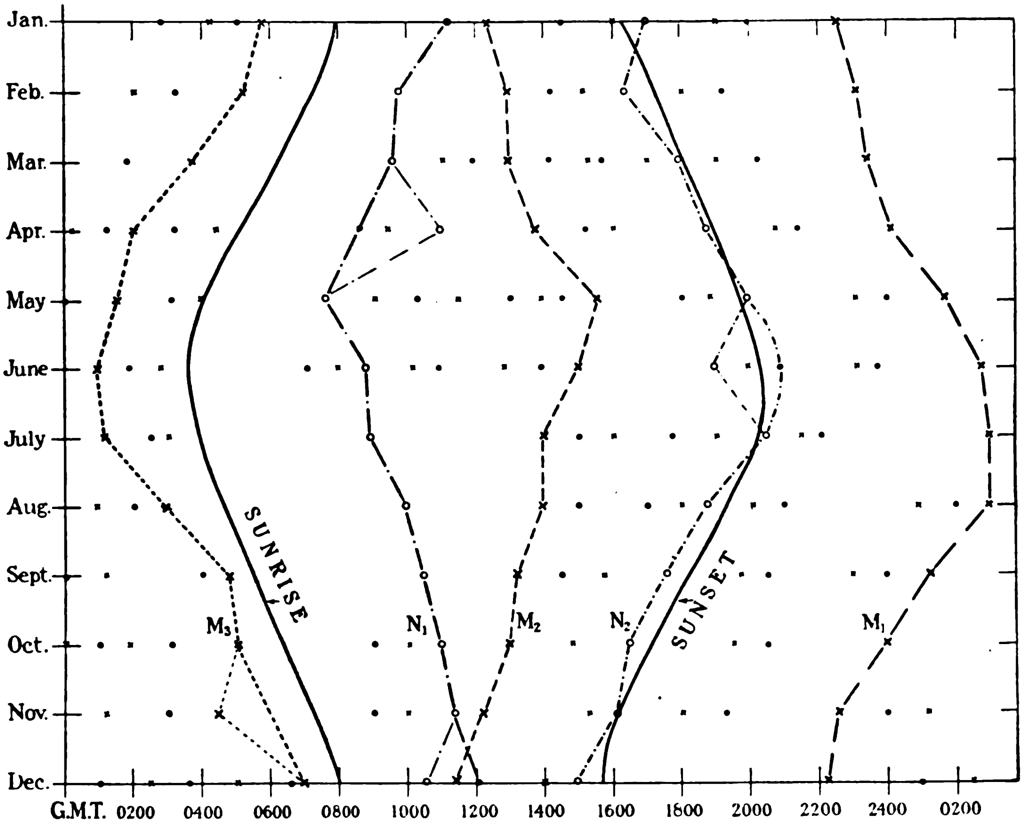

Fig. 10.—Principal stationary points in intensity curves.

Since these relations were examined, a paper * has appeared dealing with diurnal variation curves based on observations through one sample day per week in the years 1923–24. In view of the interest attaching to a comparison of these results, and of the fact that the present paper is intended rather as indicating the scope of the recording methods described than as a discussion of resulting data, it appears desirable to leave such discussion for another occasion.

VII. Diurnal Variation of Apparent Direction of Arrival.

Certain difficulties present themselves when an attempt is made to treat the apparent directions of

* L. Espenschied, C. N. Anderson and A. Bailey: "Transatlantic Radio Telephone Transmission," *Electrical Communication*, 1925, vol. 4, p. 7.

the mode or most frequent value. A careful survey of records from the apparatus described in this paper, however, shows that multiple distributions, with two independent directions of strong disturbance showing simultaneously, are sufficiently numerous to prevent the mean so determined from having a real objective significance. It was finally decided that the principal features of the records were most clearly expressed by the process described in the next paragraph.

The daily records were reduced by the allocation of the apparent direction of arrival for each revolution of the frame, i.e. for each ½ hour of the day, and a curve, continuous except for breaks resulting from inability to determine a most disturbed azimuth, was drawn through the points thus located. From this curve were read off the hourly values of apparent direction of

arrival, for hour periods, centred on hours G.M.T. These hourly values were then entered in a distribution diagram covering a whole month, which thus showed the number of occasions in the month on which, at any selected hour, a selected azimuth had been most disturbed. The whole of the 360° of azimuth, in 5-degree steps, was plotted, and entries were made corresponding to both possible senses of the ambiguous determination. These distribution diagrams thus showed the general trend of the diurnal variation during the month; there were homogeneous blocks of frequent disturbance seems to be a more sensitive index of variation than is the mode (i.e. the most frequent value), and less liable to mask objective realities than is the mean. A sample distribution diagram is shown in Fig. 11. This diagram for the Ditton Park records of October 1924 is somewhat simpler than the average, but serves to illustrate the method of extracting hourly median values, and shows very clearly the type of diurnal variation about to be discussed.

It will be seen from Fig. 11, in which the median of the principal disturbance block for each hour is under-

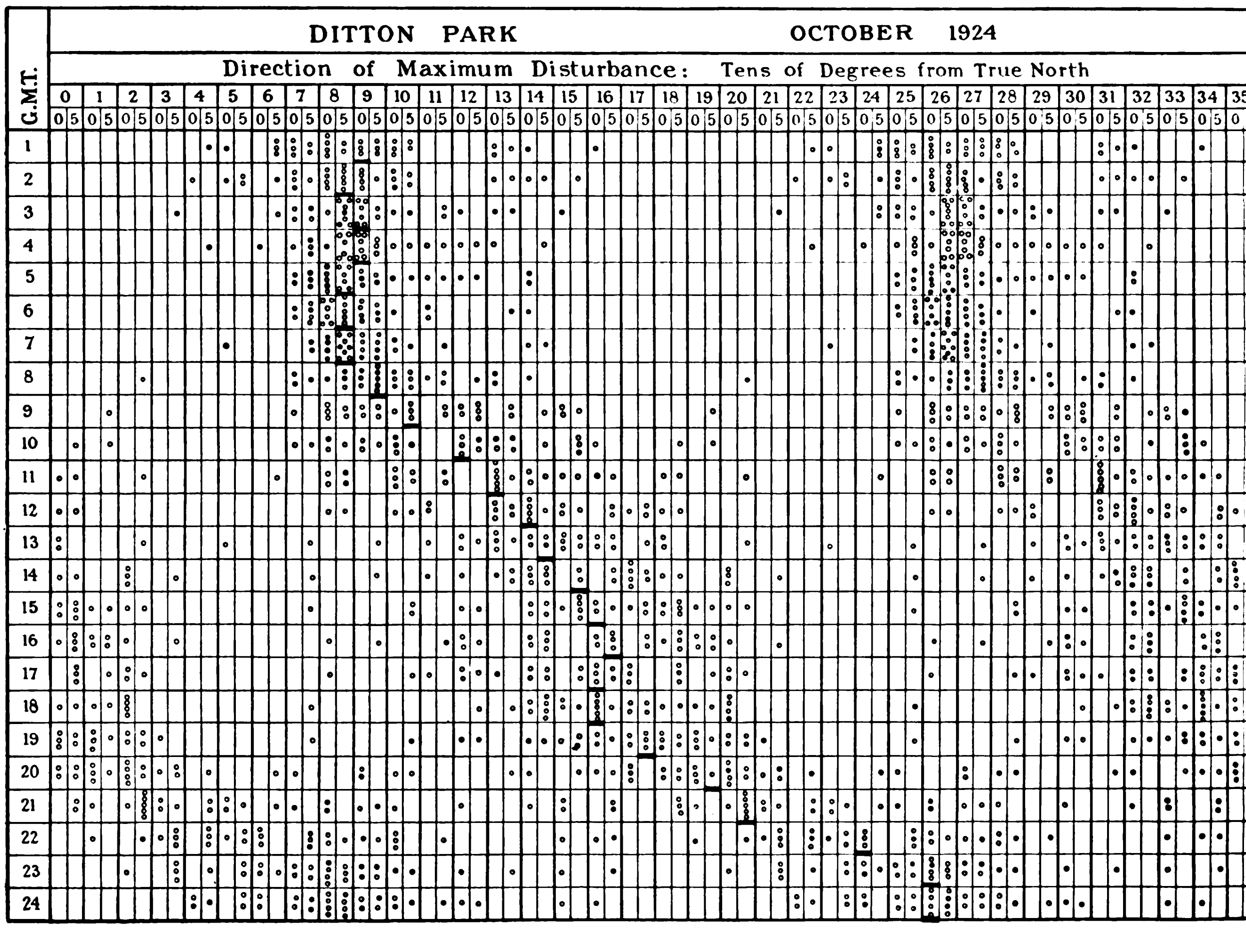

FIG. 11.—Frequency chart of hourly variation of direction of maximum disturbance.

separated by blocks showing no entries whatever for the whole of the month. Some elasticity of judgment was allowed in the separation of the blocks; in general a gap of 20° in azimuth was accepted as significant of a real difference of origin, i.e. as separating two different streams. The "medians" of these blocks, i.e. the azimuths which had as many observations (within the block) on one side as on the other, were then selected as specifying the most probable value of the predominant hourly directions of arrival for the month. If the method of separation of blocks of disturbances be accepted, no great difference occurs amongst mean, modal, or median values for the block, but the median lined, that the direction of greatest disturbance appears to swing through 180° in 24 hours. Actually it must, of course, swing through 360°; since 2400 h immediately precedes 0100 h, and, since the rate of swing is slight in the hours of darkness, there must be approximate identity between the median values of these two hours, and not the 180° difference which would, superficially, appear.

To enter into the full discussion of this most interesting aspect of the records would again be to overload a paper descriptive of an instrument and its applications, and it must be confessed that there are notable obscurities which the author could not yet undertake to remove

even in an *ad hoc* paper. He must, therefore, restrict himself to the presentation of Table 2, showing the predominant apparent directions of arrival of atmospherics at Lerwick, for the period October 1924 to March 1925. This table is offered as a second sample of the type of data which may be obtained systematically, under controlled and specified conditions and limitations, by the directional recorder forming the subject of the paper.

The resolution of the ambiguity.—Experiments were made at various times, in the course of the investigation, on the resolution of the radiogoniometric ambiguity of 180°. The first series of such experiments, in 1916, resulted in the introduction of an unambiguous direction-finder for aural work.* With this instrument it was determined that the direction of arrival during the daytime was certainly from the south-east quadrant rather than from the north-west. Economic considerations, however, enforced the adoption of the rotating frame aerial in place of fixed loops, and no extensive observations were then made with the device. It was not until 1922 that experiments in this direction were resumed, this time with a view to making the directional recorder unambiguous. The difficulties in the way of this conversion that were in the earlier work, and that are still, so far as the author's information goes, experienced by all who deal with the now fairly familiar heart-shaped diagram, were that the sharpness of minimum attainable in unambiguous direction-finders is, on the average of protracted periods, very much inferior to that attained in the ambiguous polar curve, and that the constancy of adjustment required for continuous recording on an unattended instrument is difficult of attainment. For these reasons the determination of sense has usually in ordinary radiotelegraphic practice been made a subsidiary operation with comparatively blunt minima, but an atmospheric recorder based on a similar surrender to difficulties would have been a clumsy and inelegant compromise.

* British Patent No. 129336.

The obstacles were sufficiently satisfactorily surmounted to enable simultaneous records to be taken on an ambiguous and on an unambiguous recorder in May and June 1923.

This degree of success had scarcely been attained, however, when it became necessary to erect new aerials of large capacity for work on the wave-form of atmospherics, the field round the unambiguous recorder was so distorted by the new aerials that the polar diagram returned to a figure of eight, the station staff were devoting their whole efforts to the wave-form work, and the unambiguous recording was relegated to a day, not yet reached, when pressure of more fundamental investigations should permit of its resumption.

The brief trial period did, however, provide the clue to the problem of diurnal variation. As reported in the discussion of a valuable paper by the Marconi Research Staff,* the normal type of diurnal swing in a test period in May was of the nature of that shown in Table 2, but with the important addition that the time of a somewhat sudden change of 180° in the direction of arrival was located.

Instead of attempting any complete analysis of the diurnal variation, which must on account of incomplete data and limitation of space be unsatisfactory, it appears desirable to limit the discussion to one selected sample. The relatively high latitude of Lerwick results in its showing a much simpler distribution of atmospherics than do the stations in middle latitudes, although there is some evidence from the Bangalore record that low latitudes also have relatively simple distributions. Aboukir's monthly distribution diagrams almost invariably show double maxima, and Ditton Park shows similar complexity for a great part of the year. Lerwick is, therefore, a very suitable station for an elementary study of diurnal and seasonal swings.

It will be seen from Table 2 that an apparently

arbitrary change in the adopted sense of the ambiguous directional determination occurs at about 10 hours G.M.T. There is a double justification for this; first the time of the change is approximately that of the change determined by the unambiguous determinations already mentioned; and second, the correlation with solar azimuth makes the seasonal variation readily explicable if this sense is adopted. Thus for the late evening and early hours of the morning the adoption of a westerly sense for the directions fits with a predominant source of atmospherics moving southward with the sun until the winter solstice, and then turning to follow the sun in its northward travel. Were the same sense applicable to the mid-day values the source would be moving northward during that part of the year in which the sun is moving southward.

Thus the general picture which one obtains of the course of the variations in the principal stream of atmospherics is as follows. Early in the morning—sometimes, in fact, before midnight—atmospherics arriving from the far east, where the sun has already attained some considerable altitude, begin to show themselves. Towards 9 or 10 a.m. G.M.T. they have become the dominant stream, and arrive from a direction a few degrees south of east at the time of the autumnal equinox, and from nearly due south at the time of the winter solstice. In the equinoctial season the cum-solar swing of the hourly directions of arrival is very strongly marked, and in all cases the direction of arrival swings through south to a relatively constant SW by W or WSW near midnight.* This stream from the west usually remains the dominant stream until about 9 a.m., presumably because the American Continent produces atmospherics until late in its evening, whilst the Pacific is not an important atmospheric-producing centre. Not infrequently the stream from about 250° E of N can be traced until midday.

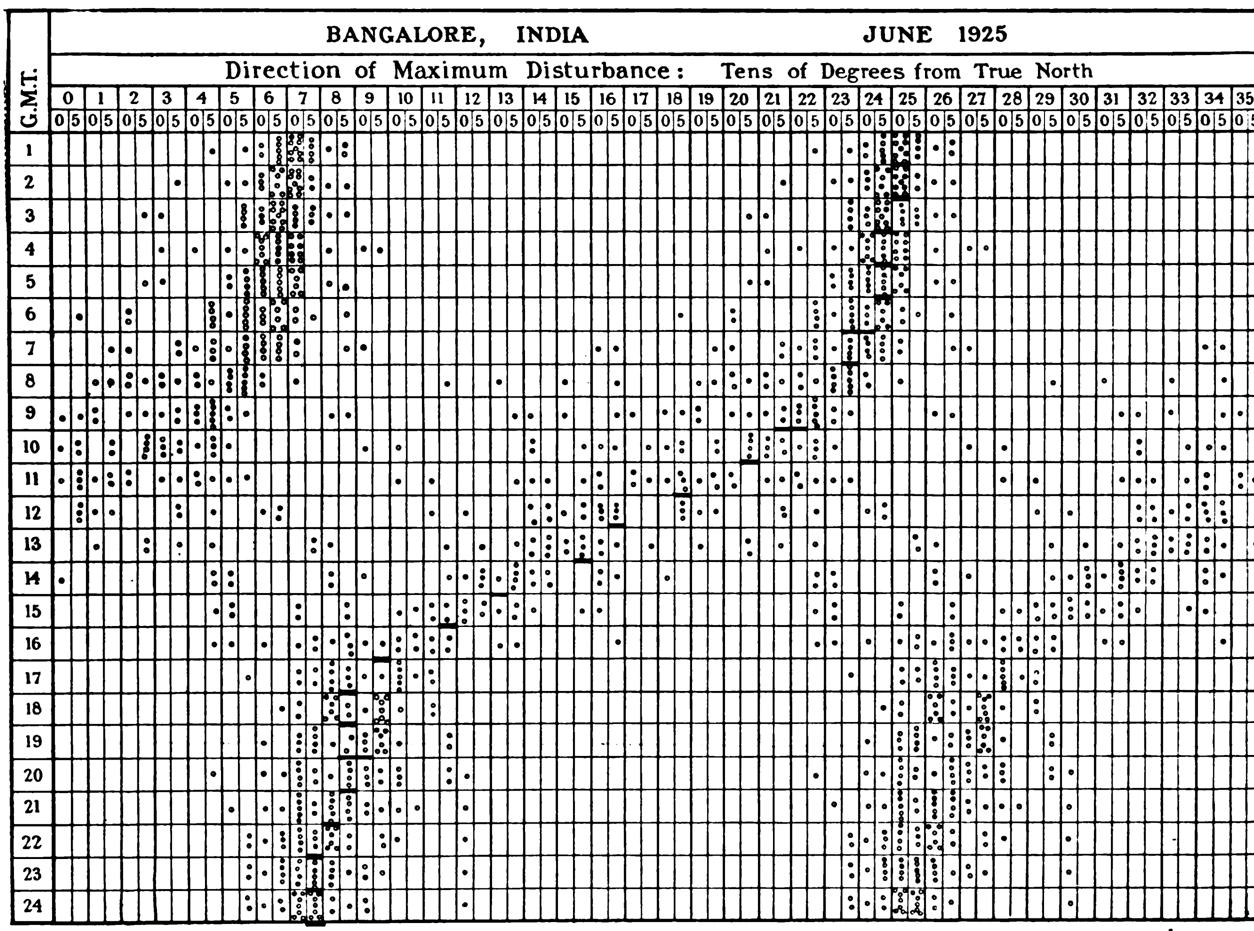

FIG. 12.—Frequency chart of hourly variation of direction of maximum disturbance.

The intensity curves show these two streams, the stream from the west giving, with the help of the improved long-wave propagation in the dark hours, the heavy night disturbance, whilst the secondary day maximum is to be ascribed to the more strongly attenuated stream from the less distant sources in the east and south. The principal minimum marks the combined influence of impaired propagation in daylight, of the diminished activity of the Western source, and of the incomplete development of the stream from the east.

* A cum-solar swing of small amplitude was observed by Schindelhauer (*Jahrbuch der drahtlosen Telegraphie und Telephonie*, October, 1923) in a single month's observations in March 1922.

The simplicity of the equinoctial distribution diagrams from south-east England, as illustrated by Fig. 11, appears to be due to the exact opposition of 180° in the directions of arrival of the decaying westerly and the increasing easterly stream.

It is significant, in relation to this solar control, that the distribution curves for Bangalore in the month of June, when the sun is north of the station, show a clearly marked reversal of the normally clockwise diurnal swing, the resulting counter-clockwise swing being still cum-solar. The diagram is reproduced in Fig. 12.

It was formerly the custom to excuse the use of ambiguous direction-finders by remarking that bearings from a number of ambiguous instruments would give unambiguous intersections. This is true for relatively short-distance work, but it is not true when the source of the observed radiation is at such a distance that the convergence of the bearings is not notably greater than the possible errors of observation, and if we admit the possibility of reception over distances comparable with the earth's semicircumference no network of ambiguous recorders will distinguish between a true source and its antipodes, and even an unambiguous recorder need not point the shortest geographical path to the source, as a long dark path may be easier (radio-telegraphically) than a shorter illuminated path. Thus investigation of the remaining obscurities in the distribution of atmospherics would be far more satisfactorily carried out by a number of instruments of deliberately limited range than by a few long-range instruments.

IX. Sources of Atmospherics.

Sufficient data have not yet been accumulated to show whether stations so far apart as Lerwick and Bangalore generally receive their atmospherics from the same source. Discussion of simultaneous bearings from all stations might, therefore, lead to misleading conclusions from inadequate data. As a last group of samples of recorded data, therefore, it is proposed to cite only two series of intersections from the group of recorders comprising :—

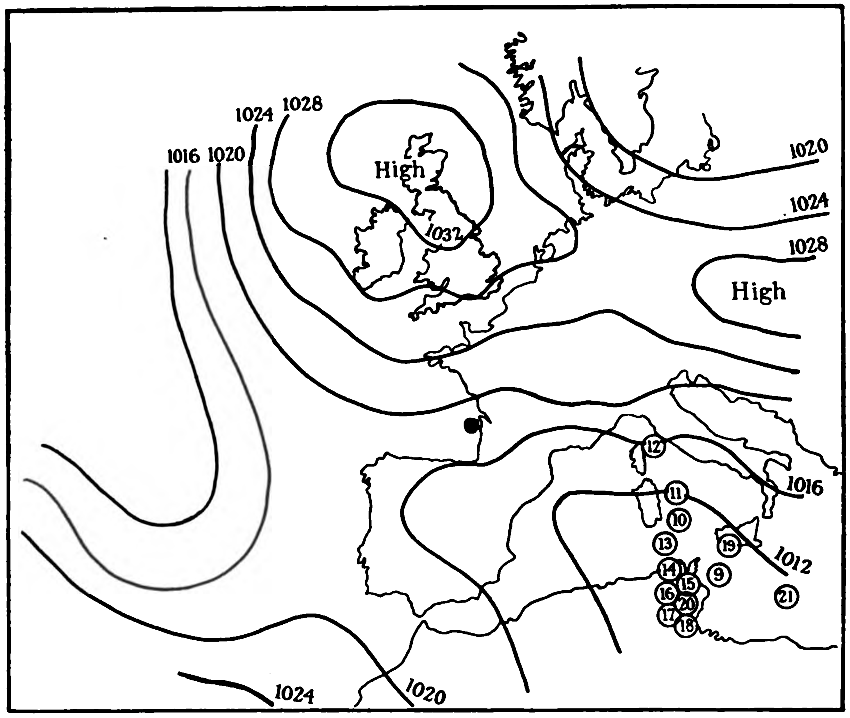

Fig. 13.—Barometric situation on the 7th November, 1924, at 1800 G.M.T. Locations from recorder intersections shown thus (1); hour of location inscribed.

Station	Position	Installed
Aldershot *	51° 15′ N ; 0° 45′ W	Dec. 1921
Lerwick	60° 10′ N ; 1° 10′ W	July 1924
Ditton Park, Langley	51° 30′ N ; 0° 35′ W	Aug. 1924
Aboukir, Egypt ..	31° 20′ N ; 33° 0′ E	Nov. 1924
Bangalore, India ..	12° 55′ N ; 77° 35′ E	Nov. 1924

Typical results.—The first test of this form of simultaneous recording has already been mentioned elsewhere,† but the results may be repeated here. The recorder at Lerwick began routine work at 10 a.m. on the 12th July, 1924. At 2 p.m. on that day the apparent directions of arrival of atmospherics at the two stations intersected off the Hebrides. The intersections of successive hourly values crossed Scotland, reached

* Transferred to Ditton Park on date shown against latter.
† Watson Watt: *Journal of the Royal Aeronautical Society*, loc. cit.

Ross-shire at 6 p.m. and May Island 9 p.m.; directions became indefinite during the night, but an intersection over the North Sea at 6 a.m. next day was followed by a series over Norway, reaching Stavanger at 1 p.m. Thunderstorms occurred at these three places near the times mentioned, the coincidence at Stavanger being exact in point of time and involving an accuracy of 2° in each bearing. The tracking continued as far as the Black Sea; in particular the apparent source lay 800 km south-east of Posen at 1 a.m. on the 14th, when a thunderstorm was in progress at Posen. The 1 a.m. location is not, however, to be regarded as directly related to the Posen storm. The series of locations was associated with a well-marked trough of low pressure crossing Europe, the trough marking the progress of a "cold front" along which air of polar origin was undercutting warm air. At 1 a.m. on the 14th July the radiotelegraphic location of a source of atmospherics still coincided with the instantaneous position of the cold front, within the close limits of accuracy with which the front could be located by synoptic data of pressure and temperature, the distance between source and receiver then being 2 700 km.

The second example is taken from the first week's simultaneous running of three recorders. On the 7th November, 1924, at 9 a.m. G.M.T., the directions of arrival of atmospherics at Lerwick, Ditton Park and Aboukir when plotted on a terrestrial globe of 50 cm diameter, intersected to indicate a source at 36° N 13° E, just east of Tunis. The successive hourly bearings over a period of 12 hours lay almost all along the meridian of 10° east, and the published meteorological data show that the trough of a shallow depression lay in this position during the day in question. Fig. 13 shows the hourly locations from 0900 to 2100 and the barometric situation at 1800.

It is hoped that a further discussion of such sources may be published when the data for the first 6 months of simultaneous recording have been examined in relation to the available meteorological data.

X. Conclusion.

A survey of the published data on atmospherics has impressed on the author's mind the complete inadequacy of sampling represented by these data, the diversity and absence of specification of the variables at the receiver, and the immense loss of value resulting from the non-coordination of the observations. The present paper has been planned to offer a description of an instrument which is certainly not the best that can now be designed, but which has proved itself capable of providing consistent data at a minimum cost. The nature of the data has been indicated by samples of three aspects; it is hoped that means may soon be found for placing at the disposal of those interested the whole of the data obtained. The instrument has already been made the basis of series of observations at stations widely distributed in the eastern hemisphere, but the network is of far too open a mesh at present. It is suggested that the time has now arrived for the organization of an international scheme, which need not absorb much labour or capital, for the collection of data on the lines indicated. The author is glad to be allowed to say that a second step in such a scheme is being taken, by the installation of two recorders of the pattern described, at German meteorological observatories.

The facilities for carrying out the work described were provided, and permission to communicate this paper was granted, by the Department of Scientific and Industrial Research, on the advice of the Radio Research Board established under that Department. Thanks are due to the Board, under the chairmanship of Sir Henry Jackson, R.N., G.C.B., K.C.V.O., F.R.S., Member, and its Committee on atmospherics, under the chairmanship of Col. H. G. Lyons, F.R.S., for their interest and advice. Thanks are also due to the staff of the Radio Research Station, Mr. J. F. Herd, Associate Member, Mr. J. E. Airey and Mr. F. E. Lutkin, and to a former member of staff, Mr. W. S. Hay, for their enthusiastic and skilful assistance in the design, construction and maintenance of the recorders and the reduction of the records, to Mr. J. Hollingworth, M.A., B.Sc., of the National Physical Laboratory, Associate Member, assisted by Mr. H. A. Thomas, M.Sc., for the calibration shown in Fig. 5, to the Air Ministry for the installation and maintenance of the recorders at Lerwick and Aboukir, and to Prof. J. K. Catterson-Smith, Member, for similar collaboration at the Indian Institute of Science, Bangalore.

[The discussion on this paper will be found on page 617.]

AN INSTANTANEOUS DIRECT-READING RADIOGONIOMETER.

By R. A. Watson Watt, B.Sc.(Eng.), and J. F. Herd, Associate Members.

[Communicated by permission of the Radio Research Board.]

(*Paper first received 6th January, and in final form 12th February, 1926; read before the* Wireless Section *3rd March, 1926.*)

Summary.

The paper describes a visual direct-reading radiogoniometer capable of indicating the apparent azimuth of arrival of wave-trains the durations of which need not exceed 0·001 sec. The special properties of the device, which comprises essentially a combination of directional aerials with a cathode-ray oscillograph, are discussed. Amongst these properties is that of giving simultaneous bearings on two or more stations transmitting simultaneously on the same wave-length. A typical installation is described, and specimens of observations on the distribution in azimuth of received atmospheric disturbances are shown. A possible solution of the problem of navigational beacons is suggested.

I. Introduction.

The defects and limitations of radiotelegraphic direction-finders of the types in commercial use have now been clearly realized and frequently enumerated. Some of these defects are inherent in the use of the simple vertical loop as a receiving element, since multiple-ray effects are then liable to produce errors in the apparent azimuths read by the instrument. Other defects are peculiar to the means adopted for determining this apparent azimuth.

The work on which the authors are engaged, the investigation of the nature and origin of atmospherics, is peculiarly suited to call attention to these defects. The directional side of the investigation is concerned with the determination of the place of origin of electromagnetic disturbances which are arriving in very rapid succession from very diverse azimuths, from distances ranging from a few miles up to or exceeding the earth's semi-circumference, with peak field strengths varying from several volts per metre down to the lowest measurable values, with durations varying widely about a mean of the order of a few thousandths of a second, and of diverse forms.

The standard forms of radiogoniometer have been applied to the study of this heterogeneous distribution, and although the results of such applications have been very illuminating, one can only express surprise that they should have yielded data capable of interpretation.

The rotating-loop method—embracing the Marconi-Bellini-Tosi-Artom radiogoniometer with its ingenious method of rotating a large "effective loop" by means of a small search coil, the single-coil direction-finder, and the Robinson crossed-coil instrument—is not well suited for work on any signal other than a simple wave-train sustained or repeated over a period of the order of several seconds, from a sensibly stationary source, and free from interferent signals capable of producing, in the loop, electromotive forces amounting to so little as ½ of 1 per cent of the maximum electromotive force from the desired signal. The inertia of the moving elements prevents the taking of bearings on brief wave-trains, or on wave-trains the apparent azimuth of which is varying at a rate exceeding a limit which may be generously estimated at 1° per sec. The form of the cosine polar curve is such that only the position of minimum electromotive force can be used for accurate determinations, and ensures that any interferent train capable of producing E.M.F.'s of the same order of magnitude will effectively mask this minimum when the apparent azimuths of desired and undesired signals differ by 60° or more, whilst much weaker signals from azimuths within 20° of the minimum will also mask the latter. Thus it is certain that at the best this type of direction-finder will, when applied to the study of atmospherics, merely indicate the mean apparent directions of arrival of the predominant streams of atmospherics, and that there is always a high probability that two physically independent streams will be merged into one statistically true but physically fictitious stream in the indications of the instrument. When to these defects we add the extreme crudeness of the discrimination in amplitude afforded by aural reception, or by any simple recording system, it is abundantly clear that there is a pressing need for radical changes in direction-finding apparatus in general, and in that used in the study of atmospherics in particular.

The ideal radiogoniometer would record the true azimuth of arrival, i.e. the horizontal projection of the direction of propagation at the point of incidence on the receiver, of any desired signal, of whatever form or magnitude, and however brief its duration, and would at the same time record at least one fundamental parameter determined by peak field strength or one of its derivatives. The indication should be independent of the presence of simultaneously incident signals of any form or distribution.

The purpose of the present paper is not to describe the ideal instrument, but to describe a device which is believed to be a much closer approximation to that ideal than were its predecessors.

II. Description.

The general principle of the device is almost too simple to require detailed notice. Consider, for example, two loop aerials, A and B, identical in every respect, with their planes vertical and at right angles to one another. Then a vertical wave-front, in which the maximum vertical electric force is E, and the ray direction of which makes an angle ψ with the plane of loop A, will produce E.M.F.'s proportional to $E \cos \psi$

and $E \sin \psi$ in A and B respectively. The E.M.F.'s across the identical capacities C_A and C_B will have the same ratio. Let the two perpendicular and identical deflector systems, ns and ew, of a cathode-ray oscillograph be connected across C_A and C_B respectively. Assuming for the moment that the deflectors have their centre points in a plane perpendicular to the axis of the undeflected beam, the two fields will recombine to produce a resultant field of strength proportional to E, and making an angle ψ with the axis of deflection corresponding to plates ns. Thus the fluorescent spot traces on the screen a line the length of which is linearly related, through the intervention of simple circuital constants, to the E.M.F. which would be induced in a loop, similar to loop A, with its plane in the ray direction; this E.M.F. in its turn is proportional to the rate of change of electric force in the wave-front, and is related to that rate of change by the well-known equation of the loop antenna. Further, the angle which this fluorescent line makes with the reference axis ns is equal to the angle between the ray direction and the plane of loop A.

Similar considerations apply in the case of magnetic deflection, but in general it is desirable to operate by electrostatic deflection, since the impedances involved are usually of an order which enables greater sensitivity to be attained by this method.

If sensitivity comparable with that of the standard direction-finding installations of commerce be required, then in general the component electromotive forces induced in the two loop aerials will require amplification before being applied to produce deflecting fields in the oscillograph system. It will be shown later that this amplification can be successfully employed.

In passing from the ideal case to the actual apparatus, employing the type of oscillograph mentioned, several minor points are to be noted. In the first instance it should be observed that in the instrument used the disposition of the deflector systems is as in Fig. 1. The change of field during the time occupied by an electron in traversing the paths between either pair of deflectors, or from the one system to the other, may be neglected, since the total path xy is executed in 0·0015 microsecond, corresponding to a phase angle of $\frac{1}{2}°$ at a frequency of 1 million per second, so that no error is introduced from this cause, even at the shortest commercial wave-length now in use. For still higher frequencies the re-design of the oscillograph to reduce this time-lag to negligibility does not appear to present serious difficulty.

A second point arising from the same feature of the tube design is that whilst the angular deflection produced by unit E.M.F. in the two systems is the same, the plates producing horizontal deflection are nearer the screen than are those producing vertical deflection, the distance ratio being 1·08. There is consequently an angular error which varies with azimuth, reaching a maximum of $2\frac{1}{4}°$ around the 45° points. As this source of error is independent of amplitude and frequency, a permanent scale correction is readily applied when necessary. Again the error is not inherent in the system, but is incidental to the particular instrument used. In any case it can be compensated by a method to be mentioned later.

In cases, such as the study of atmospherics, in which there is no possibility of even a rough check on the faithfulness of the indications, it is desirable to eliminate even remote possibilities of error. For this reason the installation at Ditton Park, to be described, is by no means the simplest or cheapest that can be realized within the scope of the general principle of making an ionic beam the self-setting moving element of the goniometer. It is, however, based on circuits which most completely satisfy the requirements of symmetry and freedom from risk of unequal amplification of the component electromotive forces.

The circuit of this typical installation is represented in Fig. 2. The receptive system comprises two loops in two vertical planes intersecting at right angles along a line bisecting the horizontal sides of each loop. To ensure freedom from "antenna effect" or "vertical," the mid-points of these horizontal sides are all connected to earth, as is also the anode of the oscillograph. The tuning devices—loading inductances if required, and tuning condensers—are split and arranged symmetrically on either side of the central earth lead. There are

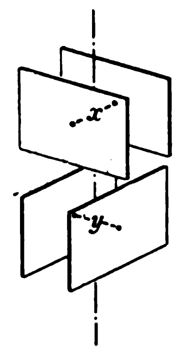

FIG. 1.—Deflecting plates of cathode-ray oscillograph.

consequently, in each main loop, two tuned half-loops, the tuning of each half being nearly independent of the tuning of the other. Carrying still further the provision for complete symmetry, special oscillographs have been obtained in which each deflecting plate is separately terminalled. It will be noted that in the standard pattern of oscillograph two of the plates are joined directly together and to the anode, whilst the other two, one of each pair, are joined to the anode through external resistive paths, so that complete symmetry is not attainable with this form of tube.

In the case of strong signals the oscillograph deflecting-plates may be connected directly across the tuning condensers as shown in Fig. 2. For weaker signals the general scheme of single-stage or multiple-stage amplification is illustrated in Fig. 3. Since the load impedance of the oscillograph, with its plate-to-plate capacity of about 10 $\mu\mu$F and its gaseous conduction path of about 2 megohms, is high, the conditions are especially suitable for "voltage amplification" by a resistance-capacity amplifier employing triodes of high voltage factor.

It will be seen from Fig. 3 that symmetry is maintained by using a circuit of the so-called "push-pull" type, in which (considering only one stage) the filaments

are connected to the central earth lead, whilst the grids are each connected to the high-potential sides of the tuning condensers in the half-loops. The oscillograph deflecting plates are joined through coupling condensers to points on the high resistances included in the plate circuits.

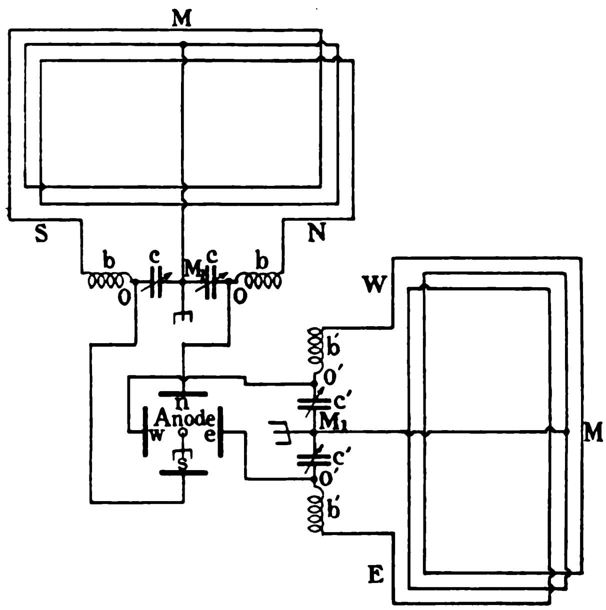

FIG. 2.—General arrangement of cathode-ray direction-finder.

In the actual installation under description, the loops are supported on a mast system comprising a central wood lattice mast 200 ft. high, and four wood box masts 150 ft. high, at the corners of a square of 1 200 ft. diagonal. Each loop comprises five turns, which can be grouped in series or parallel, each turn measuring

at about 10 kilocycles, comprises a coil of 136 mH and an air and mica condenser assembly with a maximum capacity of $0\cdot006\ \mu$F. The arrangement of these units will be referred to later.

The amplifiers are based on the use of the D.E. 5B triode, and with anode resistances (wire wound) of 10^5 ohms, and plate circuit voltage 300, give a voltage magnification of 15 per stage. The first anode resistance in each side is tapped approximately in thirds, so that the available voltage magnifications are 5, 10, 15, 75, 150 and 225.

The oscillograph has a deflectional sensitivity of 1 mm per volt, so that the sensitivities of the combination of amplifier and oscillograph are 1 mm for 200, 100, 67, 13, 7, and 4 millivolts respectively on grid. Full-scale deflection, reaching the outer edge of the oscillograph screen, amounts to 50 mm, the angular scale value then being $0\cdot87$ mm per degree of angle. So far as reading goes, therefore, accuracies of 1° can be attained on any deflection exceeding half scale.

The two special features of this installation are the precautions taken to ensure symmetry, and the large areas of loop used. This latter feature is part of a general policy which has guided all our quantitative work on atmospherics, namely that the antenna system should be of such dimensions as to allow measurements to be made with a minimum of amplification. It is a general experience that quantitative uncertainties increase rapidly as amplification is increased, and for fundamental work the more antenna and the less amplifier the better. It must not be thought, however, that acres of antennæ are essential to the system, nor that the somewhat uneconomical duplication of triodes, giving only a doubling of amplification, in the push-pull system is inevitable. The use of loops the individual turns of which have an area of 30 m², with one pair of vertical sides coincident, in combination with normal amplifiers and the standard form of cathode-ray oscillograph, has already been shown to be practicable,

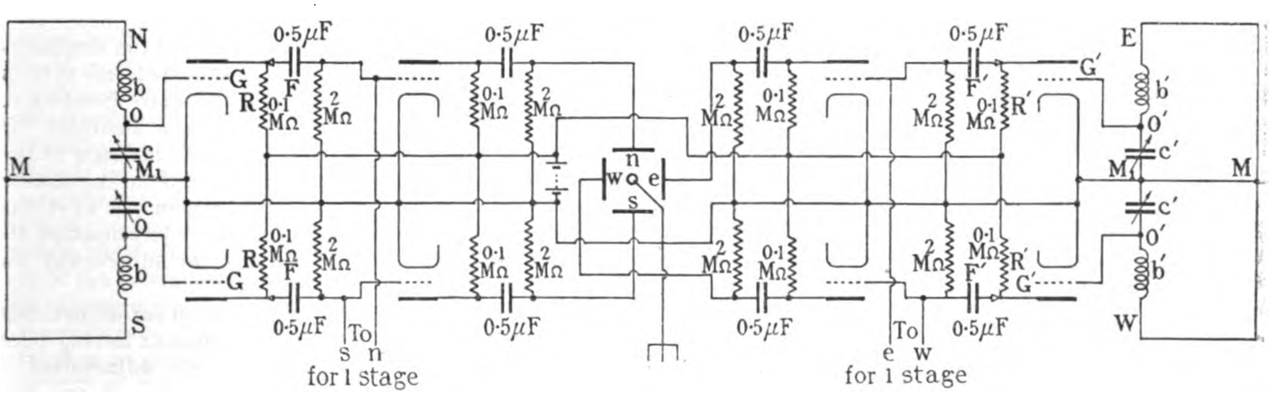

FIG. 3.—Details of circuits.

1 200 ft. horizontally by some 150 ft. deep, the area-turns in the series grouping being thus about $8\cdot4 \times 10^4$ m² (about 20 acres). The inductance of the series arrangement is 19 mH, and the effective resistance at 10 kilocycles is 200 ohms. Each unit of the tuning system, as used for atmospheric observations

and further wide modifications should result from systematic development work, which has not been required for work on atmospherics but is desirable for the production of a compact visual direction-finder for general use.

The principal conditions to be fulfilled by the system

refer particularly to the amplifier and the oscillograph. The amplifier should give a distortionless linear magnification, without rectification, over a range of $\pm$ 50 volts output, unless an oscillograph more sensitive than the standard 300-volt pattern is used. There is room for some very interesting work on amplifiers specially adapted to meet these conditions when working into such a high-impedance terminal apparatus as the oscillograph. Such work has been begun, but need not be discussed at present. It should, however, be noted that the previous visual direct-reading radiogoniometer due to Artom involved rectification, which results in the introduction of further ambiguities in addition to the ordinary radiogoniometric ambiguity of 180°, since it gives bearings which are concentrated in one quadrant, so that there is no distinction of a given bearing from its image with respect to one of the principal axes, giving a fourfold ambiguity when the non-discrimination of sense is taken into account. In the present device the only ambiguity is that of sense, and it can be resolved by methods already used in radiogoniometry, and also by methods peculiar to the oscillographic arrangement.

The conditions to be fulfilled by the cathode-ray oscillograph are not, except in respect of the one point already discussed in relation to the different distances between screen and deflecting systems, different from those to be fulfilled by a general-purpose oscillograph. These are, summarily: (*a*) That the indicating spot shall be small, symmetrical and sharply defined, and shall remain so at all velocities of deflection; (*b*) that the deflections shall be linearly related to the applied field over the full range of the screen; (*c*) that the axes of the two deflecting systems shall be strictly at right angles; (*d*) that the deflectional sensitivity shall be as high as possible; (*e*) that the fluorescent material shall give the most brilliant response possible to the lowest electron speeds and densities used; and (*f*) that the life of the instrument shall be as long as possible.

It is a truism to say that the cathode-ray oscillograph as a general laboratory and industrial tool is in its infancy, since the inconveniences of the older forms have only recently been removed. Rapid improvement in quality and uniformity of the product may be expected to accompany increased demand, and it is significant that nearly half the November issue of the *Journal* was devoted to this instrument. Recent work * has resulted in the production of an oscillograph with a sensitivity of nearly 1 cm per volt, and work initiated by the Radio Research Board has shown that very considerable improvements in fluorescent screens for visual work are within immediate reach. The future of the cathode-ray direction-finder is intimately linked with the progress of the cathode-ray oscillograph, and must not be judged alone on its performance with existing oscillographs, good as that performance is.

It is clearly necessary that provision should be made for the tuning, testing and adjustment of the radiogoniometer system, and the arrangements adopted at Ditton Park will serve as an illustration of this provision. When the whole system is correctly tuned and adjusted, the arrival of a sustained signal of the selected frequency causes the indicating spot of the oscillograph to trace a straight line which makes with the two principal axes—representing the deflections due to the two pairs of deflecting plates acting independently—angles which are the angles between the direction of arrival of the signal and the planes of the corresponding aerials. The effect of slight mistuning is to open this straight line into an ellipse, since the spot is now under the control of two misphased fields. This opening to an ellipse is a very sensitive index of mistuning, and is, in the case of "single ray" propagation, at least, an effective safeguard against errors of bearing due to bad tuning. The ellipse is quite wide before its major axis begins to depart by a measurable amount from the correct angle. This tuning operation may be performed directly on the signal, or it may be performed on locally generated oscillations of the desired frequency. A screened, calibrated oscillator is coupled to a testing instrument in which the main loading inductances already mentioned form the secondary windings of a crossed transformer, the loading coils belonging to one loop being coaxial and having their common axis at right angles to the common axis of the coils belonging to the other loop. The primary is a coil capable of rotation about an axis in its own plane perpendicular to these axes, and is fed from the oscillator. The system is in fact similar to the crossed transformer of the Bellini-Tosi radiogoniometer, the search coil being excited and inducing into the field coils, instead of the inverse operation as in directional reception. The primary may first be coupled to one loop alone and this loop tuned up, then the other loop may be tuned independently; finally both may be tuned to identity as tested by the closing of the ellipse. If, as may happen, the operation is complicated by the presence of signals, the loops may be replaced by dummy circuits of the same inductance and resistance. This instrument also permits the testing of the voltage amplification on each side of the system. In the ideal case these amplifications should be identical, but in practice circumstances may call for a ratio differing from unity. For instance, the difference in distance from screen to deflectors, already mentioned, is most easily corrected by the increase of the amplification factor on the side connected to the deflector system nearer the screen, until the deflections corresponding to identical inputs to the two systems are identical. It will be seen that as the only convenient measure of the relative amplifications is by length of line on the screen, the operator is not required to remember anything about this correction *per se*—its compensation is automatically included in the general adjustment for amplification.

The methods of determining the need for adjustment of amplification and for testing its amount having been indicated, it remains to show how the adjustment is performed. The method may of course vary according to the typle of amplifier in use, but there is probably no more simple and satisfactory method for general purposes than the provision of a variable tapping of the anode circuit resistances in one stage of resistance-capacity amplification, so that the proportion of the whole voltage released across this resistance which is transferred to the oscillograph or to the next grid may be varied over wide limits. Preliminary selection of matched triodes

* BUCHTA: *Journal of the Optical Society of America*, 1925, vol. 10, p. 581.

then ensures that very little correction is necessary in most cases, whilst the correction even of large divergences can be effected.

III. Properties.

In its application to signal work the system has many interesting and attractive properties which are believed to offer considerable advantages over earlier systems, and a brief enumeration of some of these may be permissible.

Some outstanding advantages have already been described in sufficient detail to show that the device will provide an automatic visual and direct-reading radiogoniometer, capable of operation by the navigator on the bridge or in the chart-room, without requiring a knowledge of morse, and that it will deal with signal trains of exceedingly short duration.

Attention has not yet, however, been called to one of its other outstanding advantages. The difficulties of direction-finding in cases of even slight jamming are well known. The cathode-ray direction-finder alone has the valuable property that it will give correct bearings, simultaneously, even in the extreme case of two or more signals of the same frequency and the same field strengths arriving from different azimuths during the same period. That this is so will be seen from the fact that the ionic beam gives instantaneous response to every impulse, so that if a marking impulse arrives from one transmitter while the other is spacing, the beam will trace out a line having the bearing of the former transmitter, and conversely. There are three types of pattern which may be obtained in practice. If the stations are working independently at hand speed, then the marking periods in both cases are interrupted by comparatively long spacing gaps, during which many marking impulses from the other station will arrive. The predominant features of the image on the fluorescent screen will then be two bright lines, each indicating the correct bearing and amplitude of the corresponding signal, and standing out perfectly clearly from a background of faint fluorescence. If the stations are working independently at high speeds with very brief spacing periods, then the pattern becomes a parallelogram full of fluorescence the clearly defined sides of which are respectively parallel to the two required bearings, and of lengths proportional to the two signal strengths. The faint background referred to in the first case is also a parallelogram of this type. The clear definition of the edges of the figure is of course due to the fact that each point on them is a stationary point on the high-frequency path of the indicating spot, and has therefore a relatively long exposure, giving correspondingly greater brilliance of fluorescence. Lastly, in a case which is never likely to be met in practice, if the two transmissions are not independent but fed from the same source, then the pattern becomes a generalized Lissajou figure, from which the two bearings may be inferred. Excluding this case, however, it is seen that in the worst practical case of jamming, two identical stations sending identical text, on identical frequencies and with identical field strengths, the two bearings are still read directly and easily. Increase in the number of the jamming stations merely increases the complexity of the image. With three high-speed stations, beyond which we have not had an available jamming mixture on which to test, the three bearings are still easily read simultaneously.

The next application of the special properties of this device which calls for mention is that to the wide general class of "bad minima" so troublesome in the older

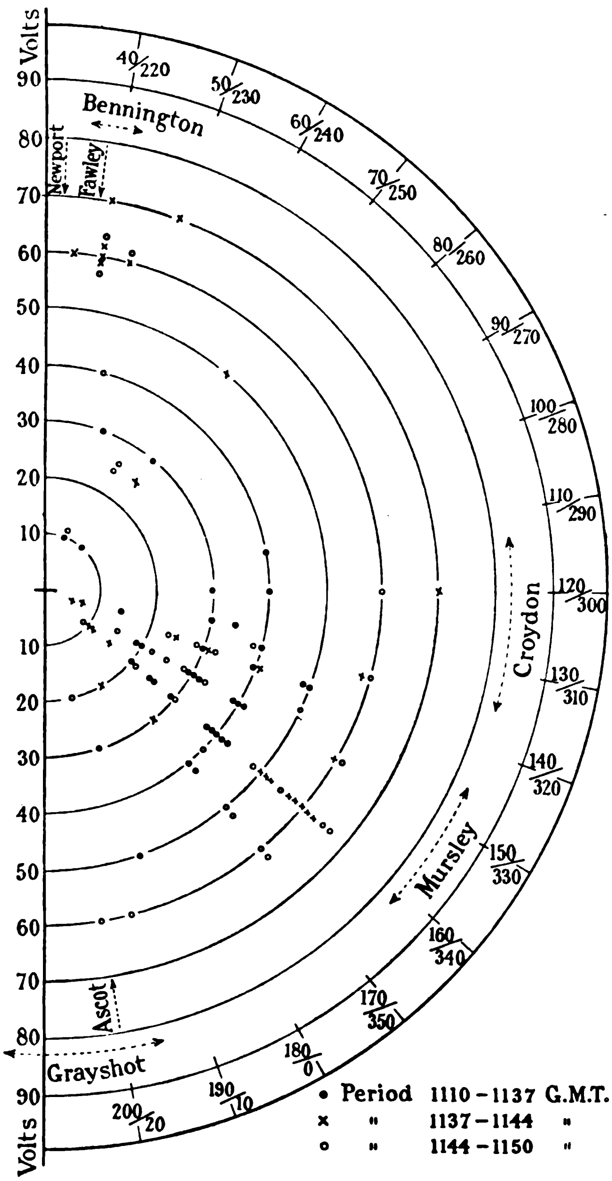

Fig. 4.—Azimuthal distribution of atmospherics and thunderstorms on the 10th May, 1925.

systems. The cathode-ray direction-finder, with its freedom from inertia effects and its discrimination in amplitude, will throw light on the particular cause of bad minimum which happens to be operative in any given case, and will in very many cases allow a determination to be made, with a direct measure of its probable error, in cases where otherwise no measurement at all could be made or relied on. Thus the flickering bearing due to intermittent contacts in metallic rigging will

give a measurable sector of swing of the fluorescent trace, probably accompanied by the elliptic opening indicating dephasing of one aerial, and the phenomena of night effect will be delineated in detail.

IV. Typical Observations on Atmospherics.

The first decisive test of observations on atmospherics with the device described was made on the 5th May, 1923. Between 2000 and 2300 G.M.T. on that date thunderstorms were in progress in Yorkshire and other northern districts, and the lightning of these storms was visible at Aldershot; this lightning varied in azimuth between N.N.W. and N.N.E. Simultaneous determinations of the apparent azimuth indicated by the cathode-ray direction-finder and of the azimuth of the visible lightning showed in a large majority of cases agreement within 5°, which was approximately the limit of estimation in the direct observation of the somewhat faint and diffuse glows produced on the horizon by the distant flashes. The failures were due to the complex screen image produced in the direction-finder by relatively near discharges. The direction-finder also provided azimuthal determinations for a very large number of discharges for which no corresponding visible lightning was observed.

More recent samples of the discriminating powers of

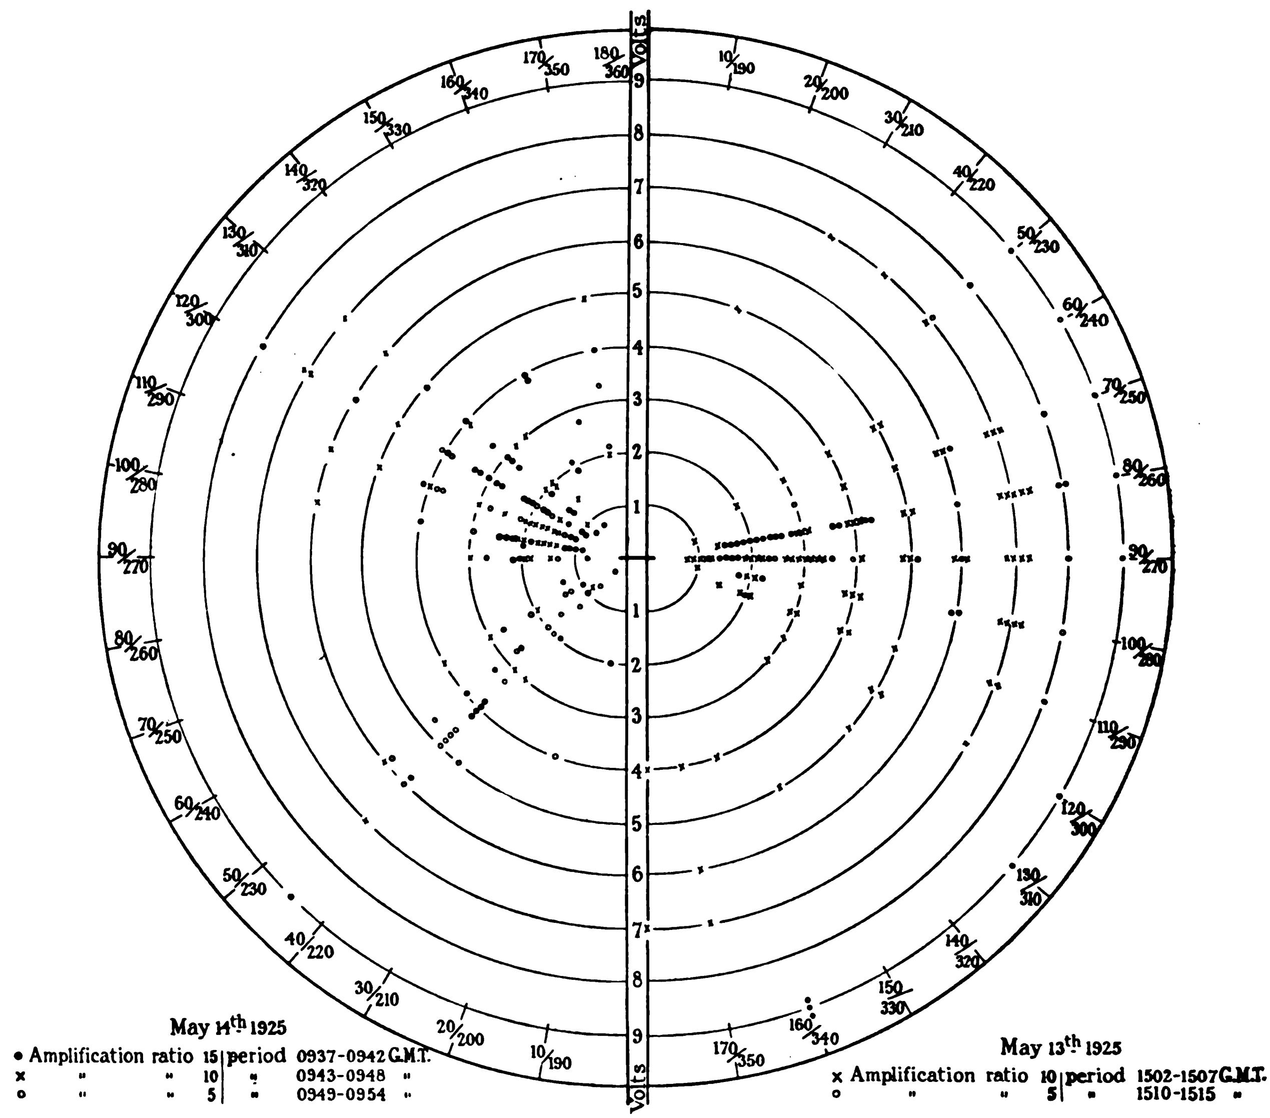

Fig. 5.—Azimuthal distribution of atmospherics on the 13th and 14th May, 1925.

the device may be cited, with reference to Figs. 4 and 5. In these figures are plotted polar co-ordinates representative of individual atmospherics, the angular position indicating the apparent azimuth, with its ambiguity of 180°, the radius vector the voltage produced across the tuning condenser in the apparatus described. No more fundamental measure of the intensity of the atmospheric can, in the absence of data as to the wave-form of the individual discharges, readily be given. The observations of Fig. 4, made without amplification,

correspond to an oscillographic scale value of 10 volts per cm, those of Fig. 5 to scale values varying, with the amplification factors used, from 0·7 volt to 2 volts per cm. These are all plotted to a uniform voltage scale.

Fig. 4 represents observations on the morning of the 10th May, 1925, between 1110 and 1150 G.M.T. On the conclusion of the observations, examination of the sky showed thunderclouds at the approximate azimuths 340°, 240° and 120° E. of N., the most formidable being that at 340°, the least that at 120°. It will be seen that the most disturbed direction is that of the principal cloud, and that disturbances appear to have arrived from all three clouds, though no thunder was heard at the Radio Research Station. Subsequent examination, however, showed very complete agreement between observed thunderstorms and the apparent azimuths of arrival of atmospherics. There have been plotted in Fig. 4 the results obtained by assuming thunder to be audible up to a distance of 12 miles from the station reporting it, and plotting the arc subtended by a line extending for 12 miles from meteorological stations in the direction in which thunder was noted by the meteorological observers. The arcs thus delimit the azimuthal regions from which atmospherics would have been expected to arrive. The main disturbance is seen to have originated in a thunderstorm reported from Mursley, Bucks (S.W. at 1040 to N.E. at 1230). The next most important source was the thunderstorm reported from Bennington, Herts (N.E. at 1100), whilst disturbances were also received from thunderstorms near Croydon (S. at 1123), Ascot (1130 to 1230), and Grayshott (W. at 1145). Two of the clouds seen probably belonged to the Mursley and Croydon storms; the third, producing the discharges from 60°–240°, has not been traced in thunderstorm reports.

For comparison with Fig. 4, Fig. 5 presents data of the distribution at two periods, 19 hours apart, in neither of which was thunder reported in England, Wales or Ireland. It is of interest to note that, despite this absence of near reported thunder, E.M.F.'s of 4 volts and over were produced across the tuning condenser of 0·001 μF in the aerial circuit (cf. page 613) tuned to 12 kilocycles.

V. The Beacon Problem.

The sum of these special properties has, in the authors' opinion, a very important relation to the vexed question of the navigational radiotelegraphic beacon. The problem posed is the provision of a network of beacons which, while sufficient for position-fixing by directional wireless observations, must produce the minimum of interference with other radiotelegraphic traffic. Were the cathode-ray direction-finder adopted as the standard instrument for observation on beacons, what form of beacon would be required? A continuous-wave transmitter modulated m per cent with a frequency f, is the generally accepted beacon in all cases, but the authors believe that the important fact is that for observation by the cathode-ray direction-finder f need only be a fraction of 1 cycle per second, m can be made large, while both m and f can be given values which become characteristic of a series of beacons. The beacons may work continuously and simultaneously on the same narrow wave-band, and the form of the modulation may be made such that the period of sensible amplitude is relatively very brief. The form of a typical screen image in a direction-finder taking a cross bearing on two beacons might then, for example, consist of two lines intersecting at an angle of 55°, one varying once in 3 seconds from full length to half length, the other once in 5 seconds from full length to quarter length. The navigator reads the two bearings, finds in his list the stations characterized by $m = 50$ and $f = 0{\cdot}33$, and by $m = 75$ and $f = 0{\cdot}2$ respectively, and the problem is solved. It is admitted that the scheme involves wide organization, but wide organization, reorganization and control will in any case be enforced by the seriousness of the problem of interference prevention.

The facilities for carrying out the work described were provided, and permission to communicate this paper was granted, by the Department of Scientific and Industrial Research, on the advice of the Radio Research Board established under that Department. Thanks are due to the Board, and to its Committees on atmospherics and directional wireless, for their interest and advice; and also to the Director of the Meteorological Office for the data used in Section IV.

Discussion before the Wireless Section, 3 March, 1926.

Admiral of the Fleet Sir H. B. Jackson: I have had the opportunity of watching the progress of this work during the past few years. At its commencement amplifiers were not in their present high stage of development, and the amplifier alone was one of the things which took a very considerable time to design. I think it will be admitted, however, that, judging from the results obtained, the design which has been retained all through has been satisfactory. The same remark applies to the other details of the apparatus described, which has now been thoroughly tested and is giving satisfactory and valuable results.

Dr. G. C. Simpson: In common with Sir Henry Jackson, I have seen practically the whole of this investigation; in fact it began under the Meteorological Office. One aspect of the work is the meteorological side, and this is again divided into two. There is the actual practical use of this apparatus for meteorological work, which I hope Mr. Giblett will explain later in the discussion, and there is the theoretical side. When this work started we had not the slightest idea of the origin of these atmospherics, i.e. as to whether they came from the upper atmosphere after some electrical discharge, whether they were connected with the aurora or with electrical storms; in fact we were not certain that they were terrestrial at all. At the same time we did know that there were atmospherics connected with thunderstorms, and although early in the work Mr. Watson Watt came to the conclusion that all atmospherics were due to terrestrial thunderstorms,

personally I did not feel that that was likely. I doubted whether there were sufficient thunderstorms in the world to supply these atmospherics, but as the work progressed I gradually became converted to the opinion that all these atmospherics do arise as the result of lightning flashes in some part of the world. If we can prove that, I think it will be a very great advance, because there is no doubt that it will help very much in our efforts to guard against atmospherics, and to apply the results of this work to radio telegraphy, when both the source of the atmospherics and the reasons for them are known.

Prof. J. T. MacGregor-Morris: The author of the first paper points out that in the revolving-coil apparatus only the resultant direction of atmospherics coming either in one direction or in the diametrically opposite direction are recorded at any one instant; it is, however, possible that the component at right angles might be simultaneously recorded. Suppose two coils are fixed at right angles to one another so that they rotate together, and that a duplicate of the arrangement used with the first coil be connected to a second Bloch oscillograph; then the pens of these two recorders could be so arranged that they could operate very near to the same spot on the drum. Red ink could be used in one and black ink in the other. If I am right the records will give the resultant of the atmospherics in one direction and their resultant at right angles at any instant. One should therefore be able to deduce from the two simultaneously obtained records, the direction and strength of any atmospheric by taking the resultant of those two points. I admit that this complicates the apparatus, and the author has been definitely working to make the apparatus as simple as possible. However, it is for those who are directing the work to consider whether the complication is justified.

With regard to the second paper, I should like to submit that the term "electron jet" be used in preference to "cathode ray." I quite realize that in the past the term "cathode ray" has been universally used; but now that we understand that it is primarily a jet of electrons I think it would be helpful to call it an "electron jet." The authors call attention to the fact that the two pairs of plates in the Western Electric cathode-ray oscillograph shown in Fig. 1 are at different distances from the recording plate, and so are unequal in their recording sensitivity. One possible method would be to split the A-phase plates in half and arrange so that the electron jet first traversed the first half of the A-phase plates, then the complete B-phase plates, and finally the second half of the A-phase plates. With regard to the fluorescent screen, a good deal of work has been done recently in improving this, and I should be glad if the authors would give some information as to the improvement which has been made during the past two years, because a great deal depends on the sensitivity of the screen. Quite recently in America these tubes have been used with quartz plates at the end, so that a photographic plate placed in contact with the quartz plate requires only an extremely short exposure. I am not clear why the apparatus was adjusted to a periodicity of 10 000 cycles. I do not think anybody would say that all lightning flashes had this frequency. Is it not possible to have another circuit in parallel with the first circuit, tuned to another frequency, so that both are operative on the same plates? This would enable records due to the two to be obtained. Another point is with regard to the making of this apparatus so that it is photographically continuously recording. Is it worth using two of these oscillographs and losing the simplicity of this polar diagram? Only one pair of plates must then be used in each, with a quartz slip at the end of the bulb so that the ray simply travels backwards and forwards in each of the oscillographs, letting the ray shine on the photographic film, the two pairs of plates being connected to two frame coils at right angles. If these photographic films are continuously recording it will then be possible, from the readings of the two films, to combine them at leisure.

Mr. R. H. Barfield: Although the first paper nominally describes only the construction and working of an instrument, the masses of observational data which are dealt with in it throw an interesting light on the nature and magnitude of the work on which Mr. Watson Watt and his staff are engaged in their systematic study of atmospherics and must, I think, arouse a considerable amount of admiration for the scientific and persevering nature of their attack on this problem. As regards the instrument itself, by paying attention to every detail of its design Mr. Watson Watt has constructed an elaborate piece of mechanism which, as he has demonstrated, fulfils a relatively novel purpose with complete success. Mr. Watson Watt shows that it is possible to gain from the records of this instrument a certain amount of information regarding the intensity of the atmospherics received. Has he ever found any confirmation of the effect described in some detail by Dr. Eccles in the *Proceedings of the Royal Society* (1912, vol. 87)? Dr. Eccles here records that he observed quite regularly over a prolonged period a marked diminution in intensity of all atmospherics for about a minute at the hour of sunrise, and gives a plausible explanation of this phenomenon based on atmospheric ionization of solar origin.

Squadron-Leader E. L. Johnston: I propose to discuss the papers from the point of view of the navigator. With the advent of wireless direction-finding apparatus an entirely new method of navigation has been achieved, and I claim that it is not too much to say that this branch of science will completely revolutionize the practice of navigation in the very near future. In particular, wireless direction-finding is of the greatest importance to fast-travelling aerial transport on transcontinental and transoceanic flights.

I have come to the conclusion that the radiogoniometer described in the second paper is an instrument which may be second to none in its importance to navigation and that it more nearly approaches the conception of a "wireless compass" than any other apparatus developed on the principle of wireless direction-finding. In discussing the beacon problem the authors say that the navigator reads the two bearings, finds in his list the characteristics of the periods of the beacon stations and the problem is solved. If that were so, there would be no further need for navigators. It is not generally recognized that science, employing

the mathematician and the engineer alike in the problem of shortening the duration of transcontinental and transoceanic transit, has accomplished as much by causing the vehicles of transit to travel fewer miles as by causing them to travel faster. In this age of aerial transit the route of minimum distance and the determination of position by long-distance wireless telegraph bearings is coming to take the place which was held by the route through regions of favourable winds and free water and the determination of position by observations for latitude and longitude by means of celestial bodies as in the days of sail and steam propulsion. By increasing the rate of travel, modern motive power, by making possible a departure from the old meteorological routes, has had another and greater effect in the progress of the universal policy of civilized nations to accelerate transit from place to place to the utmost possible extent, because aircraft may yet get further toward their destination in a given time since they may be navigated along the arc of the great circles of the earth. The increasing recognition among navigators of the sound principles of navigating along the arc of the great circle, and the expanding sense of the advantages to be gained by a knowledge of this branch of the science of navigation, have greatly enhanced the value of methods which place the benefits of the knowledge and use of the great-circle track at the service of the navigator without the labour of the calculations involved in the practice of great-circle sailing. The general lack of the application of the principles of the great circle in the past seems to have resulted not from the want of recognizing that the shortest distance between any two places on the earth's surface is the distance along the great-circle arc passing through them, nor that the great-circle course is the only perfect course and that the courses steered by the magnetic or gyrostatic compasses are circuitous, but to the tedious operations which have been necessary for rendering these benefits available. The rhumb line, or the line of constant bearing, which is that steered by the magnetic or gyrostatic compass, although appearing on the Mercator projection as a straight line, gives a false idea that it represents the shortest route, and is in reality a roundabout track. The great circle on the other hand appears on the Mercator projection as a curve, concave towards the pole and, whilst being actually the shortest distance, appears as a roundabout way. It crosses the meridians, however, at a constantly changing angle and therein lies the great drawback in its application to everyday navigation. The navigator is then supposed to conduct his craft by one of two methods: (1) He is supposed to follow a simple line, the rhumb, and go the longest way about, or (2) he is supposed to go the shortest way, by the great-circle arc, and endeavours to follow a complicated curve. The navigator, however, being a practical man, does neither. He first of all finds out how much his rhumb-line distance differs from the great-circle distance, and, if the difference is sufficiently considerable to have any material effect upon the length of his journey, he approximates his great circle by a succession of rhumb lines which are chords to the great-circle arcs. But now we have this cathode-ray direction-finder which gives a visual indication on a graduated dial of the bearing of a transmitting beacon station, and therefore, provided that the place of destination is equipped with a beacon station and that it transmits at sufficiently short intervals, it would appear that the navigator only requires to steer his craft in the direction of the fluorescent ray and the result would be that he would follow the great-circle arc and thus take the shortest route. The installation of beacons to fulfil this function on every route would, however, be a very costly business and would probably be prohibitive on those grounds. Therefore, for some long time yet the navigator will have to make use of whatever wireless telegraph stations are available, and it is highly improbable that he will always be fortunate enough to have a wireless telegraph station at his destination to guide his passage, nor would it, if this condition were fulfilled, transmit at sufficiently short and regular periods to enable him to steer a great-circle track. Some auxiliary means of steering would be necessary. The next thing then is to make use of the instrument for position-fixing by means of cross bearings. Let us consider the question of position-fixing by means of wireless bearings. Mercator's projection, as perfected by the English scientists, Bond and Wright, is the most suitable for the solution of the everyday problems which confront the navigator, but unfortunately the great-circle bearing cannot be laid off upon it as a simple straight line without the application of the angle of half convergency. If, then, the navigator is going to make use of the cathode-ray direction-finder, he will wish to have a projection which will show all the great circles as straight lines so that they can be simply laid off. The gnomonic projection is the one which most nearly fulfils his requirements, inasmuch as all great circles are projected as straight lines, but unfortunately the orientation of the bearings is only correct from the tangential point of the projection and there cannot be any constant linear scale on it. From the foregoing I trust that I have made it sufficiently plain that instead of the problem of navigation being solved by the use of the cathode-ray direction-finder, the navigator's work really only begins at its introduction.

Mr. M. A. Giblett: Dr. Simpson has already mentioned the subject of the meteorological applications of the author's apparatus. The practical application to which he referred was the application to the meteorological protection of the proposed long-distance airship routes to Egypt and India. The one meteorological phenomenon of which we have to take great notice in the case of airship navigation is the thunderstorm, not so much because of the electrical phenomena but because of the strong associated vertical atmospheric currents. It will therefore be very necessary to include in the meteorological organization for those long-distance routes some means of keeping track of all thunderstorms and similar disturbances. It would hardly be possible even with unlimited funds to have ordinary ground observing stations sufficiently close to keep all thunderstorms under observation. Therefore I think that the author's apparatus does open up possibilities. By using a few thunderstorm directional observing installations at various points along the route, the observers' visual horizon could be extended

to areas where no ordinary meteorological observing stations can be placed. In addition to the use of such apparatus on the ground, I think it would also be useful if it could be arranged to have such an apparatus in the airship herself, because the meteorological organization would be divided between a ground organization which would pass general advice to the airship, and a minor organization in the airship herself for co-ordinating the information received from the ground. The ground organization would give general information as to the disturbed areas on the whole route. Such an apparatus on the airship herself would begin to function when the airship approached one of those disturbed areas, and would be used for short-range work in circumnavigating them. There is another meteorological aspect of this work. In modern meteorology it has become general to link up everything we can with what is called the "polar front." The "polar front" may be visualized, very much simplified for present purposes, as the battle-front between cold air currents of polar origin and warm air currents of tropical origin, the one striving to go south and the other to go north. The battlefield may be visualized as a chain lying round the northern hemisphere, being composed of links of three different kinds, links where neither side is gaining, links where the cold air is gaining southwards, and links where the warm air is gaining northwards. Those three links have certain different characteristics. Where the "front" is stationary nothing very important happens; where the warm air is going northwards there is in general a gradual ascent of that warm air over the cold; but where the cold air is gaining ground there are often very strong vertical currents. The cold air undercuts the warm air and pushes it up violently. It will become, therefore, very important for the meteorological advisers to the airship pilots to indicate where these various links are and how they are moving. The "polar front" often lies south of the British Isles, and therefore an airship flying from India to England will very frequently have to cross it; and the question arises as to what route the pilot must follow in order to cross the "polar front" in the easiest and safest manner. The best way to cross it is where the "front" is stationary; the second best is to cross it where the warm air is gaining, but as the third link may sometimes be 700 to 1 000 miles long it may have to be crossed or a delay incurred. For meteorological reasons it is difficult at present to say exactly how intense these vertical currents are in that link on any particular occasion. We know sometimes they are very bad indeed. The recent airship disaster in America occurred on such a "front" where the vertical currents were strong. On the other hand, airships have passed across this link in the "polar front" with safety, and the design of future airships will of course take into account the magnitude of vertical currents which may be met. I suggest that Mr. Watson Watt's apparatus may give us some means of picking out the really violent parts of this "polar front." French investigators, headed by M. Bureau, actually claim that the links of this chain where the cold air is gaining are fruitful sources of atmospherics, whereas the other two kinds of links do not give rise to atmospherics at all. It might therefore serve a very useful purpose if Mr. Watson Watt were to put that to the test with the data which he has accumulated, and if he were to investigate whether there is any proportionality between the intensity of the "fronts" as regards vertical motion and the intensity of the atmospherics. If so, there will be a very practical application of this apparatus to aerial navigation.

Mr. E. H. Shaughnessy: I gather that generally the result of Mr. Watson Watt's work is to show that there is a relation between meteorological conditions and atmospheric conditions as we know them in wireless telegraphy. I do not think, however, that the determination of that relation can be claimed as being due to the use of the cathode-ray apparatus which has been described. Probably any good direction-finding apparatus might have been able to show the place of origin of atmospherics. I understood that the cathode-ray oscillograph circuit was tuned to 10 kilocycles, and a very interesting direction-finding result on Rugby and Leafield obtained. It seems to me that that case shows a serious defect, as the plot on that result being so indefinite does not inspire confidence in that particular direction-finder as compared with other well-known and well established direction-finders. Is it not possible with this set to cut out one station from another? With an ordinary direction-finder working on Rugby there would be no difficulty in cutting out Leafield from Rugby.

Dr. R. L. Smith-Rose: On page 603, in the first paper, in referring to the accuracy of discrimination of the automatic direction-finder, the author seems to have some doubt as to whether the accuracy of 2° associated with the instrument itself may have any meaning practically when dealing with the apparent direction of arrival of the atmospherics. I have had some considerable experience in observing the apparent directions of wireless signals, and from the analysis of data on this point I think it possible to draw some conclusions which should be very consoling to Mr. Watson Watt. These data show that for wireless bearings taken on signals averaged over the whole period of 24 hours it is extremely rare for more than 2 per cent of those bearings to be more than 20° in error; and only about 10 per cent of them are over 10° in error. Therefore, though the errors of individual observation may sometimes be 40° or 50°—and it is from such readings that direction-finding has in the past derived such a bad name—yet when the results are analysed statistically the accuracy is quite comparable with that of the instrument itself. With regard to the cathode-ray oscillograph, I think we ought to be clear that quite a big step has yet to be made before it is ready to place on board ship. To one who is used to dealing with direction-finders using frame coils with an equivalent area of 100 or 200 sq. ft., it comes as rather a shock to find that loops having an equivalent area of 20 acres are being used to obtain a readable deflection on the oscillograph! It is quite obvious that if reduction in area of the loop is to be made, the compensation can only be made by an increase in amplification. When one turns to the amplifier which is being used by the author one finds that it is dealing with voltage amplifications of the order from 5 to 200; and we do not yet

know how to produce amplifiers which give an amplification of more than about 2 000. Thus, before the system becomes a workable one in the field of navigation, considerable progress has to be made in the direction of the development of a suitable amplifier.

Major G. H. Scott: Some time ago Mr. Watson Watt came to Pulham to investigate the provision of loops for this type of direction-finder on H.M. Airship R33. It meant having loops very much smaller than those with which he had been working, and I should like to ask him whether the smaller loops have been successful in practice.

Messrs. R. A. Watson Watt and **J. F. Herd** (*in reply*): In order to avoid misunderstanding it seems desirable to amplify Dr. Simpson's statement of the provisional conclusions reached in the research on atmospherics conducted for the Radio Research Board. We would say that the available evidence indicates that all atmospherics may be accounted for by discharges of lightning character occurring in the terrestrial atmosphere; the estimated numerical distribution of lightning flashes throughout the world, the known quantities involved in typical lightning flashes, the general solar control, and the detailed study of meteorological environment of individual sources of atmospherics as located by direction-finding all favour this view.

The double orthogonal coil system of pen-recording outlined by Prof. MacGregor-Morris was proposed and adopted in principle some years ago, but it was not found economically possible to put it into practice without interfering with the progress of work regarded as more fundamental. The matter might profitably be considered again in the near future.

Prof. MacGregor-Morris counsels the substitution of "electron jet" for the traditional "cathode ray" in the description of such apparatus as that of the second paper. Habit and sentiment favour the older term, whilst reason favours a change, but not, in this instance, to a term so narrow as "electron jet." In view of the essential rôle of the heavy ions in the sensitive oscillograph which we owe to the Western Electric Co., and to Mr. J. B. Johnson and Dr. Van der Bijl in particular, the terms "ionic jet" or "ionic beam" would appear more appropriate. The latter term has in fact been used in the patent specifications (British Application No. 28971 of 1924 and related foreign applications) covering the device. We think Prof. MacGregor-Morris has given a solution as neat as any likely to be attained of the problem of combining equal deflectional sensitivities for the two plate systems with uniformity of each deflecting field.

The present position of work on fluorescent screens is that, at the request of the Radio Research Board, Sir Herbert Jackson, K.B.E., F.R.S., Director of the British Scientific Instrument Research Association, has prepared screen materials which give a more intense visual effect on brief exposures, such as those due to transient deflections, than does the usual screen material. The work is, however, still in progress; we think that the limit of screen sensitivity on short exposures to low electron velocities is far from having been reached. It is hoped that an opportunity for a report on the progress already made may present itself during the next few months. The provision of a quartz window, as mentioned by Prof. MacGregor-Morris, is certainly a useful step towards photographic recording.

The frequencies of 10 and 15 kilocycles adopted for observations on atmospherics are merely compromise values ensuring freedom from interference by signals and an adequate supply of atmospherics. It is well known that the intensity of interference by atmospherics usually increases steeply as the oscillation frequency of the receiving circuits is decreased towards the 10 to 15 kilocycle band, and there is no evidence, either in ordinary reception or in the observed wave-forms of atmospherics and our knowledge of their mode of action, that interference experienced on higher frequencies is normally absent from this lower band. Further, Mr. Shaughnessy's alarm at the appearance on one record of signals from Rugby and Leafield is sufficient confirmation of our success in the deliberate and extreme flattening of tune adopted to prevent selective preferences for atmospherics of one brand.

We feel that the answer to Prof. MacGregor-Morris's query as to sacrifice of the simplicity of the polar diagram must be an emphatic negative. He will recognize that the simplest recording of components would re-introduce the ambiguities referred to on page 614 in the second paper, but, even were this overcome, the prime consideration must be the overwhelming volume of arithmetical and statistical work so sympathetically referred to by Mr. Barfield, a volume which dictates study by limited samples from direct-reading instruments in preference to more sustained sampling by methods in which recombination of components is performed by human effort and not by the instrument.

Mr. Barfield's interesting reference to Dr. Eccles's description of the "sunrise minimum," which he reported as being particularly marked in November 1909, recalls also Round's description of a similar phenomenon at sunset [*The Marconigraph* (London), 1912, vol. 2, p. 310], and his suggestion that the timing of this minimum might serve for the determination of longitude at sea. We have never found the phenomena so well marked as in these descriptions, but the minimum N_2 of Fig. 10, is doubtless the sunset minimum in question, and is, as shown by Table 1, closely associated with the time of sunset at the receiver.

We are indebted to Squadron-Leader Johnston for a valuable discussion of the problem of navigation with and without the aid of the "wireless compass." We are sure that he will believe that we did not think the navigator's occupation gone; the problem solved by the suggested beacons was that of position-finding only, providing the successive starting points for the navigator's further work in course-setting.

We think ourselves privileged in having evoked two such lucid summaries of the problems of airways as that just referred to and the graphic summary of airship meteorology contributed by Mr. Giblett. We are strongly of opinion that the widening of the observer's horizon by the use of the instrument described will considerably reduce the total cost of providing an adequate and effective meteorological network for the great air routes.

We welcome this opportunity of expressing our appreciation of and interest in the important work being

done by M. Bureau and his colleagues in France. Whilst there appear to be important divergences between some of M. Bureau's conclusions and our own, divergences which will doubtless be cleared up by further discussion and experiment, there can be no doubt on the main point that the atmospheric is frequently a signal from the polar front, and whilst we do not regard ourselves as competent to read the text of the signal we are assured of the collaboration of Mr. Giblett, with his profound knowledge of the physics of meteorology, and of " polar front meteorology " in particular, in seeking an answer to the important question which he has now posed.

We can hardly accept the modest summary of our work made by Mr. Shaughnessy; its modesty is doubtless explained by the fact that he is a member of the Radio Research Board. Nor can we go far with him in his argument as to relations between methods and results. A discussion as to what might have been done with " any good direction-finding apparatus " might be interesting—the preliminary skirmish on this definition would certainly be so. But " has been " must always carry against " might have been," and the results quoted have only been obtained by the use of the two pieces of apparatus described, which forms strong evidence for our argument that at the best they could not *economically* have been obtained by previously existing means. Moreover, we beg Mr. Shaughnessy to refer us to any other instrument which could, in any circumstances, have disentangled the complex distribution of local sources of atmospherics shown in Fig. 4 (page 615) of the second paper. On reference to page 613 it will be found that the frequency of 10 kilocycles was that used in atmospheric observations and that the effective resistance of the circuits was very high. For the Rugby-Leafield plot to which Mr. Shaughnessy refers, the tune was set midway between their widely differing frequencies, and the damping chosen ensured that adequate E.M.F.'s could be derived simultaneously from both transmissions. We think it will be sufficiently clear from a reading of the paper that the direction-finder described possesses, in addition to its directional selectivity, all the ordinary properties of frequency selectivity, and that it is only by deliberate choice that this frequency selectivity is sacrificed in the application to atmospherics, and in the obtaining of sufficiently bad jamming to demonstrate the exceptional powers of discrimination possessed by this direction-finder. The reply to his question is thus that there is, with this direction-finder, as with ordinary direction-finders, no difficulty whatever in separating frequencies very much closer than those of Leafield and Rugby.

We thank Dr. Smith-Rose for confirmation, from his wide experience of directional observations, of the faith which is implied in our reliance on the methods described for the location of sources of atmospherics. We agree that the development work now in progress has to go further before the standard ship installation is designed, but, as the paper indicates, much smaller loops have already been used, and we have no doubt as to the early production of a mobile set. We would particularly emphasize that in none of the signal traces shown at the meeting did the voltage amplification exceed 5. Thus there is, apart from the other factors involved, a wide margin between the amplification used and that regarded by Dr. Smith-Rose as the present limit.

In reply to Major Scott, we would say that the development of an apparatus working on the much smaller loops permissible in the application to airships and other mobile stations is progressing satisfactorily, and would repeat the assurance contained in our reply to Dr. Smith-Rose.

INSTITUTION NOTES.

National Certificates and Diplomas in Electrical Engineering.

The following have been approved under the scheme drawn up by the Board of Education and the Institution :—

Approved for Ordinary Grade Certificates (Senior Part-time Course) :

Crewe Technical Institute.

Approved for Higher Grade Certificates (Advanced Part-time Course) :

Wigan and District Mining and Technical College.

54th (East Anglian) Divisional Signals, T.A.

The Secretary is informed that there are vacancies in the above unit for commissioned officers.

Candidates for commission in the lowest rank must be between 18 and 31 years of age and of British nationality and parentage, and have had previous service in an O.T.C. and possess Certificate " A," *or* have served for 6 months in the Regular or Territorial Army, or for 3 months overseas with any military or naval Unit between August 1914 and November 1918, and be recommended by an officer under whom he has served, *or*, alternatively, must undertake to pass for Certificate " A."

Candidates must also accept liability for service overseas, but cannot be sent overseas until a Special Act of Parliament is passed authorizing despatch of Territorial Army overseas.

The work of a Divisional Signal Company in the Field includes maintenance of communications and, if necessary, co-operation with Air Service. Among the means of communication used are :—

(i) Wireless telegraphy, with sets up to 120 watts and of a maximum range of approximately 200 miles (wireless telephony will probably be brought into use later).

(ii) Cable, by cable wagons (horse transport) using fairly light surface cable with telegraphic apparatus and by telephone wagons, using both telegraphy and telephony.

(iii) Visual, by means of flags, heliographs and electric signalling lamps. Popham panels (for use with aircraft) are also used.

Officers need a good general knowledge of all means of communication, specializing in either (i) or (ii).

Training is carried out with the equipment held by the Unit which includes all wireless equipment, cable and telephone equipment (including commercial-type internal-combustion engines and 3 kW and 1 kW generator sets), accumulators, telegraph and telephone instruments, switchboards and Field exchanges. There is also instruction in riding, management of animals, etc. Ability to drive motor cars and motor cycles and to carry out running repairs is an advantage. Training also includes the usual drill and musketry courses, an annual camp (15 days) and, during the first two years, an initial course of 14 days (this may be done in two parts) with a Regular Army Signal Unit. Associate Members of the Institution are exempt from the initial course.

There is an oufit allowance of £40 on first commission, or, if previously commissioned, an allowance to cover renewal and repairs to outfit.

Pay of rank held is allowed while at annual camp, or on any military duties.

Inquiries should be made to the Officer Commanding at the Headquarters of the Unit, Bay Lodge, The Green, Stratford, London, E. 15.

The Benevolent Fund.

The following is a list of the Donations and Annual Subscriptions received during the period 26 March–25 April, 1926 :—

POWER FACTOR AND TARIFF.

By EDWARD VINCENT CLARK, B.Sc., Associate Member.

(*Paper first received* 18*th May, and in final form* 24*th August*, 1925; *read before* THE INSTITUTION 4*th February, before the* NORTH-WESTERN CENTRE 2*nd February, and before the* SOUTH MIDLAND CENTRE 31*st March*, 1926.)

SUMMARY.

The great amount of attention now being given to the question of poor power factor suggests that tariffs such as are commonly used to-day are unsuitable in present circumstances. The paper contends that a wattless component of current, despite its having no energy content, involves the supply undertaking in extra running costs, and that therefore a charge should be levied for supplying it. A three-part tariff is proposed, embracing a periodic charge per kVA of maximum demand, a charge per kWh of energy, and a charge per kVA-hour of lagging wattless component. The additional running costs caused by wattless component are briefly touched on, and it is suggested that in a station with an average power factor of 0·7 the charge per kVA-hour of wattless component should be about one-ninth of the charge per kWh of energy. The question of metering the three-part tariff is discussed, and a method is shown whereby, with balanced load, a three-phase wattmeter may be "biased" to record the total energy consumption, plus or minus any desired fraction of the kVA-hours of lagging or leading wattless component.

INTRODUCTORY.

One of the troubles of many supply undertakings to-day is the low power factor of the load. Experience has shown that without constant endeavour to effect an improvement, the power factor of a system is apt to grow steadily lower as more and more small users of power are connected. The induction motor, of size appreciably greater than is necessary for the work it has to do, and running frequently at less than half load, is the chief offender in producing poor power factor. Manufacturers are able to supply motors having good power factor at all loads, and can supply various types of phase-advancing apparatus to neutralize directly or indirectly the lagging current of induction motors. The problem is therefore not a technical but an economic one; and it is from this standpoint that it must be studied.

From the point of view of an outsider, the present state of affairs presents a strange paradox. On the one hand are thousands of consumers of electricity using ordinary induction motors and perfectly satisfied with their operation, although they use a good deal more electricity for the same power than would other types of motor which are procurable. On the other hand are supply undertakings, whose business it is to supply electricity, complaining bitterly that their customers are taking more electricity than they need, and urging them, by argument and by bonus, to adopt a different type of motor or to install phase-advancing apparatus in order to reduce the quantity of electricity they consume. In what other field of supply and demand are these conditions possible? One cannot imagine, for example, a gas company imploring its satisfied consumers to adopt, for the benefit of the company and the supply generally, a type of engine which uses less gas.

The word "electricity" has been deliberately used in the preceding paragraph, to emphasize the point which lies at the root of the whole matter. A supply undertaking is essentially a supplier of electricity and not merely of power. An electric motor is essentially a piece of apparatus which absorbs electricity and delivers mechanical power. Electricity is a vague term; and for clear thinking we regard it as a matter of amperes, volts, phases and power factor; and we consider a given alternating supply as being made up of so much energy component and so much wattless component. Owing to the law of the conservation of energy, we know that a motor delivering so much brake horse-power requires a certain minimum energy component in the electricity it consumes. In accordance with its inefficiency as a converter of energy, so it requires a greater energy component in the electricity it absorbs; and in accordance with its inefficiency as a converter of electricity into energy, so it requires a wattless component in addition to the energy component.

(1) THE CASE FOR A THREE-PART TARIFF.

The Electric Lighting Acts of 1882 and 1888 and the Board of Trade Regulations made thereunder were responsible for a good many conditions which permeate the supply of electricity in Great Britain to-day; and one provision of the early Regulations was that electricity should be sold by its energy content. It was very soon found that to sell electricity at a flat rate per unit, no matter for how many hours per day it might be used, was extremely unsound from the economic standpoint. Dr. Hopkinson, in the early 'nineties, laid down the fundamental principle that the cost of supplying electricity was divisible into two items, (*a*) the running costs incurred in actually supplying the electricity required, being approximately proportionate to the units of energy consumed, and (*b*) the cost of being ready to supply, approximately proportionate to the kilowatts of the peak load; and of these two the latter was in many cases by far the greater. And Wright, with his maximum-demand indicator and method, showed how a tariff based generally on the Hopkinson principle might be made to comply with the requirements of the Regulations and receive the sanction of the Board of Trade.

The Hopkinson principle was formulated primarily for the supply of direct current, or for alternating

current used almost exclusively for lighting, where the power factor would be nearly unity, as the induction motor was not then developed. To-day the principle is very widely adopted for power supply, the charge for running costs being based on the kWh of energy consumed, and the standing charge being based on the kVA of maximum demand. By using kVA and not kW an attempt is made to charge users of current at poor power factor in accordance with the cost that their supply entails. But the fact that supply undertakings working with a tariff of this kind are not fully satisfied with their station power factor, however low it may be, is surely evidence that this tariff departs seriously from the ideal.

Extending the Hopkinson principle a stage further, one might suggest dividing to-day's cost of supplying electricity into four parts as follows :—

(*a*) The running costs involved in supplying the energy component of the electricity consumed.

(*b*) The running costs involved in supplying the wattless component of the electricity consumed.

(*c*) The standing charges incurred in being ready to supply the energy component of the maximum demand.

(*d*) The standing charges incurred in being ready to supply the wattless component of the maximum demand.

If it were possible to devise a suitable tariff based on these four items of cost, metering each item separately, and assessing the tariff under each head in such a way that any consumer must show an adequate percentage of profit on the amount of his bill, no matter how small any three of the items might be, we should have a tariff such that all customers afforded a profit to the supply undertaking, no matter what their individual power factors. And further, the lower the power factor of the general supply, the better would be the financial returns for any given demand for energy. For example, if one supply undertaking had a peak load of 10 000 kW at unity power factor and an annual sale of 20 million units, also at unity power factor, it would make adequate profits under items (*a*) and (*c*) above. A second undertaking with a peak load of 10 000 kW at 80 per cent power factor, and an annual sale of 20 million units at 70 per cent power factor, would make the same profits as the former under items (*a*) and (*c*), and in addition would make further profits on the sale of 20·4 million kVA-hours of wattless component, and on the standing charges receivable from plant capable of supplying a demand of 7 500 kVA of wattless component over and above 10 000 kW of energy component.

An ideal tariff, however, is not always a practicable one; and it seems quite impossible to frame a tariff which would differentiate adequately between standing charges on plant to supply energy and on plant to supply wattless component. To combine these two items (*c*) and (*d*) into one charge, based on kVA of peak load, though not strictly rational is undoubtedly advisable. It would appear at first sight that a customer whose maximum demand is 1 000 kVA at 70 per cent power factor entails upon the supply undertaking somewhat less standing charges, *cæteris paribus*, than a customer whose maximum demand is 1 000 kVA at unity power factor; but this is not necessarily the case, since diversity factor has material influence, and the diversity factor of wattless component is in general much lower than that of energy component.

Combining (*c*) and (*d*) into a common charge, we arrive at a three-part tariff for the supply of alternating current for power purposes as follows :—

(*a*) A charge based on the kWh of energy used.

(*b*) A charge based on the kVA-hours of wattless component used.

(*c*) A charge based on the kVA of maximum demand.

With an appropriate tariff of this nature, due regard being paid to the fact that item (*c*) is not quite ideal, the undertaking should gain by increased supply of electricity, no matter what the power factor, since energy component and wattless component would alike bring grist to the mill. The use by consumers of the simplest and most reliable form of motor—the plain induction motor rated appreciably above its normal load—would no longer be a source of annoyance to the supply undertaking, but a direct gain. Customers who preferred this type of motor would pay adequately in their bills for the expense and trouble incurred in supplying the wattless component they required. Those who desired a reduced electricity bill could secure it at the expense of increased capital cost, attendance and upkeep, if they decided that it was economical to do so, by using synchronous motors or phase-advancers. The onus of improving the power factor would be placed upon the consumer and the manufacturer's salesman, whilst the supply undertaking would be interested in the matter only to a secondary extent.

The suggestion that a low power factor should be a source of profit to a supply undertaking, rather than a disadvantage, may appear revolutionary; but it seems impossible to avoid such a conclusion, given a rational tariff. In the past, encouraged no doubt by the electric lighting Regulations, engineers have regarded wattless component as incurring too small a running cost to be worth charging for; and as long as this is supplied free of charge it naturally follows that its supply is an added expense and trouble to the undertaking. But directly it is charged for at a price, however small, which covers its cost, its supply is no longer a disadvantage, but on the contrary a direct source of profit.*

(2) The Charge for Wattless Component.

When one endeavours to ascertain the actual running cost of supplying wattless current, one encounters many difficulties. The cost is made up of a number of items, each so small as to appear practically negligible, whilst it is assuredly the case that the cost per kVA-hour of wattless component is largely dependent upon the ratio of the wattless component to the energy component demanded of the station. An undertaking with an

* An analogy may be drawn from the sale of sulphuric acid. If it were the custom, or the law of the land, that sulphuric acid, whatever its degree of dilution, should be sold at a rate based solely on its acid content, on the ground that water is of too little value to be worth considering, then it would be to the advantage of sulphuric acid manufacturers to sell acid at that degree of concentration at which it was most cheaply made. It might pay them to keep a staff of men whose main duty was to urge customers to use strong acid, and to show them how strong acid might conveniently be used in their businesses. It would certainly pay manufacturers, while still charging on acid content, to allow a discount based on the degree of concentration of the acid required. But with the realization that water, though practically valueless compared with acid, still costs something for distilling and for delivery, the manufacturer may frame a tariff based not merely on the acid content, but also on the water content of the dilute acid he is asked to supply. And with an appropriate tariff it will be more profitable to him to sell 100 tons of concentrated acid broken down to a specific gravity of 1·2 than 100 tons in the concentrated form.

average power factor of 95 per cent, for example, supplies 1 kVA-hour of wattless component for every 3 units of energy supplied; and the economy in running costs secured by supplying at unity power factor would be barely perceptible. Yet where the average power factor is about 70 per cent, so that the kVA-hours of wattless component are equal to the kWh of energy, the total running cost of the wattless component is quite appreciable, and certainly much more than three times that in the former case. And if the kVA-hours of wattless component were double the units of energy supplied, so that the average power factor was 45 per cent, the station engineer would certainly cite his power factor as a reason why his running costs could not be kept as low as those of neighbouring stations having an equal energy load at much better power factor.

The chief item comprised in the actual running cost of wattless component is the increase in I^2R loss in generators, cables and transformers. Upon a system of average power factor of 70 per cent, whose layout is such that the units spent in these I^2R losses are 10 per cent of the units generated, it is evident that a saving of 5 per cent of the units generated would be effected by abolishing all wattless current. Hence it follows that in a system such as this the running cost per kVA-hour of wattless component from this cause alone is about one-twentieth of the running cost per kWh.

A second item of loss inseparable from lagging wattless component is the extra excitation required on generators, to compensate not only for the extra drop in the system but also for the actual demagnetizing effect of such wattless component. With a station of the above nature the order of this loss would be about 1 per cent of the units generated.

Another cause of increased cost due to poor power factor lies in the increased iron, friction and windage losses in generators, etc., due to their being designed on a kVA basis. This, however, is a loss incurred in the design of the station, and may perhaps be covered by the standing charges. But a direct increase in running costs may arise from wattless component being sufficient to require an extra turbo set to be operated, with reduced station efficiency, at times when the running turbine has not yet reached its limit of capacity, owing to the overloading of the alternator. Loss from this cause should be quite trivial, except in the case of a station whose average power factor is appreciably less than that for which the station was designed, when it may be the case that the maximum efficiency of the turbine can hardly ever be attained.

Other disabilities of wattless component lie in the greater complexity necessary to maintain a satisfactory pressure on the distribution system, since wattless component as a rule causes a larger drop than an equal current in phase, and in the increased difficulty it causes in effectively tying two distant stations; whilst the use of reactances to prevent disturbances in one part of a system from affecting other parts would be feasible to a much greater extent if wattless component were absent. In general, these disabilities have to be met by increased capital expenditure, and therefore cause increased standing charges rather than increased running costs. It is quite certain, however, that under heads such as these, supply undertakings are caused to incur running costs which could be avoided if wattless component were absent; and that even though such costs are not directly influenced by the actual demand for wattless component they are indirectly increased as the general power factor of the system falls. And if, on a three-part tariff, standing charges are levied on the kVA of peak load irrespective of power factor, it is desirable that extra expense due essentially to wattless component should be regarded as running costs rather than as standing charges, whenever any doubt occurs as to their allocation.

No doubt a station engineer, with a full knowledge of the system of supply and having available the station log sheets for the past, could compute approximately what saving in running costs he could have effected in the past year had there been no wattless component to supply, and hence could deduce the approximate running cost per kVA-hour of the wattless component supplied. Undoubtedly the ratio of the running cost per kVA-hour of wattless component to cost per kWh of energy would differ markedly in different stations, increasing steadily as the power factor fell. But seeing that in a station with an average power factor of 70 per cent and an I^2R loss of 10 per cent of the units generated, a saving of 5 per cent of the units generated would be effected in I^2R loss alone by abolishing wattless component, the author would suggest that for such a system a reasonable assumption is that the total running cost per kVA-hour of wattless component is in the neighbourhood of 10 per cent of the amount normally regarded as the running cost per kWh.

In other words, if this assumption is correct, an undertaking with a system of the above nature which at present operates on a two-part tariff of £Z per annum of kVA peak load, plus $10Y$ pence per kWh of energy supplied, might appropriately adopt a three-part tariff of £Z per kVA of peak load, plus $9Y$ pence per kWh of energy, plus Y pence per kVA-hour of wattless component. Or, more specifically, a two-part tariff of £5 per kVA demand plus 0·5d. per kWh might be replaced by a tariff of £5 per kVA demand plus 0·45d. per kWh, plus 0·05d. per kVA-hour of wattless component.

Naturally, such a tariff might include any of the ordinary provisions for discount according to quantity, and sliding scale in accordance with price of coal, etc.

Assuming for the sake of argument that this ratio of 9 : 1 is correct for the cost per kWh of energy component and per kVA-hour of wattless component in the case of the station above cited with 70 per cent load factor, it follows that the cost per kVA-hour of wattless component will be proportionately much less in the case of a similar station of 95 per cent power factor, and proportionately much greater in the case of a station having an average power factor of 55 per cent. And this leads to an important difference between the assessment of the charge per kVA-hour on a three-part tariff and the charge per kWh on a two-part tariff. In the latter case we know that increased sales mean, in general, reduced costs of generation—that an extra 10 per cent in units generated will not increase the generating costs by 10 per cent—and conversely that a 10 per cent decrease in units generated will not result in a 10 per cent

decrease in generating costs. Consequently, it pays to assess the running costs per unit on a low basis, including all doubtful items in the standing charges, in order to encourage the use of as great a number of units as possible. With wattless component, however, the opposite is the case. Additional kVA-hours of wattless component, unless accompanied by a corresponding increase in the kWh required, involve greater running costs than the average cost per kVA-hour; and therefore the tariff per kVA-hour of wattless component should be on the high side, tending to discourage rather than encourage an undue demand for wattless component. Thus it follows that in assessing the running cost of wattless component, an undertaking may with advantage assume an average power factor somewhat worse than that actually existing.

A further point arising from this is that with a three-part tariff it should in general be profitable to a supply undertaking to allow for leading wattless component a bonus equal to the rate charged for lagging. This would not be the case if there were any possibility of the power factor of the system being thereby raised to unity or anything approaching such a figure, as in that case the profit accruing to the undertaking from the supply of wattless component to one consumer would be handed back to another. But seeing that the most one can expect in the way of improvement in power factor from this cause is a matter of a few per cent only, one may regard leading wattless component as having an intrinsic value to the undertaking equal to the cost of the most expensive kVA-hours of lagging component, and therefore as fully justifying a bonus assessed at a rate showing some profit on the average cost. This applies, of course, only to leading component taken at time of load. Leading component taken by static condensers during the slack hours is on quite a different footing.

It is often suggested that as it is poor power factor that is of serious import, whilst with a good power factor of, say, 90 per cent the wattless component adds very little to the running costs, it is rational to levy no extra charge for out-of-phase current upon those customers whose power factor is above a named figure, merely surcharging in some way those whose power factor is decidedly bad. This course, however, appears to be both illogical and impolitic. It is the power factor of the station as a whole which determines the running cost of the wattless component; and a particular customer's individual power factor has little bearing on this cost, save as regards losses in that part of the system —transformers and service lines—of which he is almost the sole user. Given two neighbouring consumers having identical power loads, except that one has a power factor of 0·7 and the other of 0·89—that is to say, each taking the same kWh per annum, but the one taking twice as many kVA-hours of wattless component as the other—there is identical benefit to the supply authority, as far as running costs are concerned, if the latter consumer improves his power factor to unity as if the former improves his to 0·89; and tariffs should be such as to encourage the one improvement as much as the other. Further, it is quite probable that a power consumer whose average power factor is 0·89 has already installed some phase-advancing apparatus, and by a little care might readily improve his power factor still more if offered suitable inducement; whereas the consumer whose power factor averages 70 per cent probably operates nothing but induction motors, and could not effect much improvement except at considerable cost.*

(3) Metering under a Three-Part Tariff.

A lesson learnt in the early days of electric lighting is that any form of charging for electricity which is confusing to the lay mind is intrinsically bad from the psychological standpoint. If a consumer can read his meters and compute his electricity bill he is usually satisfied, the only dubitable point being the accuracy of the meter. If, on the other hand, he cannot read his meters, or cannot follow the manner in which his bill is computed from them, he is prone to consider that the supply undertaking may be defrauding him, and that any increase in his bill over the previous amount is probably unjustified. On these grounds most undertakings which adopted the maximum-demand tariff for lighting supply found it expedient to offer as an alternative a flat rate; and this was preferred by most customers. Many forms of tariff based on power factor suffer from the defect that the meter readings are not directly converted into terms of money. But the three-part tariff suffers from no undue trouble on this score, nor in most cases from difficulty in metering.

For measuring a single-phase supply on the three-part tariff one would require three meters, viz. a maximum-demand kVA meter, an ordinary watt-hour meter, and a sine meter, i.e. an ordinary watt-hour meter modified by introducing a time-lag of 90 degrees into the current or voltage. For three-phase work, similar meters of a three-phase type might be suggested, but in most cases a simpler form of metering may be used. The kVA-hours of wattless component will never exceed twice the kWh of energy consumed by any normal power user, and will rarely exceed it by 50 per cent; whilst the rate charged will be of the order of one-tenth. It follows that an error of 5 per cent in the measurement of kVA-hours is of less importance than an error of 1 per cent in the measurement of kWh. Consequently, in the majority of cases it will be quite sufficient to assume that the three-phase load is balanced, as far as the measurement of wattless component is concerned; and with this assumption the sine meter need be nothing more than a simple single-phase watt-hour meter, the series coil being connected in one main and the pressure coil between the other two, the reading of such a meter on a balanced load giving $1/\sqrt{3}$ of the total kVA-hours of wattless lagging component taken, with a negative reading if the current is leading. With such a meter the dial might be marked to read $\sqrt{3}$ times the actual

* The case cited illustrates incidentally one of the anomalies caused by assessing standing charges upon the kVA of maximum demand. If these two consumers have simultaneous peak loads, each of 100 kW, but one at 0·70 power factor and the other at 0·89, their standing charges at £5 per kVA per annum will be £715 and £562 10s. respectively, whilst their joint peak load will be 200 kW at about 0·8 power factor. If either consumer should now install condensers taking 50 kVA leading current at zero power factor, the joint peak on the station due to the two will be 200 kW at 0·89 power factor, i.e. the technical benefit to the supply undertaking will be identical. Yet the financial benefit of the installation of condensers to the consumer will be only £62 10s. per annum if installed by the second, but £152 10s. per annum if installed by the first.

consumption, so as to record the wattless kVA-hours of the three phases; or, alternatively, it might be marked to read "equivalent units," so that the wattless component recorded might be charged for at the same rate as the units of energy.

The explanation of the use of the third meter should not involve any great confusion to non-technical consumers. Most power users probably have sufficient knowledge of the direct-current motor to understand that, in addition to the operating current through the armature, one must have magnetizing current through the field. Similarly, the induction motor requires both operating or energy current to convert into power, and magnetizing current to create the field, though in this case both currents flow through the same wires. The meters are so designed that the one records the consumption of energy current, and the other the consumption of magnetizing current. This explanation does not depart very far from strict accuracy, and is probably much more comprehensible than any explanation involving the term "power factor." Further, it at once assists the consumer to understand the disadvantage of using a motor much larger than is necessary for the work it has to do. Naturally the larger motor will require more magnetization than a small one.

The sine meter, whether three-phase or single-phase, suffers from the fact that it reverses with leading current. If it is allowed to reverse, it gives full credit for leading current taken by condensers left in circuit all night. If provided with a pawl to prevent reversing, it fails to give credit for leading current taken at the time of load. To combine the sine meter with the watt-hour meter, by providing the several armatures upon the one spindle, the sine-meter portion being appropriately weaker than the other part, would overcome this difficulty, as in this case a non-return pawl would be reasonably satisfactory; but it would involve an entirely new departure in meter manufacture.

However, there are other ways of overcoming this defect, in the case of balanced loads, without introducing additional complications or requiring special meters, since two ordinary single-phase meters, their series coils being connected in two of the mains and their pressure coils thence to the third main, measure by the sum of their readings the total energy consumption, irrespective of any want of balance, while the difference between their readings gives the kVA-hours of wattless component, assuming balanced load, from the well-known fact that the lagging wattless kVA-hours equal $\sqrt{3}(W_1 - W_2)$, or leading wattless kVA-hours equal $\sqrt{3}(W_2 - W_1)$, where W_1 and W_2 are the respective readings of the two meters.

The use of two such meters involves a little difficulty in computing the power bill from the meter readings, but not a great deal if the tariff is suitably quoted. Three methods may readily be devised, all of which enable the consumer to compute his power bill from his meters without undue complication.

Method A.—The tariff charges f_1 pence per unit for all units recorded on No. 1 meter, and f_2 pence per unit for all units recorded on No. 2 meter. (If x pence is the price per unit for energy component, and y pence is the price per kVA-hour of wattless component, then $f_1 = x + \sqrt{3}y$ and $f_2 = x - \sqrt{3}y$.)

Method B.—The tariff charges f_0 pence per unit for all units recorded, plus or minus f_3 pence per unit of the difference between the meter readings, according to which is the greater. (Hence $f_0 = x$, and $f_3 = \sqrt{3}y$.)

Method C.—The tariff charges f_1 pence per unit for all units recorded, less a rebate of f_4 pence per unit for all units recorded on meter No. 2. (In this case $f_1 = x + \sqrt{3}y$, and $f_4 = 2\sqrt{3}y$.)

Of these three methods, the last would probably prove the most satisfactory. It makes use of the psychological fact that a high price less a rebate is in general preferred to a low price plus a surcharge, even though the actual cost is the same, whilst it offers an explanation of the form of tariff which would probably be fairly satisfactory to the lay mind. The explanation is as follows:—

Motors badly designed or ill suited to their work may take so much magnetizing current as to draw double the requisite current from the line. The tariff is based on such motors, and the meters are so designed that with such a motor the entire power consumption is recorded on No. 1 meter, and No. 2 remains idle. With motors of better design, or more appropriately used, the magnetizing current is smaller and the cost of supply in consequence is less, so that the consumer deserves a rebate. Whatever the magnetizing current, the two meters jointly record the total power consumption, whilst the reading of No. 2 meter is directly proportionate to the saving in magnetizing current, and is therefore a measure of the amount of the rebate.

An explanation of a similar nature, but involving power factor instead of magnetizing current, may readily be devised, if preferred. Naturally, the consumer must take his meters on trust—just as he must with any gas, water or electricity meter—but the explanation appears to account fully for the use of the two meters, and for the method of computing the power bill.*

With two such meters, consumers get full benefit for leading power factor at the time of load, whilst the provision of a non-return pawl on No. 1 meter ensures that the consumer's rebate for leading current extends only down to a power factor of 0·5. With a lower leading power factor than this he will pay at an increasing rate; and it will therefore be to his interest to switch off static condensers when his works are at rest.

(4) The Biased Meter.

However, if the units of energy do not constitute a rational basis for the electricity bill, it seems quite unnecessary to measure them, if one can provide a meter that will directly measure something else which gives a truer basis for computing the charge. The average consumer's knowledge of electricity is very vague, and he probably has little idea of what constitutes the "Board of Trade unit" which his meter records and with which his bill charges him. If his meter records in "virtual units," and his bill is computed directly from the meter readings, charging

* The use of two single-phase meters would undoubtedly lead to confusion if one showed a negative reading. This will be the case if the average power factor is less than 0·5. But such conditions should very seldom be met, as this power factor corresponds to that of an induction motor at about one-fifth full load.

him at a flat rate per virtual unit (with or without the standing charge per kVA of maximum demand), he is likely to be quite as content to accept his bill as if it charged him a flat rate for Board of Trade units. And, by a very slight modification, a standard type of three-phase watt-hour meter is readily adapted to record, upon a balanced load, not the kWh of energy consumed alone, but the kWh of energy plus or minus any desired fraction of the kVA-hours of lagging or leading wattless component consumed. That is to say, one may adopt a three-part tariff of the type suggested, using for those consumers whose load is reasonably balanced the same instruments as are necessary to-day with a two-part tariff, namely a maximum-demand kVA meter, and an ordinary three-phase watt-hour meter, the latter being "biased" to read not in Board of Trade units but in virtual units to be charged for at a flat rate in accordance with the requirements of the proposed three-part tariff.

The three-phase meter needs only a very slight alteration. It must be of the type comprising two single-phase armatures upon a common spindle, and recording upon a common dial in the usual manner. The only modification necessary is to arrange that when one element is tested on single-phase current, the meter shall run a certain percentage fast, and that when the other element is similarly tested the meter shall run an equal percentage slow. If the elements run respectively x per cent fast and slow, we have a meter which, appropriately connected to a three-phase balanced load, measures accurately the kWh of energy consumed plus $x/(100\sqrt{3})$ times the kVA-hours of lagging wattless component, minus $x/(100\sqrt{3})$ times the kVA-hours of leading wattless component. If, as suggested above, lagging wattless component is computed to cost (per kVA-hour) one-ninth as much as each kWh of energy, then $x = 19{\cdot}2$ (that is, the two elements of the meter are adjusted to run respectively 19·2 per cent fast and slow) and by charging at 0·45d. for all virtual units recorded, we are actually charging at 0·45d. per unit of energy plus 0·05d. per kVA-hour of lagging wattless component, less 0·05d. per kVA-hour of any leading wattless component.*

The requisite bias may be given to a three-phase meter in various ways: (1) By designing the armatures or fields to have different strengths; (2) by having different ballast resistances in their shunt circuits; (3) or where current or pressure transformers are used, by having a different number of turns in the secondaries. Existing meters could probably be given the appropriate bias by so adjusting the brake as to make the meter run the required degree fast, and then inserting a suitable extra ballast resistance in the one shunt circuit.

If the consumer's load were not strictly balanced on the three phases, the biased meter would give a somewhat erroneous reading; but with any want of balance due to slightly unsymmetrical design of induction motors, or to similar cause, the error should be quite negligible. Lighting is perhaps the chief source of want of balance, but in many cases this will be taken at a lower pressure and be metered separately. Where the load is known to be unbalanced, e.g. where some single-phase apparatus is used, then by connecting that apparatus appropriately it could be ensured that the single-phase load is charged at slightly above normal rates. The amount of this surcharge will not be great; and one is justified in making a somewhat higher charge for single-phase supply taken from three-phase mains.*

With the biased meter, a non-return pawl is desirable to prevent the reversal of the meter under the effect of static condensers. A meter biased to rate wattless component at one-ninth the cost of energy would reverse with a leading power factor of about 11 per cent. A non-return pawl means that energy with a lower leading power factor than this is obtained free of cost, and condensers may be left in circuit all night with neither bonus nor charge to the consumer. Probably where condensers are installed by a consumer it is to the interest of the supply undertaking that they should be left in circuit continuously, even though the benefit accruing is not sufficient to warrant an actual rebate other than at time of load.

Naturally, in connecting a biased meter in circuit it must be put in the proper phase sequence, or it will give a bonus for lagging current instead of for leading current. This should, however, involve very little trouble in installing the meter, if the terminals are properly marked. The simplest positive test would perhaps be to place a single-phase test-coil of high inductance across the load terminals coming from the two series coils, when the meter should at once revolve if properly connected.

* This is readily established as follows:

If I is the current per phase, V the voltage (in kilovolts) between phases, and ϕ the angle of lag, then the power in the circuit at any time is $\sqrt{3}VI\cos\phi$ kilowatts, and the wattless component is $\sqrt{3}VI\sin\phi$. The energy consumed in any period Σh is $\Sigma\sqrt{3}VIh\cos\phi$ kilowatt-hours, and the kVA-hours of wattless component are $\Sigma\sqrt{3}VIh\sin\phi$.

The one armature alone should register $\Sigma VIh\cos(\phi - 30)$, but, being x per cent fast, it actually records $(1 + 0{\cdot}01x)\Sigma VIh\cos(\phi - 30)$.

The other armature alone should register $\Sigma VIh\cos(\phi + 30)$, but, being x per cent slow, it actually records $(1 - 0{\cdot}01x)\Sigma VIh\cos(\phi + 30)$.

The meter as a whole therefore records

$$
\begin{aligned}
&(1 + 0{\cdot}01x)\Sigma VIh\cos(\phi - 30) + (1 - 0{\cdot}01x)\Sigma VIh\cos(\phi + 30)\\
&= \Sigma VIh\cos(\phi - 30) + \Sigma VIh\cos(\phi + 30)\\
&\qquad + 0{\cdot}01x[\Sigma VIh\cos(\phi - 30) - \Sigma VIh\cos(\phi + 30)]\\
&= \Sigma 2VIh\,.\,\tfrac{1}{2}\sqrt{3}\cos\phi + 0{\cdot}01x\Sigma 2VIh\,.\,\tfrac{1}{2}\sin\phi\\
&= \Sigma\sqrt{3}VIh\cos\phi + \frac{x}{100\sqrt{3}}\Sigma\sqrt{3}VIh\sin\phi
\end{aligned}
$$

i.e. kilowatt-hours of energy, plus $x/(100\sqrt{3})$ times kilovolt-ampere-hours of wattless component.

If ϕ is negative, i.e. if the current is leading, clearly the second term has a negative sign.

* If a three-phase load be unbalanced, but the voltage triangle be not distorted, the nature of the error introduced by the use of the biased meter can readily be seen from the fact that any out-of-balance load may be regarded as the superposition on a balanced three-phase load of one or two single-phase loads between wires. Assume the phase sequence of rotation to be A, B, C, and the series coils of the meter to be in lines A and C. Then No. 1 armature, biased to run fast, is in line C, and the other in line A. Single-phase current taken between lines A and B is metered by No. 2 armature alone, and its wattless component is ignored. Thus single-phase load between these lines is charged for at a discount of x per cent below normal energy rate, and no charge is made for its wattless component. Similarly, single-phase current taken between lines B and C is charged for with a surcharge of x per cent above normal energy rates, again no charge being made for wattless component. Single-phase current taken between lines A and C can readily be seen to be charged for at normal rates for energy, whilst its wattless component is charged for at three times the normal wattless rate. Thus in the normal case, where the out-of-balance load is lagging, there is an undercharge if the single-phase load is connected between lines A and B, and an overcharge if between lines B and C, or A and C. Further, if the load is between mains A and C, the surcharge is zero at unity power factor, increasing as the power factor falls; whilst if the load is between mains B and C the surcharge is a maximum at unity power factor, falling to zero at 0·5 power factor. In any ordinary case the error will be trivial. For example, with power factor 0·8, and out-of-balance 10 per cent of the total load, the error in the charge for running costs will be approximately 1½ per cent if the out-of-balance is caused by load between lines A and C, 1 per cent if between lines B and C, and 2½ per cent if between lines A and B, on a system where the wattless component is assessed at one-ninth the cost of the energy component.

No doubt the sanction of the Electricity Commissioners would be required before biased three-phase meters would be allowed, in the case of many British supply undertakings. They do not record in units of energy consumed, nor is it possible to deduce from their readings what has been the actual energy consumption; and therefore they do not comply with the requirements of the Electric Lighting Acts. Nevertheless, they measure the consumption of electricity on a balanced three-phase load on a perfectly definite basis; and their accuracy can readily be tested by testing each single-phase element separately. There appears therefore to be no valid reason why approval should not be given to this type of meter in accordance with the provisions of the Electricity (Supply) Act, 1922.*

Where a supply undertaking is seriously perturbed by the poorness of its normal power factor, the use of the biased meter for the small consumer using induction motors seems to offer great advantages. The determined charge for wattless component, however small, can be introduced with no expense save the initial one of altering the watt-hour meter installed. The consumer is not troubled by the addition of an extra meter that he does not understand, nor are his bills made up in any different form from that he is accustomed to, save that he is now assessed in "virtual" units instead of in "Board of Trade" units. Any misgivings that he may have on that score will be largely alleviated by the fact that while the number of virtual units recorded is not markedly greater than the Board of Trade units recorded hitherto, the price charged for them is some 10 per cent less. With an appropriate charge, the returns obtained by the undertaking from the sale of wattless component should reconcile it to a low power factor; and only a serious drop in the average power factor would necessitate an alteration in the ratio of the respective charges for wattless component and for energy. Clearly it is only an alteration in this ratio which requires an alteration in the bias of the meters. Indeed, for all power customers, large or small, except where the load is seriously out of balance, the biased meter should be quite satisfactory to the supply undertaking; though a power user who installs a synchronous motor or other mechanical phase-advancing apparatus might prefer two single-phase meters or unbiased three-phase meter plus sine meter, in order that he might more clearly see if he was using his phase-advancer to the best advantage. Apart from the Electricity Commissioners' Regulations, there is no reason why an undertaking deciding to adopt a three-part tariff should not use a biased meter plus a kVA maximum-demand indicator as standard equipment, giving consumers who required it the option of having three meters, on the payment of extra meter rent; and requiring consumers having single-phase apparatus to connect it to a special circuit which should either be separately metered or else be taken direct from the appropriate terminals of the biased meter.

* A particular field in which the biased meter should prove useful is that of metering the supply transmitted by a tie line connecting generating stations belonging to undertakings that have no financial connection with one another. The ensuing decade will certainly see in England a great extension of tie lines between power stations, both large and small; and one may anticipate that the economic problems concerning the basis of payments for the supply transmitted through such lines will be considerably more intricate than the technical problems involved in their provision. The importance of the power factor of the supply furnished by one undertaking to another, and the technical difficulties involved in delivering power at a specified lagging power factor, are such that it appears essential for any tariff to pay considerable regard to this matter, since a charge which ignored power factor of the load transmitted would tend to cause endless disputes between the engineers operating the various stations connected to the tie line. A composite tariff embracing a charge per kWh of energy, plus a charge per kVA-hour of lagging wattless component, with the latter charge set at such a figure that each station preferred to carry as much of its own lagging current as it could adequately handle, would have a great deal in its favour. The biased meter, without the non-reversing pawl, should afford a very simple means of metering such a composite tariff.

Conclusion.

In conclusion the author submits that, although it has no energy content, wattless component of electricity supplied to consumers has a real value to them, and in many cases entails a real running cost to the undertaking; that where low power factor is seriously perturbing a supply undertaking, a rational tariff should include a charge for wattless component, and that a charge based on the kVA-hours of lagging wattless component consumed, with an equal rebate for leading wattless component taken at time of load, is a reasonable basis for such charge, although not absolutely ideal; and finally, that the adoption of a tariff embodying such a charge may be arranged without undue complication of metering methods, and without entailing perplexity in the minds of non-technical users of power.

Schedule.

The following table shows the annual power bill under a three-part tariff of £5 per annum per kVA of maximum demand, plus 0·45d. per kWh of energy, plus or minus 0·05d. per kVA-hour of lagging or leading wattless component, for five consumers having the same

Table.

Consumer	Peak load	Cost at £5 per kVA	Energy	Cost at 0·45d. per kWh	Wattless component	Cost at 0·05d. per kVA-hour	Total cost
	kVA	£	kWh	£	kVA-hours	£	£
A	1 150	5 750	1 440 000	2 700	1 440 000	300	8 750
B	1 150	5 750	1 440 000	2 700	1 080 000	225	8 675
C	1 000	5 000	1 440 000	2 700	nil	nil	7 700
D	1 000	5 000	1 440 000	2 700	480 000	100	7 800
E	1 000	5 000	1 440 000	2 700	{480 000 leading	{100 (Cr)	7 600

peak load of 1 000 kW, and the same annual consumption of 1 440 000 Board of Trade units.

"A" has induction motors with a peak load of 1 000 kW at 0·87 power factor (1 150 kVA), and average power factor of 0·707.

"B" is the same consumer, but with motors rearranged to give an average power factor of 0·80.

"C" has synchronous motors operating at unity power factor at all times.

"D" is the same consumer, paying little attention to excitation save at peak load, and having an average power factor of 0·95 lagging.

"E" is the same consumer, with excitation carefully controlled and having an average power factor of 0·95 leading.*

[The discussion on this paper will be found on page 640.]

* It may be well to point out that where a consumer has synchronous motors capable of giving a leading power factor at peak load, it is wrong on either a two-part or a three-part tariff to base his standing charge on kVA of maximum demand, as he is then penalized for leading power factor at peak load.

THE IMPROVEMENT OF POWER FACTOR.

By Edgar Wall Dorey, Associate Member.

(*Paper first received 17th November, and in final form 29th December,* 1925; *read before* The Institution *4th February, before the* North-Western Centre *2nd February, and before the* South Midland Centre *31st March,* 1926.)

Summary.

The first part of the paper summarizes the principal types of apparatus employed for the improvement of power factor, and gives a description of the modern static condenser and also of types of power-factor-rectifying plant that have been developed during the past three years.

The second part of the paper outlines various forms of power-factor tariff in force in Great Britain, and is divided into two main classes; first, those based on kVA demand, and second, those incorporating a power-factor bonus or penalty on the total supply bill.

Systems of metering employed in conjunction with power-factor tariffs are briefly dealt with.

Modern Methods of Improving the Power Factor.

In a paper written by the late Dr. Gisbert Kapp and read before the Institution on the 16th November, 1922,* various kinds of plant in use at that time for the improvement of power factor were described.

Auto-synchronous and synchronous motors.—It is unnecessary to enlarge further on what has already been written in regard to the use of auto-synchronous and synchronous motors, as, since the date of Dr. Kapp's paper, there has been no appreciable alteration or addition to the types then described.

Rotary condensers.—The rotary condenser still finds little favour in Great Britain, where its field of application is very limited. The rotary condenser has a comparatively high loss, which is usually not less than 5 and may be as much as 7 per cent, and when this loss is capitalized, the rotary condenser, under the conditions ruling in Great Britain where power is mainly generated from coal, compares very unfavourably with other forms of power-factor-improving apparatus such as static condensers. Whilst in the larger sizes, say 500 kVA and upwards, the rotary condenser is, when compared with, say, the static condenser, less expensive in first cost, it is much less economical and more costly when running costs are taken into consideration.

To take as an example a 1 000 kVA condenser equipment, the difference in losses between static condensers and rotary condensers would be of the order of at least 4 per cent. With a 12-hour working day, 300 days per annum, this would be the equivalent of 144 000 units lost, and at 1d. per unit sold this is approximately £600 per annum. If this difference be capitalized it will show the static condenser installation to be by far the more economical.

* *Journal I.E.E.*, 1923, vol. 61 p. 89.

Ball and Roller Bearings for Induction Motors.

The adoption of power-factor tariffs by supply undertakings has compelled designers to produce an induction motor with a very high inherent power factor, and the introduction by many manufacturers of a.c. motors fitted with ball and roller bearings has assisted greatly to this end. The smaller the air-gap the higher is the power factor, and it is obvious that with ball and roller bearings, where the wear that is attendant upon the use of the journal bearing has not to be contended with, it is possible to use a much smaller air-gap, which is a feature of modern design.

An improvement of 2 or 3 per cent in the power factor represents quite an appreciable saving on the supply bill where a power-factor tariff is adopted, and it would appear that ball and roller bearings will play an important part in the design of a.c. induction motors in the future, and many of the leading British makers to-day adopt such bearings as standard.

Static Condensers.

The oil-immersed electrostatic condenser was briefly described in Dr. Kapp's paper, but it is now proposed to deal more fully with this type of apparatus used for power-factor improvement.

Condensers of this type are manufactured in Great Britain principally by Messrs. British Insulated and Helsby Cables, Ltd., of Helsby, and the Telegraph Condenser Co., Ltd., of London. The condensers consist primarily of so-called Mansbridge plates, these comprising a length of paper coated with tin under the Mansbridge process. In the construction of condensers the Mansbridge plates are separated by the requisite thicknesses of paper used as the dielectric, the number of thicknesses being dependent upon the voltage applied across the terminals of the condenser unit. Generally speaking, each unit of the condenser has a capacity of approximately 1 microfarad, but this may be greater or less according to the special conditions obtaining on the circuit.

Take as an example a 100-kVA 600-volt 50-cycle three-phase condenser; this would have a capacity of 885 μF and there would be approximately 295 separate units connected in parallel on each phase, the phases themselves being connected in delta.

The two principal makers of condensers referred to above assemble the units in frames, the frames being fixed into boiler-plate tanks and completely oil-filled. The modern oil-immersed static condenser, which is now the result of many years' experience in the con-

struction and application of this type of plant, may be regarded as a very reliable and efficient apparatus for the improvement of power factor.

A good deal has been said about the risk of resonance due to the connection of static condensers, but it will be agreed that experience is the best guide, and it may be safely said that over many years no difficulty whatever has been experienced in the application of condensers due to resonance. It is not claimed that resonance may not occur under certain exceptional conditions, but under the ordinary industrial conditions prevailing not only in Great Britain, but overseas, experience goes to show that resonance does not occur.

The static condenser, as built in Great Britain, is essentially a medium-pressure apparatus, the most economical voltage being about 600, but condensers have been, and are, built for direct connection to supplies up to 3 300 volts. It should be noted that only in exceptional cases is it cheaper to supply a high-tension condenser, and that the saving is not even then very material, usually not more than 10 to 15 per cent of the overall cost of the equipment.

Undoubtedly the right place to put the condenser is on the low-tension circuit, as by so doing the improvement will be effected as far as possible out on the distribution network, and it has been found in practice that the call for high-tension condensers is very small compared with that for low-tension ones.

A case has been reported from overseas of a British-made 100-kVA 3 300-volt outdoor condenser which, for the purpose of test and experience generally, is connected direct across the high-tension overhead transmission line without any protection whatever, and is therefore subject to every kick and surge on the system. Nearly 12 months have now elapsed since the condenser was first connected and it continues to give every satisfaction. This should be sufficient evidence to show that the static condenser does not in reality possess the attributes of frailty so frequently ascribed to it.

A comparatively new development is the low-tension pole-type condenser connected direct across pole-type step-down transformers, this application being particularly useful in the case of rural distribution. A number of British-made condensers of this type have been working for some considerable time in New Zealand, and it is reported by the engineer of one Power Board that, from the point of view of improved regulation only, the installation was worth while. In this case, however, the annual saving effected is sufficient to repay about 70 per cent of the cost of the equipment, and to this has to be added the increase in the useful output of the transformer, as the condenser being connected on the low-tension side of the step-down transformer unloads the transformer of wattless current, and for every 2 kVA of condenser capacity under industrial conditions the load on the transformer will be reduced by approximately 1 kVA.

The efficiency of the static condenser is very high, about 99·7 per cent, so that the losses are almost negligible. A bank of direct-connected condensers having an output of 1 000 kVA would have a loss of only 3 kW. Where auto-transformers are used for stepping up the voltage from that of the supply to the most economical voltage for the condenser, the auto-transformer losses have to be added, but the overall losses of large complete equipments for the usual industrial voltages may be taken to be between 1 and 1·5 per cent of the output in kilovolt-amperes.

It is well known that the output of a condenser is directly proportional to the plate area, and inversely proportional to the thickness of the dielectric, which latter is mainly dependent upon the applied voltage across the plates.

In the construction of paper condensers two or more thicknesses of paper are used according to the voltage applied, and it will be obvious that for each definite number of papers there is a maximum safe working voltage, and to obtain the most economical results it is desirable to work as closely as possible to this maximum safe voltage.

The microfarad capacity of a condenser is worked out from the following formula:—

$$\text{Microfarads} = \frac{(\text{kVA}) \times 10^9}{2\pi f V^2}$$

where kVA = output of condenser,
V = voltage applied across condenser plates,
f = frequency of the supply.

Taking a 100-kVA condenser on a 50-cycle supply, the capacity would be:

at 600 volts, 885 μF
and at 440 volts, 1 650 μF

With the two principal makes of condenser referred to in the foregoing the type of unit used in either case would be the same, therefore at 440 volts the condenser would require to be 86 per cent larger and approximately 80 per cent more costly than at 600 volts. To overcome this it is usual in condenser practice to step up the voltage by means of an auto-transformer to the most economical voltage for the condenser—in the above case, 440 to 600 volts. The auto-transformer is comparatively inexpensive and the overall reduction in price for the complete equipment very considerable.

A high-tension 3 000-volt condenser would comprise the requisite number of low-tension condenser units connected in series inside the tank to give the maximum working voltage across each unit. Each unit of the condenser, therefore, would be working at or near its normal designed voltage, and the number of such units would be the same as for a low-tension condenser of the same voltage as that applied across each unit. For example, 5 units in series each working at 600 volts would give the required result for 3 000-volt working; the actual number of 1-μF units used in the condenser would be the same as for 600-volt working, hence the cost would be approximately the same. It is for this reason that a high-tension condenser is usually not less, but more, costly than a low-tension condenser of the same output, and the use of high-tension condensers is not encouraged.

The connections of a standard auto-connected condenser equipment are shown in Fig. 1.

It will be seen that the condenser is connected direct to the auto-transformer, and the windings of the latter therefore provide a path for discharging the condenser on switching out or on failure of supply. If a condenser is connected direct across the supply mains some form

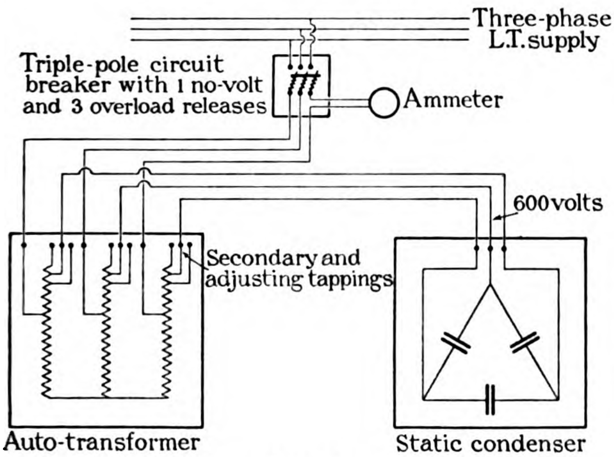

FIG. 1.

of discharge circuit is necessary, and this takes the form either of resistances permanently connected across the condenser terminals inside the tank, or of resistances so arranged inside the circuit breaker as to discharge the condenser on switching out.

course be of sufficient copper section to carry only the condenser current.

The transformer provided with an overwinding across which a condenser is connected works in parallel with other transformers, and this will result in the condenser capacity being split up over the whole bank of transformers instead of being confined to the over-wound transformer only. This point is important, as should it be necessary to add to, say, two 500-kVA transformers working in parallel in a substation a further 500-kVA transformer and, say, a 300-kVA condenser, then the new 500-kVA transformer could be overwound for the condenser, involving no alteration to the existing transformers. Fig. 2 shows the loading and phase angle of the various circuits of an overwound-connected condenser equipment.

The majority of supply undertakings in Great Britain, particularly those supplying large industrial areas, have connected to the system during no-load and light-load hours a very large transformer capacity drawing excitation current from the mains. So serious is this in many cases that some supply undertakings, such as the Clyde Valley Electrical Power Co., give in effect a substantial bonus to those consumers who keep static condensers or other power-factor rectifiers on the system during no-load hours.

Where a supply undertaking is faced with bad voltage regulation and low power factor, whether or not a power-factor tariff is in force, it should be possible to improve matters considerably by connecting direct across the

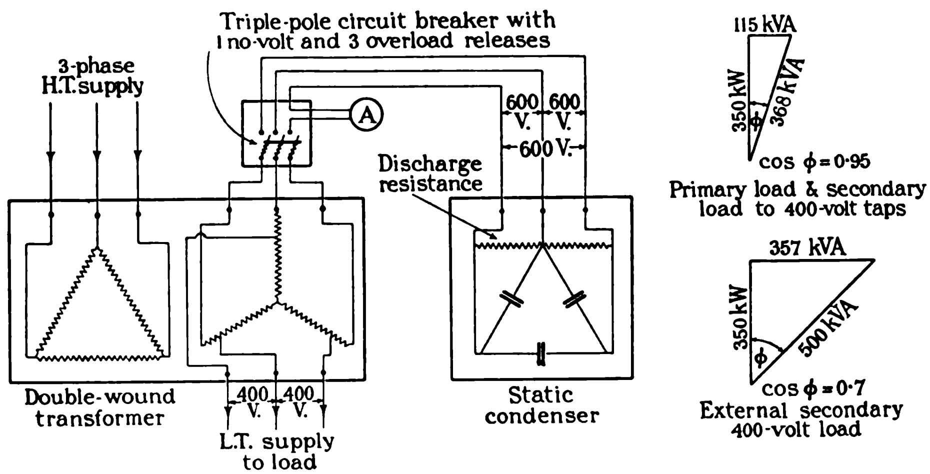

FIG. 2.

Load on primary = 368 kVA (resultant of two secondary loads).
External load on secondary at 400-volt tappings = 500 kVA.
Internal load on secondary between neutral and 400-volt tappings = 368 kVA (resultant of two secondary loads).
Load on 400–600 volt winding = 300 kVA (condenser load).

Where new step-down transformers are necessary, either as separate units or to bank with existing transformers, and in addition a condenser is required, it is possible to overwind the secondary of the transformer to give the most economical voltage for the condenser. By this means the auto-transformer is avoided and the whole scheme simplified, a considerable monetary saving being effected. The overwinding is a comparatively inexpensive addition to the transformer, and need of

low-tension busbars in each substation feeding industrial load, sufficient condenser capacity to neutralize the magnetization current of the whole bank. Condensers connected in this way would cut down the losses in transmission and reduce the wattless load on the alternators in the power station, and might in many cases enable one set to be shut down. In addition, an overall general improvement in the power factor of the system would be effected at load times, and a small but additional

benefit would be the increased, useful kVA output of the transformers in the substation. Such a scheme should not in any way interfere with the improvement of power factor by the individual consumer.

The static condenser is a very flexible apparatus and may be connected to the circuit in any convenient position on the load side of the meters. The condenser may be put across the main switchboard, the sub-distribution board, or the motors themselves, the further out on the load end of the feeder the better, provided the installation is correctly designed.

A great advantage of the static condenser is its mobility; it can be put down at the end of an overloaded circuit, but if later on this circuit is underloaded, it can be moved to another position as may be required.

When effecting improvement of a load comprising a number of squirrel-cage or slip-ring induction motors by means of a static condenser, full advantage can be taken of the diversity and the condenser be designed for the average conditions obtaining at the time of maximum load. Such a complete installation has a very high overall efficiency, comparatively low initial outlay, and small upkeep cost.

As to cost, the price per kVA of condenser capacity varies according to voltage, frequency, and climatic conditions, but, taking conditions in the United Kingdom and a three-phase 50-cycle supply at from 400 to 440 volts, the cost of equipments ranging in size from 100 to 300 kVA varies approximately from £3 5s. to £2 9s. per kVA, a good average figure being, say, £3 2s. per kVA.

Taking the average industrial load to be at 70 per cent power factor, it would be found that, when the power factor is improved to between 90 and 95 per cent, for every 2 kVA of condenser capacity the load is reduced approximately 1 kVA; therefore for every £6 4s. per kVA spent on condensers the demand is reduced 1 kVA. The capital expenditure on supply undertakings varies considerably, and a round figure of £40 to £50 per kVA may be taken. The installation of static condensers should therefore be a very sound and profitable investment for either consumer or supply undertaking.

Phase-Advancers.

The term "phase-advancer" is applied to apparatus built in the form of an a.c. exciter to improve the power factor of a slip-ring induction motor. Whereas in the auto-synchronous motor a d.c. exciter is used, which reduces the (synchronous) stalling torque to less than that of the equivalent induction motor, in the case of the a.c. exciter or phase-advancer the motor with which it works in conjunction retains all the characteristics of the induction motor.

The Kapp or oscillatory phase-advancer has been fully described in a previous paper, and reference has also been previously made to the rotary type of phase-advancer.

Fig. 3 shows a typical arrangement of a rotary phase-advancer, which may be driven either by a separate motor as shown, or from the main motor.

The characteristics of various kinds of phase-advancers of this type are shown in Fig. 4. Curve A is for a three-phase exciter with series characteristics, employing pure armature reaction and no commutating poles. Curve B is for an exciter similar to A, but provided in addition with stator excitation and commutating poles. Curve C is for a three-phase exciter with separate excitation and commutating poles.

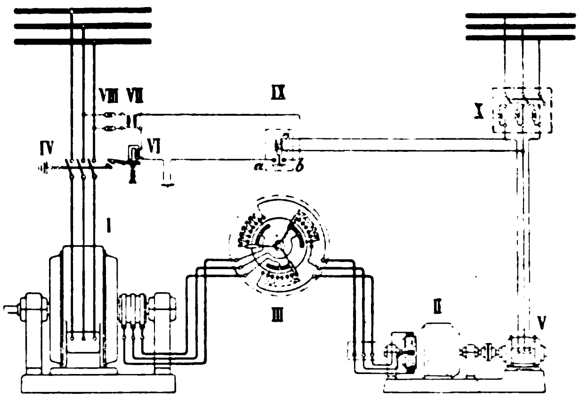

FIG. 3.—Diagram of connections of an induction motor with phase-advancer.

These a.c. exciters, which literally short-circuit the slip-rings of the induction motor and inject the necessary leading current into the rotor, may be built entirely without a stator, that is to say, as a simple d.c. armature revolved by a separate motor or other means. In other forms, a stator is provided with stator excitation devised by passing the rotor current in series through the stator windings.

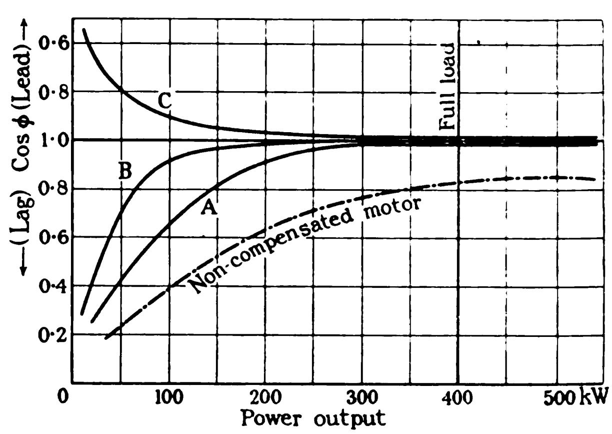

FIG. 4.—Range of compensation of various systems.

These types of phase-advancers have been used extensively on the Continent, but do not appear to have found much favour in this country.

Compensated Induction Motors.

A comparatively new type of induction motor capable of running at a high power factor at all loads is the so-called compensated induction motor. Among machines of this type is one built by the British Thomson-Houston Co., Ltd., and given the trade name of "No Lag." Characteristic curves are shown in Figs. 5 and 6 of a

$17\frac{1}{2}$ h.p. 1 000-r.p.m. 415-volt 50-cycle B.T.H. motor, but machines of this type can be built in sizes up to 200 or 300 h.p. for either two-phase or three-phase circuits up to 600 volts at any commercial frequency. The B.T.H. compensated motor has a commutator which enables the phase of the secondary to be controlled and, hence, the power factor to be corrected. The kVA handled by the commutator is very small, and so the commutator is of very small dimensions with simple and inexpensive brushgear. This compensated motor is as simple to operate as a plain induction motor, and standard starters as used for the slip-ring-type induction motor can usually be used. It is capable of giving as

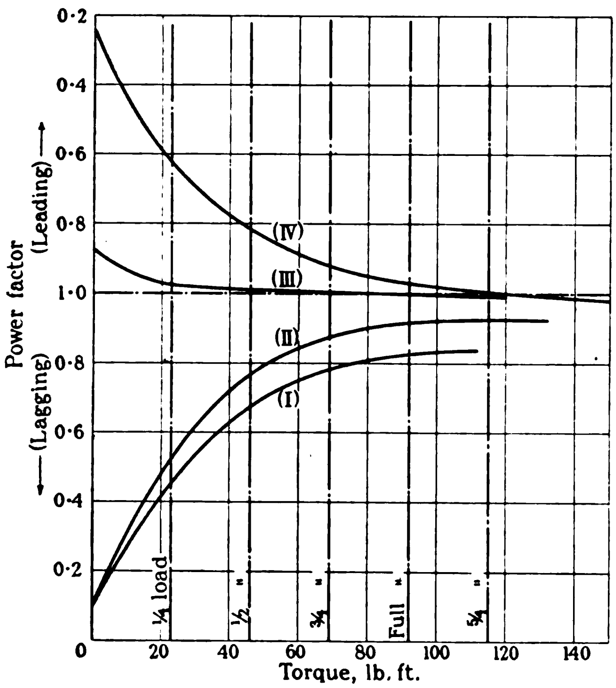

FIG. 5.—Power factor curves of compensated induction motor; $17\frac{1}{2}$ h.p., 1 000 r.p.m., 6 poles, 50 cycles.

(I) Power factor as induction motor.
(II) Power factor as compensated induction motor; min. compensation.
(III) Power factor as compensated induction motor; unity power factor.
(IV) Power factor as compensated induction motor; max. compensation.

large a torque at starting as the slip-ring induction motor.

Fig. 5 shows a typical power-factor curve of a $17\frac{1}{2}$ h.p. B.T.H. "No Lag" motor, and, as before stated, the power factor can be adjusted within the limits to give the figures shown by curve (III) or (IV). Usually the motor would be arranged to operate with characteristics such as those of (III), but, if desired, a leading power factor of 90 per cent at full load can be obtained, and in certain cases an even greater leading power factor.

Fig. 6 shows the speed and efficiency characteristics of this motor, from which it will be observed that they approximate to those of the plain induction motor. It will be noted that this is an asynchronous motor, so that for applications where a slight drop in speed with increasing load is necessary, or desirable, it is admirably suited. As no separate exciter or expensive switchgear is necessary this motor is less expensive than the auto-synchronous motor, and as it can be built in small sizes of the end-shield type it should have a wide field of application.

POWER-FACTOR TARIFFS IN FORCE IN GREAT BRITAIN.

A very large number of supply undertakings in Great Britain have adopted tariffs which provide a bonus for improved power factor, and it is reasonable to assume that the time is not very far distant when the great majority of undertakings supplying alternating current will adopt some form of power-factor tariff.

The power-factor tariffs in force in Great Britain may be divided into two main classes as follows:—

Class (*A*).—A two-part tariff incorporating a fixed charge per month, per quarter, or per annum, per kVA of maximum demand, with a running charge or flat rate per unit consumed.

Class (*B*).—A tariff which may be either of the two-part type based on the kW demand and the running charge per unit, or a one-part tariff based on units consumed only; in both cases, however, subject to a

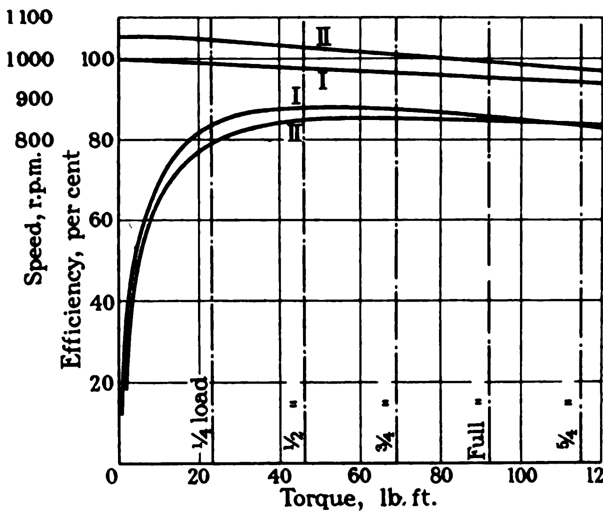

FIG. 6.—Efficiency and speed curves of compensated induction motor; $17\frac{1}{2}$ h.p., 1 000 r.p.m., 6 poles, 50 cycles.

percentage decrease or increase (bonus or penalty), depending upon the power factor of the load.

Typical power-factor tariffs in force in Great Britain to-day are as follows:—

Class (*A*). *kVA maximum demand.*

Tariff 1.—Straightforward kVA maximum-demand system. A fixed charge per kVA of maximum demand, which in the case of the majority of the undertakings may vary between the equivalent of £3 10s. and of £7 per kVA per annum. The general average appears to be about the equivalent of £5 per kVA per annum.

A number of supply undertakings adopt a quarterly, and in some cases a monthly, kVA demand charge about one-quarter or one-twelfth of the annual figures given above. A typical case of one large supply undertaking in the London area is the following:—

Fixed charge :—

	Per kVA per quarter
Demand to 50 kVA	£1 5s.
Demand over 50 up to 100 kVA ..	£1 3s.
Demand over 100 up to 200 kVA ..	£1 2s.
Exceeding 200 kVA	£1 1s.

In addition there is a sliding-scale running charge per unit metered, plus a coal clause.

Among supply undertakings adopting this form of tariff may be mentioned :—

The North Metropolitan Electric Power Supply Co., the South Metropolitan Electric Light and Power Co., Ltd., the Yorkshire Electric Power Co., the Wolverhampton Corporation, the Leeds Corporation, and many others.

Tariff 2.—In some cases an alternative tariff is quoted, and one typical instance, namely, that of the Bolton Corporation, is as follows :—

(*a*) *Fixed charge* :—

(1) Over 75 kW demand at 80 per cent power factor.

	Per kW per annum
Over 75 kW demand up to and including 100 kW	£3 18s.
For the next 100 kW demand or part thereof	£3 14s.
For the next 100 kW demand or part thereof	£3 12s.
For the next 100 kW demand or part thereof	£3 10s.
For every additional kW demand over and above 400 kW	£3 8s.

(2) Over 75 kVA demand.

	Per kVA per annum
Over 75 kVA up to and including 100 kVA ..	£3 3s.
For the next 100 kVA demand or part thereof	£3 0s.
For the next 100 kVA demand or part thereof	£2 18s.
For the next 100 kVA demand or part thereof	£2 16s.
For every additional kVA demand over 400 kVA	£2 14s.

(*b*) *Running charge* :—

Flat rate 0·34d. per kWh, based on coal at 10s. per ton, with an increase or decrease of 0·015d. per kWh per shilling per ton.

Tariff 3.—In this tariff the fixed charge is a kW charge, but varies with the average power factor of the load, and is the system adopted by one of the leading power companies in Scotland. It is as follows :—

(*a*) *Fixed charge* :—

	Per kW per annum
0 to 250 kW	£10
1 000 kW	£8
10 000 kW	£6

Intermediate demands *pro rata*.

(*b*) *Running charge* :—

0·4d. per kWh, flat rate, based on coal at 20s. per ton.

The above rate is based on a standard power factor of 80 per cent, and the fixed charges are increased or decreased inversely in proportion to the power factor, i.e. at 90 per cent power factor the fixed charge is eight-ninths of the basic figures ; at 60 per cent power factor it will be eight-sixths. The power factor is the average power factor obtained by the readings of a sine and cosine meter.

It will be noted that in all the foregoing tariffs the fixed charge only is affected by the power factor.

Class (B). Tariffs embodying power-factor bonus or penalty on total bill.

Tariff 4.—One important supply undertaking in this country has a two-part tariff with kW demand and unit charge, and the following bonus or penalty is incorporated in their rates :—

Per cent	Bonus or penalty per cent
Power factor 95 and over	− 8
Power factor 90–95	− 7
Power factor 85–90	− 5
Power factor 80–85	− 3
Power factor 75–80	− 1
Power factor 70–75	+ 1
Power factor 65–70	+ 4
Power factor 60–65	+ 7

It will be noted that in this case the basis is a power factor of 75 per cent.

Tariff 5.—The following tariff adopted by one supply undertaking is a variation of Tariff 4. The charges are as before on a kW and running-charge basis, but the power factor adjustment is as follows :—

Basic power factor: 80 per cent.

Bonus. For each 1 per cent improvement in power factor above 80 to 90 per cent the overall charges, that is, both running charges and unit charges, will be reduced by 1 per cent. For each 1 per cent from 90 to 95 per cent the charges will be reduced by ½ per cent.

Penalty. For each 1 per cent the power factor is below 80 per cent the charges will be increased by 1 per cent.

Tariff 6.—A further variation of Tariffs 4 and 5 is as follows :—

For a power factor maintained at 85 per cent and over, a discount of 5 per cent on the total bill.

For a power factor maintained at 90 per cent and over, a discount of 7½ per cent.

Some undertakings have adopted a similar tariff but with different discounts.

It will be seen that the tariffs divide themselves as indicated in the foregoing into two broad classes, those which give a bonus for reduction in kVA demand only and no bonus on the running charges, and those which give a bonus on the total bill, that is, the capital charges and running charges.

It may be safely said that the majority of supply undertakings are favouring the kVA demand tariff, owing, no doubt, chiefly to its simplicity, in that a satisfactory meter can be provided to record the kVA

demand and an explanation of the term "power factor" is not involved.

Those supply undertakings which charge, on kVA demand, the equivalent of about £5 per kVA can be shown to offer the necessary inducement to the consumer to improve the power factor by the various means available at the present time, and in the majority of cases quite a good return on the capital expended in power-factor-improving devices can be shown. For this reason, where this type of tariff has been adopted it will be found that the great majority of the consumers on such systems have set about improving their power factors, with a resultant overall economy and a relatively low average price per unit for the general industrial user of electric power.

In the case of Class (B) tariffs, several difficulties are met with in getting the consumer to put in plant for the improvement of power factor, the chief of which are as follows :—

(1) In the case of an overall bonus or penalty on the power-factor supply bill it follows that a consumer running with a relatively high load factor has a large supply bill compared with the low-load-factor consumer, both running with the same maximum demand and power factor. To improve the power factor would require the same condenser capacity in each case, but the consumer with high load factor would get a proportionately greater saving than the one with low, and the inequity of this type of power-factor tariff is very evident.

(2) In those cases where a bonus is given for improvement of power factor above definite limits, such as 85 and 90 per cent, the objections referred to in (1) above also apply, but in addition there is another serious objection, and that is that the consumer with, say, 83 per cent power factor can, with a comparatively small condenser, correct to either 85 or 90 per cent power factor and obtain the bonus, but the consumer with a very low power factor, say 50 per cent, would have to correct right up the scale to, say, 84 per cent without getting a penny piece by way of bonus, in other words the low-power-factor consumer would have to put in such large condenser capacity that in the majority of cases it would not pay.

(3) This type of tariff involves an explanation of the term "power factor," and it will be generally agreed that the less explanation of power factor one has to give to the consumer the better.

Metering.

The two chief methods of metering adopted in Great Britain may be illustrated by the two vector diagrams shown in Fig. 7. Meter A, in both cases, is a cosine meter or ordinary kWh meter, whereas meter B integrates the kVA-hours and, when fitted with a maximum-demand indicator, gives the true kVA demand. Meter C is the so-called sine meter, and integrates the wattless-component kVA-hours. Such an instrument is not usually fitted with a demand attachment.

(A) *For kVA demand tariff.*—For small loads the thermal demand-indicator is generally adopted, this instrument being reasonably accurate, and is usually a secondary instrument working across a current transformer. There may, of course, be three instruments for a three-phase load.

The new Hill-Shotter voltage-compensated kVA demand indicator built by Messrs. Aron Electricity Meter, Ltd., is an interesting development; whilst the instrument is comparatively costly, its introduction is in the majority of cases warranted for larger loads, where extreme accuracy is of such importance.

The foregoing instruments are purely for the purpose of arriving at the kVA maximum demand, and it will be appreciated that the thermal demand-indicator is governed by the current only and is therefore calibrated only for the declared pressure, whereas the voltage-compensated Hill-Shotter type of meter gives an accurate reading in kVA demand. In both cases there would, in addition, be the usual meter registering B.O.T. units.

The combination of these meters provides a simple equipment which can be read by any consumer and does

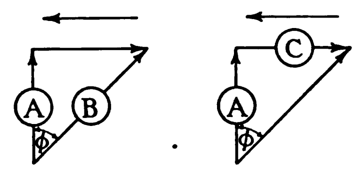

Fig. 7.

not involve any intricate mathematical calculations to arrive at the power factor.

(B) *Tariffs embodying power-factor bonus or penalty on total bill.*—In this case it is usual to employ the cosine or unit meter in conjunction with a sine meter as (C) above. The sine meter is quite a simple type of instrument and is constructed to record accurately the apparent kVA-hours of the wattless component of the load. Such instruments may be either single-phase, two-phase, three-phase or three-phase 4-wire, and would in the usual way be secondary instruments working in series with the unit meter off the current transformer. At the end of the period the integrations of the unit meter and the wattless-component meter are noted, and from the ratio of these two can easily be determined the so-called average power factor of the load. Taking as an instance the following :—

Unit meter recording	..	1 000 kWh
Sine meter recording	..	882 apparent kWh

$$\tan\phi = \frac{882}{1\,000} = 0 \cdot 822$$

$$\cos\phi = 0 \cdot 75 = \text{power factor}$$

The sine meter can be fitted with a ratchet mechanism to prevent its reversal when the power factor is leading or if static condensers only are left on circuit with the load off. In the case of one large power company it is customary not to fit such ratchets but to allow the watt-

less component meters to be reversed. It may here be pointed out that consumers are allowed to reverse the sine meter in order to encourage the connection of static condensers and the like during no-load hours, to neutralize the heavy lagging wattless component of the load on the system due to the magnetization of idle transformers, etc.

A similar average-power-factor result is obtained in many cases by the two single-phase kWh meter method

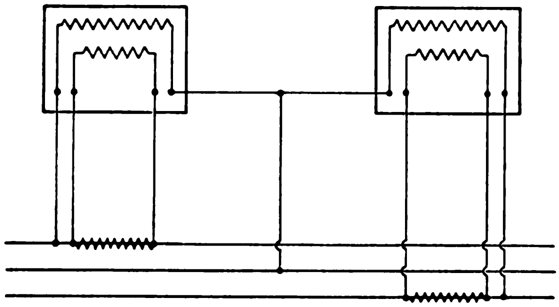

FIG. 8.

in which the instruments are connected up as shown in Fig. 8. The readings of the meters give the following :—

$$\tan \phi = \frac{(W_1 - W_2)}{(W_1 + W_2)}\sqrt{3}$$

W_1 being the reading of the one meter and W_2 that of the other. From the formula it is possible to ascertain the angle of lag, ϕ, and thus the power factor.

It is suggested that neither of these two systems would be understood by the great majority of industrial users of a.c. power.

Either of the foregoing systems of metering for average power factor may be considered to be sufficiently accurate for the purpose of arriving at the bonus or penalty in the case of those tariffs giving a percentage reduction or increase on the total bill, but to apply this system of metering in a case where the power factor is obtained for the purpose of determining the ratio of kW demand to the kVA demand is not strictly equitable, as the average power factor must of necessity be lower than the power factor at the time of maximum load. As the kW charge would be that occurring at maximum load it would mean that this charge would be increased in accordance with the power factor based on average conditions, whereas it should be the power factor at the time of peak load.

Other methods, which may be regarded as not very satisfactory, of arriving at power factor are the periodical spot test and the use of an indicating power-factor meter.

A spot test is obviously a very insecure basis to work upon, as conditions may vary from day to day, or from month to month, and it is impossible to be continually spot-testing.

The power-factor indicator has somewhat the same disadvantages, as the meter reader cannot be continually visiting the consumer to ascertain the power factor under varying conditions; also the commercial power-factor indicator of to-day is hardly an instrument in which any very great reliance as to accuracy can be put.

The correction of low power factor is one of the few important economies remaining to be effected, and there seems little doubt that, converted into £ s. d., low power factor is resulting in enormous losses to supply undertakings, not only as regards capital charges but also running charges, and the losses are being borne by the industrial user of a.c. power. Admittedly, the consumer is responsible for the power factor of the load, but it behoves every undertaking supplying a.c. power to make it worth while for the consumer to raise his power factor and thereby effect a general reduction in the electricity charges, thus ultimately benefiting industry in general.

DISCUSSION BEFORE THE INSTITUTION, 4 FEBRUARY, 1926.

Mr. R. O. Kapp: This question of power factor has received a good deal of attention during the past few years. A great many papers have been read and discussions have taken place on the subject, and one might think the question had been exhausted, yet here we have two papers each treating one aspect of the matter and each containing something new and important. Mr. Clark's paper deals very largely with the question of tariffs, and that is a most important and complicated problem. Broadly speaking, there are two aspects from which the problem of tariff-making can be studied. I propose to call one aspect the accountant's point of view. It is that of finding exactly what a given consumer or a given class of consumers costs, and devising a tariff so that precisely that amount, plus a reasonable profit, shall be obtained. That, however, is not the whole story of tariff-making, as everyone knows who has to deal with the subject. There is another aspect, which may be called the salesman's. The salesman has to consider such aspects of the matter as cannot be expressed strictly in terms of pounds, shillings and pence. He has also to consider—and this is a very important point—the mentality of the consumer. Every tariff is based as nearly as possible on the accountant's point of view, but also takes the salesman's into account. I think perhaps that Mr. Clark's paper does not give as much emphasis to this latter as the practical tariff-maker would have to devote to it. I should like to mention, therefore, two points from the salesman's point of view which have to be considered in connection with power factor. One of them, which Mr. Clark mentions, though without a great deal of emphasis, is the question of voltage regulation. A bad power factor means bad regulation. This point is important on installations containing a number of transformers, and more particularly on any system having a considerable mileage of overhead line work at a low voltage. In order to keep within any given limits of voltage regulation, the number of kVA-miles transmitted by any particular line must be restricted. Now, at a

power factor of 0·8 the kW-miles that can be transmitted for a given voltage-drop are, broadly speaking, about half what can be transmitted at unity power factor. That is quite an important point. In a footnote at the end of that section of Mr. Clark's paper which deals with the charge for wattless component the author gives an illustration of two consumers, and from other points of view he shows that the technical benefit to the supply undertaking would be identical with certain adjustments of power factor, but he omits to say that one consumer would give more benefit to the undertaking than the other, from the point of view of voltage regulation. It does not mean that in order to make up for the inferior regulation on the lower power factor one must increase the cross-section of the copper conductor. That is only a partial help. If a line is approaching the limits of permissible loading from the point of view of voltage-drop, it means that either boosters or another line must be installed. Probably, on the ground of expense, one would install boosters. Not only the prime cost but the losses of such regulators are important, as appreciable iron losses are going on all the while. Bad power factor, therefore, adds something to the cost over and above what the accountant's method, as mentioned in this paper, would take account of. There is one remark in the early part of Mr. Clark's paper which I should like particularly to stress. He says: "But the fact that supply undertakings working with a tariff of this kind are not fully satisfied with their station power factor, however low it may be, is surely evidence that this tariff departs seriously from the ideal." That, of course, is true. The ideal tariff is not only an accountant's but also largely a salesman's tariff, and this must take account of mentality, and by mentality, to speak crudely, I mean the ignorance of the consumer. There are two ways of meeting this particular point of the ignorance of a consumer with regard to power factor. One is to educate him; but that seems rather a hopeless task. If the tariff is devised on such lines that a consumer receives a bonus for an improved power factor it may be possible to educate him. If, however, the tariff is on the lines that the consumer pays a penalty for a bad power factor, his mind will work slowly and he will have great difficulty in understanding what power factor means. Another way of dealing with the problem is to devise such a tariff that the consumer need not know anything about the power factor at all; and from this point of view it seems to me that a two-part tariff, composed of a kVA maximum demand, plus a unit charge, is probably most likely to meet the case. The consumer does not really know the difference between kW and kVA. He can think of one or the other in much the same terms, and if he is in the habit of paying for kVA maximum demand and is told that by putting in a power-factor-improving device he will reduce his current bill, he will not need to worry about power factor and all these troublesome mathematical problems. He will have a vague idea that he is being instructed how to improve the efficiency of his motor, and he will think that this power factor device will reduce his losses. He will not understand it, but he will do the right thing to the benefit both of himself and of the supply undertaking. There is one other point with regard to the accountant's tariff which I should like to mention. Mr. Clark suggests a three-part tariff which, however, eventually boils down, from the consumer's point of view, to a two-part tariff after all, because he has only two meters. It is assuming that the two-part tariff is an accountant's one, i.e. that it is calculated on a basis of accurate costing and that the power factor adjustment that would be made by this very ingenious biased meter would introduce a further refinement into the costing. I am not at all sure that the average two-part tariff is completely and wholly an accountant's tariff. I believe that the figure given in the paper, for instance, which is a very fair average figure of £5 per kVA maximum demand, plus 0·5d. per unit, is not justifiable on the costing basis only. On this basis the demand part of it would have to be higher and the unit charge lower, because in making up most two-part tariffs quite a lot of factors are attributed to the running costs which should, more strictly speaking, be allocated to the fixed charges. I believe that nearly the whole of the wages in a power station is a fixed charge. Quite a large part of the coal bill is a fixed charge. Radiation losses through steam pipes, and losses in accessories, are fixed charges. Even the coal-handling charges are largely fixed, because a station has to have a staff for that purpose whether they are working full time or not. Too close an approximation to strict costing, therefore, seems hardly practicable. In the early part of the paper the author says: ". . . the diversity factor of wattless component is in general much lower than that of energy component." I should almost think that it would be the other way round, and that there would be less variation amongst the energy components than amongst the wattless components. It may be a question of the way this term "diversity factor" is taken. It is generally defined as a figure greater than unity, but possibly in his paper the author took it as meaning a figure less than unity.

I can confirm what Mr. Dorey says as to the risk of resonance being negligible in condenser installations. I was particularly interested in his development of "pole-type condensers." The importance of overhead lines, particularly of rather low voltage, makes this pole type very useful. There appears to be a big future for something of the sort. There is a tendency for more rural electrification, and I do not see how that will be possible on a commercial scale unless we have some cheap means of improving the power factor of the low-voltage overhead lines which will no doubt be used. There is one type of consumer who is very troublesome to an industrial undertaking, and that is the user of a.c. fans. These have a particularly bad power factor. Consumers in tropical countries are usually very scattered over a large residential area and there is generally a considerable distance of overhead line, so that the question of power factor is quite important. I should like to ask Mr. Dorey whether he thinks that an individual condenser to improve the power factor of either a single house or of each fan is a practicable proposition. I had occasion to estimate that some years ago, before condensers had reached their present stage, and I found then that the first cost was such that the installa-

tion of such condensers would not be commercial. One point which Mr. Dorey does not mention, but which I think is quite important with regard to these static condensers coupled with transformers, is that an installation of this kind is generally put in well in advance of the loading. One puts in one's transformer and condenser installation to meet the load expected in three or four years' time, and, to start with, there is very little. However, the condensers have to be of the full kVA capacity of the final installation, and, as Mr. Dorey knows (because he and I collaborated on a scheme of that sort), what has been done has been to tap the transformers so that the voltage by which the condensers were supplied could be increased year by year as needed, this increase in the voltage being equivalent to an increase in the injected leading kVA given by the condensers.

Mr. S. H. Hart: The frequent articles appearing in the technical Press and the discussions which have taken place, both in this country and abroad, as to the best methods of dealing with the difficulties arising out of low power factor, are a clear indication of the importance, to both supplier and consumer, of the subject now under discussion. There is no doubt that this question is steadily becoming more serious and is keeping the cost of electric supply considerably higher than it would be with good power factor. The problem of low power factor may be viewed from three different points, namely: (1) The avoidance of low power factor by a judicious choice of apparatus; (2) the use of special apparatus, the sole aim of which is to improve the power factor; and (3) the correct method of charging consumers who use a large wattless component. With regard to the avoidance of lower power factor, it is universally agreed that the main difficulty is the induction motor and all small machines of this type. In the case of the induction motor, the design plays an important part in determining the power factor at which it will work, the main factors being: (1) Maximum torque at full load; (2) speed; (3) type of rotor (squirrel-cage or slip-ring); and (4) output margin. When a motor is installed with a greater pull-out torque than is needed, the result is a considerable reduction in power factor at the normal working load. The speed of an induction motor plays an important part in determining the power factor; the lower the speed the lower the power factor, and hence it is advisable to run the motor at as high a speed as possible. The squirrel-cage motor has a much lower leakage coefficient than the slip-ring motor and hence has a higher power factor, and for this reason it is advisable to install squirrel-cage induction motors. Another important factor causing a low power factor is the installation of motors of which the normal output is two or three times the service requirements; it is obvious that the remedy for this is to use motors of which the capacity is determined by the usual load they have to carry and not by the possible maximum.

Mr. Dorey states that the rotary condenser compares very unfavourably with other forms of power-factor-improving apparatus, such as static condensers, but in the case of a low supply frequency it is cheaper to install rotary condensers than static condensers, as the capacity required per kVA of the latter varies inversely with the frequency at which it operates, whereas in the case of rotary condensers the frequency determines the number of poles that must be used for a given speed, and the effect of having a low supply frequency (e.g. 25 cycles instead of 50) upon the cost per kVA is not very marked. At the present time there are divided opinions as to whether the supply undertaking or the consumer should be responsible for the improvement of power factor. In the case of large consumers the adoption of a scale of charges sufficiently favourable to the maintenance of a high power factor will result in the consumers recognizing that the use of power-factor-correcting apparatus will prove to be a sound financial investment, especially if, as in the case of phase-advancers applied to the rotor circuits of induction motors, other improvements, such as increased breaking-down or "stalling" torque, reduction in stator current and hence increased continuous rating, are obtained. With small consumers it is probable that both the consumer and supply undertaking will work in conjunction for the improvement of low power factor. In any case the undertaking should be ready to supply the necessary machinery for the improvement should the consumer be unwilling to do so. The best way in which the undertaking can help is by having a favourable tariff in operation. It has been suggested that new power consumers should be advised to install apparatus to correct the power factor, and if they take a leading power factor a rebate should be allowed on their account. It seems to me that the most suitable tariff is that based on the kVA maximum-demand system with a flat rate per unit consumed.

Mr. W. B. Woodhouse: There is no doubt that idle current does involve extra cost to the supply undertaking, and consequently the consumer must pay for it. The commercial question is: What is the best way to make the consumer pay for idle current? That, I think, rather turns on the answer to the question: Is it more easy and economical for the undertaking to correct for power factor, or for the consumer to do so? Generally speaking, I think it will be agreed that the small consumer cannot be troubled with a matter of this kind. If his installation has a power factor that is less than unity, then the supply undertaking must do the correction. With the large consumer, however, the position is different. A great many large consumers can, by attention to their installation, or by putting in some means of correcting for idle current, increase the power factor to something approaching unity, and therefore the tariff in which the charge is based on kVA is a good one, because it affords a direct inducement to them to improve the power factor. In Yorkshire we have charged on the kVA basis plus a unit charge since we started the supply in 1904, and the effect has been striking, because in many cases the consumer has realized the very large saving that can be made. I know of one case where the saving was something like £2 000 a year. In another case the consumer saved £6 000 a year on his energy bill—a very important consideration. The method of charging for idle current brings up another point: Is the consumer to be charged with the idle current at the time of maximum demand

—which, after all, is the time when the plant and cables are most heavily loaded—or is he to be charged on the basis of the idle ampere-hours ? I think that, generally speaking, the method of charging on the basis of idle current at the time of maximum demand is more in accordance with the actual cost to the supply undertaking. Its drawback is that there is at present no quite suitable meter for ascertaining this charge. The thermal indicator, though it is a very excellent instrument, and though it agrees very closely with the heating characteristic of the plant and cables, is yet independent of voltage, and if the voltage is not kept constant the indication of kVA is not very accurate. Where a charge is made for maximum demand in kW we have in use a very accurate instrument, the Merz attachment to the ordinary watt-hour meter, accurately giving maximum demand over a predetermined interval of time. What is needed is a similar instrument to give kVA in the same way. The method of summing idle ampere-hours or volt-ampere-hours is, I think, open to some objection, in that the costs of the undertaking are not in proportion to that total; they are more nearly in proportion to the idle current at the time of maximum load.

Mr. R. A. Chattock: It seems to me that the question of correcting for power factor depends very largely on the nature of the load that the supply undertaking is called upon to give. Comparing an undertaking such as mine in Birmingham, where the majority of the supply is given by direct current, with an undertaking such as Mr. Woodhouse is in charge of, where practically the whole of the supply is alternating current, my particular undertaking is placed in a much more favourable position with regard to power factor than his, because we have installed in the district a considerable number of rotary-converter substations which can be used for correcting the power factor on the main trunk lines that supply them. The distributing cables to the a.c. consumers which run from those substations are subsidiary lines and are practically never loaded to their full capacity. Whilst it is very important to keep the trunk lines well loaded because they are the main carriers and are the most expensive lines we have to put in, it is necessary to see that there is a minimum wattless current passing through them, so that by arranging the rotary converters in these substations to run with a leading power factor one can correct to a very large extent the most important part of the network. In that way it is not so attractive to us to get the consumers to correct on their own premises as it is to an undertaking such as Mr. Woodhouse has described. Whilst it is true that we do offer a discount for a certain percentage of power factor, it has not really attracted the consumers in Birmingham to any great extent. We have some large consumers who correct, but at the present time it would not be to our interest to increase the discount in order to produce a greater correction than there is at present. The time may come, of course, when the a.c. load becomes very much greater than the d.c. load, but I wish to point out that it does not follow that the problem of one undertaking is the same as that of another undertaking.

Mr. Dorey describes the installation of condensers in rural districts. I have had some experience with a condenser on the premises of a large consumer in connection with power load, and in that particular case we found that when the condenser was left on at night-time when the works were shut down, as was done on one or two occasions, it gave a serious leading power factor to the system and upset our regulation in the stations when there was only a small percentage of load going out. We had to be very careful not to allow the condenser to be left on when that consumer was not using his motors. If in a rural district we have a number of condensers left on the line all night when there is practically no load, I am afraid we shall get very considerable leading power factor, and the regulation may be very difficult to arrange for. However, that will, of course, have to be gone into when the thing is developed, but I should like to know whether Mr. Dorey can tell us anything about the experience in New Zealand, where I believe condensers are being used in rural districts.

Mr. L. W. Migotti: In Buenos Ayres we supply roughly 500 million, in Rosario some 60 to 70 million, and in La Plata some 20 million kWh. In those three undertakings I do not think we have one consumer of any description who is charged on a kVA basis, whether this be assessed by an integrating or a demand meter. The only people we have met who would take the slightest interest in this sort of thing were some of the representatives of the British-owned railways. We are, however, in the fortunate position of being able to correct our power factor, owing to a large tramway load and to districts we supply with direct current. The power factor over all generating stations is certainly not lower than 0·93 during the day and 0·97 during the peak load, which of course is the most important time. The problem of a low power factor, therefore, does not cause us much anxiety at present, although it may do in time. Our method is to make a complete study of the tariff question each year, and to put down against each class of client the minimum rate we expect to receive in each case, and on these data we base our arguments to our clients. I think that we should do much better, in general, if we took charge of the power factor question and, if we found a consumer with a particularly low power factor, to include that in his tariff. He would then not know whether he was paying on a kVA or any other basis.

The point Mr. Clark has made in connection with the interchange of current between two undertakings, is certainly very important, because that opens up quite a different view of the matter. There is undoubtedly room for discussion of tariff questions between two undertakings supplying one another with energy. As far as the ordinary client is concerned I think we should find it much better to take a commercial view of the problem and either correct the power factor ourselves or ask those who have designed automatic substations to produce automatic power-factor-correcting plant so that the question of condensers or other apparatus left on the line during the time of no load will disappear. I feel that consumers should not be worried with questions of power factor unless they are fully able to understand and discuss this matter.

Mr. A. H. Bennett: I think that Mr. Clark in putting

forward his three-part tariff is trying to prove on paper something which is not really necessary; in practice, as Mr. Woodhouse says, a two-part tariff is all that is required. We find very little difficulty in getting consumers to accept this two-part tariff. We do not try to explain to them the full effects of power factor, in spite of the help we have had from one of the authors on methods of explaining it. What we do is to show them in pounds, shillings and pence exactly what it means to them. A very simple illustration will bring it home; on the average 50- to 200-kVA installation, working with Mr. Dorey's figures, it can easily be seen that a consumer can, if he has a power factor in the neighbourhood of 0·7 and wishes to improve it to 0·9, save the cost of new condensers in approximately 18 months. In other words, we find on the North Metropolitan Electric Power Supply's system that if we want a consumer to put in a condenser we have only to offer him that condenser on hire-purchase terms and he will actually save enough on his quarterly bills to pay for the apparatus. After two years he is entirely in pocket. On page 625 Mr. Clark points out that our aim is to sell electricity, not energy, but I am afraid I do not agree with him. The public wants energy and it is up to us to supply energy produced from coal or in other ways in the form which is most suitable and economical for the use of the public. Mr. Clark says we are not satisfied with the working tariff. That is certainly the case, but I think it is only a matter of a very few years now, using examples such as I have quoted on the hire-purchase basis, before we shall convince all consumers that it is worth while for them to put in the necessary apparatus to improve power factor to something over 0·9. We have very largely done so already, and I think Mr. Woodhouse has also. One of our consumers has a 1 200-h.p. rolling motor the power factor of which, corrected by static condensers, is practically unity from one-quarter load, which is the light running load of the mill, to full load.

Mr. P. M. Baker: I feel that a tariff which requires the consumer to understand the meaning of power factor is useless. I have never yet met a consumer who understood what I meant by power factor. I think, therefore, that we must aim at something which does not require him to grasp that somewhat abstract idea, and for that purpose I think the kVA charge, plus a unit charge, is better than most other forms of tariff. It seems to meet the case more or less satisfactorily and it does not involve any very serious amount of explanation. It seems hopeless to try to make an ordinary consumer understand that the product of volts and amperes does not always represent power.

Mr. J. H. Johnson: It seems to be difficult to get unanimous agreement on the question of charging on a kW or kVA basis. There are many consumers who are charged on a kW basis and who are a source of great trouble to supply undertakings. Some of these consumers have a power factor as low as 0·4. Naturally it is to be expected that any supply undertaking would desire to raise the power factor of such a consumer or on that particular feeder, to make the consumer pay extra charges. On investigating a number of these cases it was found that the low power factor was due to the use of a number of small induction motors which were working at about one-third load. I mention this particular point as in the early part of Mr. Dorey's paper he refers to the use of ball and roller bearings for induction motors and points out very definitely that a reduction of the air-gap will increase the power factor. That is quite true, but there are limitations, because in these days of keen competition one has to remember that there is the workmanship to be considered. The increased diameter of shaft and the rings inside the bearing are matters for consideration, as they affect reliability. Mr. Dorey refers to static condensers; these certainly serve a very useful purpose, but they have their limitations. The power factor cannot be varied with changing load, as in the case of a rotary condenser or a synchronous motor. The first cost also must be considered, whilst above all there is what I may call the commercial value of the motor when it is no longer used for the duty for which it was first required. A comparison between a static condenser and an auto-synchronous motor which will give mechanical power as well as leading or lagging power, as may be required by load conditions, will show that the latter is a more serviceable and commercial proposition as compared with the former. Mr. Dorey refers to the Clyde Valley Electrical Power Co. and speaks about leaving the static condensers in circuit all night and during the week-ends, but I believe in that particular instance there are three generating stations, and the trouble was not in the actual load on the supply, but on light loads and during week-ends. It was found that the power factor was so low that if it was raised by installing static condensers on consumers' premises and left in circuit, it was possible to shut down the power station on that particular district. This cannot, however, be put forward as an advantage which may be obtained generally. It has been pointed out by various speakers in the discussion that there is a certain disadvantage, especially in rural districts, in having at the end of a feeder a consumer with a varying load. With a synchronous motor the power factor could be adjusted by the excitation, this not being possible commercially with a static condenser. Recently I had occasion to supply an auto-synchronous motor with a lagging power factor of 0·45, simply to compensate the leading power factor on that particular transmission system. Reference has been made to phase-advancers and to the compensated induction motor; the latter has limitations, in that it is inadvisable to have a supply voltage higher than about 600. It is only commercially possible at present in sizes from 5 to 100 h.p.; above that size it compares unfavourably with an asynchronous-synchronous, or auto-synchronous motor. In the Crompton auto-synchronous motor, with a two-phase induced winding, the motor can be built for high tension or extra-high tension, and the neutral of the induced winding earthed. In addition, provided the exciter is large enough, it is possible to arrange for the same kVA capacity to be absorbed either with a leading or lagging power factor. To the power user in ordinary industrial concerns this is a point of considerable importance if charged on a kVA basis. In London there are two auto-synchronous motors now running, each equivalent

to 2 800 h.p. at 360 r.p.m. with a 0·9 leading power factor and operated by unskilled labour. The use of condensers in this particular installation would have been uncommercial. Auto-synchronous motors are now applied to the driving of every form of industrial machinery of the heaviest class and with a starting torque of 2 to 3 times that of full load, synchronizing automatically.

Mr. H. S. Ellis: Has Mr. Dorey considered the merits of the Maxigraph kVA demand indicator, which I believe is made by Messrs. Landis and Gyr and which I have used quite successfully as an alternative to the other makes of kVA demand indicators referred to in the paper? This is an instrument which I think can be depended on to register kVA correctly, although perhaps the range of power factor through which the instrument is correct may not be so wide as the range of other instruments. However, it has one advantage which was not apparent in other instruments which we carefully considered in one particular case I have in mind. A supply of electricity in bulk is obtained from a feeder which runs through the bulk-supply area, and it is necessary to have a set of meters at each end of that area, the reason being that the feeder is continued beyond the bulk-supply area to a district where other supplies are afforded. In this case it was necessary to synchronize the meters at each end of the feeder in order to ascertain the actual demand of the bulk supply at any particular time during any particular period, which meant that the kVA indicators had to be of the recording type and such as could be synchronized. This quality is found in the Maxigraph indicator, and as the demand is recorded at the end of any predetermined period, say 20, 30 or 60 minutes, or whatever the period required may be, it is a very simple matter to bring the two charts together and subtract the readings of one from the readings of the other. I am not aware that there is any instrument other than the Maxigraph which would satisfy this condition.

[Mr. Dorey's reply to this discussion will be found on page 652. Mr. Clark's reply will be published later.]

North-Western Centre, at Manchester, 2 February, 1926.

Mr. J. Frith: We should no longer expect the supply undertakings to give us wattless current free, but I do wish to make a strong protest against any more complicated tariffs. I know, from experience, that the complication and treachery (in appearance at any rate) of these tariffs does militate against the use of electricity. Consumers do not like them because they do not understand them. In metering for power factor, why not specialize on the 2-wattmeter method? It gives the consumer some idea of what is happening. He is shown two ordinary unit meters and is told that his total consumption is the sum of the reading of these two meters, that the greater the difference between the two the lower his power factor is and that when the power factor is unity the two meters will read alike. The papers might with advantage have dealt at greater length with the difference in actual use between the synchronous motor and the static condenser for correcting power factor. One or other of those is, I think, the method which will be adopted. The high-power-factor motors mentioned, besides costing more and being less efficient, all have commutators which are much worse than those of the old d.c. motors. I advocate the use of large squirrel-cage induction motors; a supply undertaking need no longer object to these. There is no doubt that static condensers are more efficient than synchronous motors. (In parenthesis I wish to protest against Mr. Clark's use of the term "efficiency"; kW loss expressed in terms of kVA input is not efficiency.) The synchronous motor is, of course, the easier to adjust, for which purpose a power factor indicator showing the corrected power factor should be placed near to it. With a static condenser no such control is possible unless it is made in smaller units switched on and off separately; this, of course, adds greatly to the expense and trouble. I should like to know if the supply undertakings are content with the main condenser being switched on and off so as to keep the readings of the two watt-hour meters approximately the same. This seems to be the only way, especially if the consumer is given no credit for leading power factor—which very often he is not. With regard to the question of resonance it seems to me that when the power factor is unity, $L\omega = 1/(k\omega)$, which is exactly the condition for resonance. What other resonance is there in the circuit? I wish to protest against the compulsory use of auto-transformers. When we wish for a motor to work on a 400- or 440-volt supply we are not told by the makers that they only make a 600-volt motor and that we have to use an auto-transformer with it to get the right voltage. I have seen these condensers being made, paper being used, and have been told that one thickness of paper is not enough for 400 volts and that two thicknesses will be sufficient for 600 volts, and I am still not convinced.

Mr. L. Romero: I am rather surprised that Mr. Clark advocates a tariff based on the kVA of maximum demand. This means that the consumer is charged just the same for kVA as he is for kW and it seems to me to be altogether wrong. If it really costs as much to supply kVA as it does to supply kW why have not the supply undertakings improved the power factor themselves; they would have effected a very large saving in doing so. In my opinion the financial effect of low power factor is considerably exaggerated. I have just worked out, on the tariff that the author gives, a concrete case—a power consumer with a maximum demand of 100 kW at 0·5 power factor, using 200 000 units per annum. The annual cost to him for power is £1 447. He then installs a condenser at a cost of £375 which raises his power factor to 0·9 and thus reduces his annual bill for power to £950. It is perfectly obvious that the saving of £497 on his annual bill will not be reflected in the saving made by the supply undertaking; this will be nothing near that amount. The author says that item (*c*) of his tariff is not quite ideal. I should go further and say that it is distinctly inequitable. It is apparently based

on the idea that the whole capital cost of the undertaking varies with the kVA load, but of course it does not do this at all. The principal items which do not vary with power factor, or, if they do vary it is only to a very small extent, are, in the power station, land, buildings, coal- and ash-handling plant, boiler plant, turbine house plant except generators, and generator main switchgear. At the consumer's end of the line where the supply is at extra-high tension, the cost of the meter and e.h.t. switchgear on the consumer's premises, and of the e.h.t. service and main supplying individual consumers, will not be affected by power factor except in the case of very large consumers.

Mr. Dorey says that the system of varying the whole amount of a consumer's bill according to power factor is very inequitable as between the consumer with a high load factor and the consumer with a normal load factor. There is a certain small inequity, but it is very slight compared with the inequity introduced by the kVA system of charging, under which the low-power-factor consumer has to subsidize the high-power-factor consumer. This system of charging appears to be based on the assumption that the capital costs on the whole undertaking vary inversely as the power factor, but probably in a municipal undertaking only about 30 per cent of the total capital cost of the undertaking varies with power factor. I am quite convinced that it is beyond the wit of man to devise a practical tariff which will give due weight to all the factors affecting the cost of supply, and it becomes rather a question of devising a tariff which will combine simplicity with the minimum of unfairness. The four factors which have to be taken into consideration are the maximum demand, the load factor, the power factor, and the diversity factor. Unless all these factors are allowed for, a perfectly fair tariff will not be devised. We have in Salford a tariff which endeavours to allow fairly for the first three factors, but diversity factor is the most difficult of all and is generally left alone. In the table on page 631 should not the peak load of consumer B be 1 250 kVA and the cost, at £5 per kVA, £6 250?

Mr. D. B. Hoseason: The general extension of the Hopkinson tariff on the lines suggested by Mr. Clark is undoubtedly the correct way of attacking the question of wattless kVA, but I doubt whether the suggestion to meter the actual wattless kVA-hours is sound. The running cost of supplying the wattless kVA-hours is really only a matter of that due to the extra copper loss in the transmission line and in the generating station. Taking a typical case, a consumer with a power factor of 0·9 who proceeds to improve it to 0·95 reduces the transmission loss for his particular quantity of power by about 10 per cent; but actually he reduces by 33 per cent the wattless kVA-hours which Mr. Clark proposes to meter. The quantity which it is proposed to meter in the arrangement described in the paper is not proportional to the running cost of supplying the lagging kVA. One method of dealing with this question of wattless kVA is to charge for it on some system of rebates or penalties on the power bill based on the square of the consumer's power factor and the approximate transmission losses. As a matter of fact, a good many of the supply undertakings in this country already do something of this description. The maximum-demand charge to cover the interest and depreciation on plant has been extended by the author from the original Hopkinson suggestion to a charge based upon the kVA of maximum demand. This has been criticized on the grounds that the kVA maximum demand is not a true indication of the capital cost of the generating station since there is a certain amount of expenditure on land, buildings and steam plant. Against that must be put the fact that in modern generating stations employing turbo-alternators the size of the alternator is not directly proportional to the kVA. A 12 500-kVA alternator at 0·6 power factor would be appreciably larger than a 12 500-kVA alternator at 0·8 power factor. With the old low-speed-engine type of alternator the difference was not so great. It is possible that, balancing the land, the buildings and the other charges against the electrical plant, a figure directly proportional to the kVA may result.

Mr. Dorey has dealt with the various types of apparatus for improving power factor, but he has not told us the field of application of each particular type. Any attempt to correct the power factor of a system should naturally be made at the source of the trouble, that is to say in the machines themselves. An examination will almost invariably indicate that, provided the horse-power and the speed are suitable, the cheapest proposition is to install high-power-factor rotary machines, i.e. make the motor a synchronous motor or correct its power factor with a phase-advancer. There still remains a considerable field for the static condenser in the smaller installations where there are no motors of more than approximately 50 h.p. These installations are really the particular field of application of the static condenser and in view of this it was not surprising to find a reference to a self-compensating motor which has just been put on the market in this country. What was surprising was that Mr. Dorey, with all the figures and curves before him, had not seized the opportunity of showing the exact relationship in which this motor stands with respect to the induction motor and static condenser. As a matter of fact, it is essentially a motor for continuous operation; that is to say, it is not intended for crane service. The slip-ring motor is rapidly dying out for continuous operation duties and we have then to compare this motor with a simple squirrel-cage motor. On a basis of first cost it is fairly obvious that the squirrel-cage motor must be very much cheaper; it has no slip-rings, no brushes, and a much simpler form of rotor winding is used. It is estimated that the self-compensating motor will cost between 40 and 65 per cent more than the simple squirrel-cage motor. As far as reliability is concerned there is no question which is the more robust machine. The self-compensating motor has, in addition to slip-rings, a commutator, brush gear and an additional winding on the rotor; and furthermore the slip-rings and one rotor winding operate continuously on the full line voltage. The only point where it might be claimed to have certain advantages is in regard to its power factor. It is interesting, however, to examine how much the consumer pays for this high power factor. The 17½-h.p. motor given in the paper has been taken and the consumption on a basis of the 84½ per cent efficiency

given in the curves is 15·4 kW. With a squirrel-cage motor of the high-starting-torque, high-efficiency type, the usual figures would be 90 per cent efficiency and 0·87 power factor, which give about 14·5 kW input and a difference of 900 watts. This 900 watts difference would result in about £13 difference in the annual power bill with a year of 3 500 hours and power costing 1d. per unit. Extending that to a 500-h.p. installation gives the additional cost of power per annum as about £350. One of Mr. Dorey's condensers put on to correct the power factor of the squirrel-cage motors and make it directly comparable with the self-compensating machines will cost something of the order of £750—a very much cheaper proposition than the capitalized value of the £350 per year paid in the case of the compensated machines. There is not only the cost of power to be considered, however, in modern production—continuity of service is by far the most important function. It matters very little to the manufacturer whether he gets a power-factor rebate or not when his power bill is only 1 per cent of the cost of production. What does matter is that he should keep on producing. It is impossible to have a more robust machine than the squirrel-cage motor, and it requires a considerable increase in the power bill to outweigh the advantage of this reliability. The practical problem of how to improve the power factor is naturally much more straightforward than the economic one of devising a suitable tariff. There are, however, a very large number of supply undertakings in existence which are making not the slightest attempt to deal with the problem. If the authors have succeeded in drawing the attention of such undertakings to the subject they have done well.

Mr. H. C. Lamb: Mr. Dorey's paper contains many strong statements and might lead people to imagine that most of the supply undertakings are in a worse case with regard to power factor than they really are. The fact is that many of them have a large d.c. load, and the converting plant is, in one respect, a blessing in disguise, in that it helps to keep up the power factor. On the Manchester system, for instance, the normal power factor is round about 0·9, and it never falls so low as to make it necessary to run generating plant solely because of idle current. Manchester, like most other undertakings, has recognized the need for power-factor correction, and the Manchester tariff is of Mr. Dorey's Class B type, which gives a bonus for power factor above 0·8, and a penalty for power factor below that figure. Some Manchester consumers have put in apparatus to raise their power factor, and they get a substantial bonus. I agree with Mr. Romero that the importance of power factor is exaggerated, and the statement in Mr. Dorey's paper on page 636 is misleading. He says: " The capital expenditure on supply undertakings varies considerably, and a round figure of £40 to £50 per kVA may be taken." In the first place, I do not believe that the average cost per kVA is anything like so high. Just before the sentence quoted above, he says: " . . . therefore for every £6 4s. per kVA spent on condensers the demand is reduced 1 kVA." The inference is that, for every £6 4s. spent on condensers, there is a saving in capital expenditure of £40 to £50. I am sure this is incorrect, and that the saving is only a small fraction of £40; it is, in fact, not much more than the £6 4s. which would have to be spent on condensers, namely that for the reason given by Mr. Romero, only a proportion of the plant is affected by the kVA demand. I also agree with Mr. Romero that a tariff which takes into account average power factor is the most correct one; by using two single-phase watt-hour meters the average power factor is obtained, and it is on this that the bonus and penalty clause in Manchester is based.

Mr. J. S. Peck: The possibility of improving the power factor on distribution systems is a subject that has often been discussed at these meetings, but I have always felt that no great advance would be made until the supply undertakings were prepared to recognize high power factor by bonus or to penalize low power factor by an extra tariff. One of the chief difficulties in framing a satisfactory tariff based on kVA is the securing of proper meters. So far as I know, there is no really simple and accurate kVA meter on the market. There are several meters which give approximations as to kVA but none, I think, which gives accurate results. I have recently inspected a most interesting American meter. It appears to give, and give accurately, nearly everything that can be asked for, but it is complicated and expensive. This meter (1) indicates on a chart every 15 minutes the maximum demand in kVA; (2) indicates on a chart every 15 minutes the maximum demand in kW; (3) integrates kWh; and (4) indicates at any instant the power factor of the system. This meter is probably too expensive for ordinary installations but will doubtless prove very useful for temporary installation on a customer's premises in order to determine the characteristics of his load. In framing a tariff there are so many variables which may be considered that it is almost impossible to devise a simple method which will give the proper weight to each one of them. I agree with Mr. Lamb and Mr. Romero that the importance of the wattless component is often over-stressed, for until a generating plant and cables are fully loaded the power factor of the load is of little importance. There are, however, cases where a low power factor may be very objectionable. For example, if a generator is loaded to its kVA limit and there is still excess capacity in the prime mover, it may be very desirable to improve the power factor. Also, if the drop on a particular transmission circuit is so large as to be detrimental, the cost of the installation of means for improving the power factor on the feeder may be fully justified.

In Mr. Dorey's paper there are a number of statements with which I am not in agreement. A number of these have already been criticized. With regard to the synchronous condenser it should be pointed out that this apparatus is almost indispensable in certain circumstances. On long transmission lines it is used extensively for maintaining constant voltage at the end of the line or at intermediate points on the line. A static condenser would not be suitable for this purpose, for even if it were possible to adjust its capacity by cutting out sections of the condenser it would not be able to give the lagging current required in order to prevent the voltage at the end of the system from reaching too high a value at times of light load. With regard to the

saving that had been worked out in the paper for justifying the installation of static condensers, sufficient data are not given in all cases to enable the conclusions to be checked. It has already been pointed out, however, by other speakers that the figure given for the saving of generator capacity is greatly over-stated. Considerable space is devoted to a description of the "No Lag" motor. This type of motor has been very extensively advertised in America and also on the Continent, but the indications are that it has not met with quite the hearty reception that was anticipated by its makers. A motor which must have the supply voltage carried to the stator winding by means of slip-rings, and which requires an additional winding on the rotor and a commutator, can hardly be said to be as simple as an ordinary induction motor. My personal feeling is that if a high power factor is required on an individual motor of small size it is preferable to use a squirrel-cage motor with a static condenser rather than a motor having a commutator and slip-rings.

Mr. O. Howarth: The business of electricity supply undertakings is to sell electrical energy. Success will only come if the tariff is attractive to the prospective consumer. Many people will not look at any but a perfectly straightforward tariff which they can understand with ease and which can be related to their works costs. They do not want any factor in their charge which will present difficulty; in fact, they will use some alternative to electricity rather than be bothered by tariffs based on kVA or power factor. They are prepared to pay for kWh and they might possibly be persuaded to pay for kW of demand which they can understand when related to the horse-power available, but they do not understand kVA or power factor, partly because they do not want to. There is another class of consumer who knows too much about power factor to be persuaded to pay on it. Undertakers who take a bulk supply come within this class. Of course, there must be some consumers who must have electricity at any cost, and these are the victims of the tariff dissectors. On page 638 Mr. Dorey gives figures for Bolton, Lancashire, which work out at 0·49d. per unit with coal at 20s. per ton plus a standing charge of about £3 15s. per kW per annum on the kW charge and the same on the kVA charge with a power factor of 0·75. Another tariff quoted is for a Scottish undertaking, where the price is 0·4d. per unit with coal at 20s. per ton plus £10 per kW per annum for a 250-kW consumer. I am well aware of the strong objection of the Lancashire manufacturer to paying a kW charge which he regards as money paid for nothing when he is on short time, but I was always under the impression that the same thing applied to Scotland. At 30 per cent load factor the Scottish price works out at 1·31d. per unit and the Bolton price 0·83d. per unit with coal at 20s. Can the authors assure us that these differences in price actually obtain between ordinary power consumers in the different districts? Owing to the competition of oil and steam plant, most undertakers have to sell electrical energy at what they can get and not at what they would like to sell. If we have two consumers, A being situated ¼ mile from the power station and taking 100 kW at 0·5 power factor, whilst B is situated 10 miles away and takes 100 kW at unity power factor, it will obviously cost more to supply B than A, but the authors suggest that A should be made to pay more than B. The distance from the power station has to be averaged out and with the ordinary power consumer who uses a number of motors of various ratings up to about 100 h.p. the power factor should be averaged out also. Consumers have adopted the electric drive because they can sectionalize their shafting or have an individual drive for small machines if they wish. A power factor charge to them simply means that they must install additional apparatus. If 500 kW is required on one machine a consumer might with advantage be induced to install a synchronous machine and get a good power factor. It might be worth while, especially if he has to be supplied by a long transmission line, to offer him special terms for a high power factor, but he is not an ordinary consumer. The ordinary consumer likes to have some simple piece of apparatus and does not want to be bothered with complications. The induction motor appeals to these consumers because of its simplicity. I have calculated the saving that would be effected if consumers improved their power factor, and even with consumers several miles from the power station the saving was much less than that shown in Mr. Dorey's paper. The greatest saving would be effected by reducing the transformer capacity in the consumer's substation, but it is doubtful whether it is safe to do this as there is always the possibility of the consumer running without his condensers due to breakdown or mistake, in which case the transformers may be damaged. If any saving is to be effected by improvement of power factor the supply undertakings can install condensers and pocket all the saving, with the advantage that the condensers will be under their control and can be switched on and off to suit them; they will then derive full benefit from their use.

The chief objection to these tariffs is the impossibility of obtaining satisfactory metering. Many of these tariffs are framed in such a way that it is quite impossible to meter, and a compromise has to be arranged with the consumer. We can only define the kVA and power factor on a three-phase, 3-wire load by assuming symmetrical voltages, and our experience of the inaccuracies of meters which depend for their accuracy on symmetrical currents and voltages should warn us off these assumptions. We cannot measure what we cannot define. The meter artifice suggested by Mr. Clark is most unsatisfactory because the consumer may at any time ask "What *does* this meter measure," and what answer can be given? The Aron kVA meter mentioned in Mr. Dorey's paper is undoubtedly the best piece of apparatus on the market at the present time for measuring kVA. It indicates the kVA demand on the Merz system but, as he points out, it will not register kVA-hours. If it will not register kVA-hours it is obvious that it cannot accurately integrate the kVA over a period and indicate the average kVA during that period as it is required to do to work on the Merz principle. It measures the kVA if the load is approximately constant, and might be expected to give results within about 5 per cent of what the true value would be if we could define the true value. Meter manufacturers have

not yet seriously tackled the problem of making a satisfactory kW indicator. When the accuracy guarantee figures are analysed we find that the meters are only guaranteed to within 4 or 5 per cent at working loads. Let the manufacturers supply a satisfactory kW demand indicator before they go on to more complicated measurements. If an undertaking installs complicated meters which only approximate the quantities to be measured specifically, and that undertaking is challenged on the accuracy of its metering, what is it to do? It will have to come to terms. For this reason I think that these systems of charging should be avoided as far as possible.

Mr. E. P. Hill: In the summary, Mr. Dorey states that his paper gives a description of the modern static condenser and also of types of power-factor-rectifying plant that have been developed during the past three years. I find that the principal types with which he has dealt embody the principles of Leblanc (1895 patent), Scherbius (Brown-Boveri) 1912, and Miles Walker 1912, and he does not bring forward new types of power-factor-rectifying plant. Fig. 4 appears to be identical with the one given in an article * on "Phase Compensation" by Mr. T. Ellis of the A.E.G., but such methods cannot be said to have been developed during the past three years. Mr. Dorey sets out the advantages of the static condenser, and certain serious limitations have also been mentioned. One of the main disadvantages appears to be that the economical voltage is 600 volts, and that the size and cost are inversely proportional to the square of the voltage; so that at 440 volts without the auto-transformer the size of the condenser is almost double that at 600 volts. The author states that the cost of 600-volt units in series for use on 3 000 volts is approximately the same as for 600-volt working. The use of high-tension condensers is not encouraged. Is this not due to the reduced reliability at 3 000 volts which entails that in order to manufacture a reliable article the condenser is not then an economical proposition? This is of importance in many cases where the bulk of the motors are running at voltages from 2 000 to 6 600. It would be interesting to know if the condenser mentioned as being run across 3 000 volts for the purpose of test and experience was of standard construction, or whether it embodied any special features. As both the size and cost of the condenser vary inversely as the frequency, it follows that at 25 periods the economical advantages are much less, for at the price of £6 4s. per kVA other forms of phase compensation would often be preferable. Mr. Dorey states on page 636 that the static condenser is a very flexible apparatus. On the contrary, in some respects they are far less flexible than other forms of power-factor correctors, for the reason that, unless considerable cost is incurred, the amount of leading current cannot be varied with load, and this may at times be a disadvantage to a consumer. In spite of the relatively few accidents which have occurred with transformers immersed in oil, there is in some quarters a disinclination to install further apparatus in which quantities of inflammable oil are used as a cooling medium, and possibly in situations involving serious consequences in case of fire. The possibility of moisture gradually affecting the insulating quality of the thin dielectric used, is no doubt one of the reasons for the anxiety of the makers to avoid the manufacture of condensers for higher voltages than 600 volts, due to the relatively small factor of safety. Whereas in the case of a transformer, for example, the insulation and clearances can be made very ample, to ensure that breakdowns from such causes are extremely rare, in the case of a static condenser the matter is more difficult as the output is inversely proportional to the thickness of the dielectric. To sum up, it would appear, therefore, that with low frequency (i.e. where the magnetizing currents of transformers are high) the condensers are economically least suitable. On voltages higher than 600 they may become dangerous unless expensive. Below 600 volts they are apparently uneconomical unless an auto-transformer is adopted, and consequently the field of useful service is limited. If there is a d.c. load to be supplied in addition to the a.c. motor load, it is often more suitable to install a rotary converter at the substation. Earlier in the discussion Mr. Lamb mentioned the beneficial effect of rotary-converter load upon the power factor of the Manchester Corporation supply. In Dr. Kapp's paper Mr. Chattock also stated * that in Birmingham the power factor is improved from 0·66 to 0·79 by adding approximately 14 500 kW of rotary plant. The total load then was 58 000 kVA. Mr. Chattock assumed that the rotary converter was running at unity power factor. If running at 0·98 this would give a total power factor of over 0·8. A normal rotary converter is capable of running with a reasonable amount of leading wattless component without fear of serious overheating. As it is readily possible to change the transformer tapping by a h.t. tapping switch to obtain the desired leading wattless current even with wide variations of d.c. voltage (such as in the case of a converter running at 440 volts for lighting and 550 volts for traction), the rotary converter has advantages over the motor converter in this respect. The power factor of all static rectifier plant is, of course, relatively worse than that of a rotary converter, and such plant is at a disadvantage in this respect.

Mr. W. Fennell: The question of power-factor tariff is of secondary importance perhaps to those who sell in bulk to smaller undertakings, but it is of primary importance to those undertakers who have to buy power in bulk. Whilst the objection which is made to tariffs based on kVA or to charges for wattless component—viz. that they are not understood—does not apply with so much force to one undertaking selling to another, as there are electrical engineers on both sides, there is a risk of the "bulk consumer" being charged too heavily by reason of abnormal conditions, such as mains faults, etc. From that point of view it is unfortunate that so little has been said of what is being done in arriving at the power factor for bulk supply tariffs. An account of the actual arrangements made as to power factor by large undertakings selling in bulk would be interesting. With regard to tariffs for ordinary power consumers, I think it is about 5 years since I said on the occasion of a paper on "Tariffs" at Manchester something to the effect that the wise power station engineer, if in any

* *Electrician*, 1925, vol. 94, p. 590.

* *Journal I.E.E.*, 1923, vol. 61, p. 100.

case he found the tariff did not fit an important intending consumer, would not hesitate to make a new one for the occasion. The tariffs for which I have been responsible have always had a saving clause that we may sell power "by agreement." The important thing is to secure all the paying business. In cases where the maximum demand either in kW or power factor is proposed to be taken into account as an act of justice, I am of the opinion that it is of primary importance that the time of maximum demand should be considered. The question arises: Is the maximum recorded figure to be taken as a basis if it occurred in the morning in mid-summer, or is it to be taken during the time of peak load on the feeder or of the generating station concerned? A consideration of the basis of cost of generation and distribution shows that it is unscientific and unfair to fix a tariff based on maximum demand without having some scheme for determining the time of maximum demand and of ignoring or reducing the chargeable demand to a reasonable extent if it occurs at unimportant times. I have recently been engaged in negotiating a bulk supply agreement where the recorded maximum kVA is multiplied by a constant of 0·5 in summer, increasing gradually to unity in December. That is a reasonable differentiation between months but we should in justice go further. The chargeable kVA which matters and which should be chargeable is that usually existing during the late hours of the winter afternoon. Where a bulk supply is involved it is well worth while to have a recording ammeter and voltmeter and to use the valuable information so obtained as the basis for obtaining the chargeable kVA instead of using maximum-demand meters. These latter sometimes indicate readings which no one can account for and which may be due to accidental or transient excess demand or low power factor which in no way benefited the bulk consumer or caused the supplier any extra expense commensurate with the extra charge made because of it. Having those two curves—amperes and volts—the supply engineer may, for instance, ignore a certain large kVA which occurred at a time of light load on the generators, and take into account only the usual sustained kVA at times of peak load on the power station or feeder. It is not suggested that recorders should be fixed in every factory. The ordinary consumer wants a simple and definite meter system, and if discretion is exercised in its use a kVA meter will not cause any friction with the consumer who agrees to be charged on that basis.

(*Communicated*): There is one important point which the papers do not emphasize in dealing with power-factor-correcting devices. It is a common fallacy to imagine that the installation of, say, a rotary converter or special motor running at nearly unity power factor will compensate for low power factor on a system because the power-factor indicator reading improves. There is just the same loss due to wattless component as before, and this can only be corrected by installing apparatus with considerable and controllable leading power factor. For this reason the need for considering synchronous motor-generators or condensers is just as important where there are converting substations as in these cases where the system is entirely alternating current; sepecially as the ratio of a.c. to d.c. loads is likely to increase in almost every case as the area is developed.

Mr. L. H. A. Carr: Since Mr. Dorey's paper is apparently a résumé of the various types of apparatus used for power-factor correction, one feels that he has rather cursorily dismissed the synchronous and synchronous-induction motors. Whilst the salient-pole synchronous motor has been installed in large numbers during the past 15 or 20 years, it should be emphasized that the use of the synchronous induction motor has increased enormously during the past 4 or 5 years, and, judging by the number manufactured in this country, it would appear that the synchronous induction motor is at the present time the most popular type of machine for power-factor correction, a position that it probably deserves. It is unfortunate that Mr. Dorey, when dealing with compensated induction motors, should describe at such length only one proprietary type out of many, and also that he should refer to it as a "comparatively new type" although it was known, and manufactured, some 25 years ago. Compensated induction motors may be divided into two main classes. The first class is that in which power is led to the brushes at line frequency, the rotor being similar to an ordinary d.c. armature. This motor is frequently known as the polyphase shunt, or polyphase series motor, according to its connections, and was first described by Wilson in 1888. Later, about 1901, it was developed by Görges, Heyland, and Latour, and was commercially manufactured by the A.E.G. and Siemens and Halske, but failed to find a market. In recent years it has been re-introduced by several of the Continental firms. In the second type the primary winding is normally on the rotor. A small tertiary winding, or a series of tappings on the primary winding, is connected to a commutator, and the brushes pick off power at slip frequency only, and this power is fed into the stationary secondary winding. This motor was described by Osnos in 1902 in almost all its possible modifications. It is now, with minor variations, manufactured by several firms, principally on the Continent. When discussing polyphase machines with commutators, it must be remembered that the a.c. commutator has always one great disadvantage compared with the d.c. commutator. In the d.c. machine the current is collected from a point on the commutator where the value of the E.M.F. between adjacent commutator bars is zero. On the polyphase a.c. machine the flux rotates relatively to the brushes, and, no matter how low the periodicity, at some period of time each brush collects current from a part of the commutator where the voltage between adjacent commutator parts is a maximum for the machine. For this reason a.c. commutators are larger, and necessitate higher losses, than the corresponding d.c. commutators. A further type of power-factor-correcting motor not mentioned by Mr. Dorey is the self-excited synchronous induction motor, first described by Fynn in 1906, and now manufactured in small sizes both on the Continent and in America. Yet a fourth type is the Torda motor (1923) which really consists of an induction motor with a phase-advancer winding wound on the same core or cores as the main winding, but with a different number of poles so that the two sets of windings and fluxes

operate independently. All these types suffer from the same economic defects. Compared with the induction motor they are expensive in first cost, due to their extra complications, and low in efficiency. Where power-factor correction is required it is cheaper, both in first cost and in running charges, to install in the smaller sizes, say up to 60 h.p., a plain induction motor with static condensers, and above that to utilize either the salient-pole synchronous motor, or the synchronous induction motor, the exact choice depending on the starting torque required.

[Mr. Dorey's reply to this discussion will be found on page 652. Mr. Clark's reply will be published later.]

South Midland Centre, at Birmingham, 31 March, 1926.

Mr. J. Hargrove: Mr. Lawson suggested that there was no incentive for supply undertakings to adopt a power factor tariff unless its cost to them proved less than that of increasing the size of their generating plant, but it appears to me that this entirely overlooks facts which were made clear in the Weir Committee's report, namely, that whereas the average capital cost of the generating plant is £23·8 per kW, that of distribution is £28·5. It is clear from this that the increased cost of cables, etc., necessitated by low power factor is at least equal to the increased cost of generating plant, and that therefore equal attention should be given to it. It was also suggested by Mr. Lawson that a reduction in rates was in the nature of a gift to the consumer, and his remarks tended to strengthen the impression one had that supply undertakings in general did their utmost to maintain their charges at the highest possible figure. This would appear to be quite a wrong attitude to adopt, as a curve supplied by Mr. Kennedy and incorporated in the Weir report tends to show. This curve shows that whereas at 2d. per unit 110 units per head are used, if the price is reduced to 1d. the consumption rises to 500 units per head. This fact is well worth consideration, as increased consumption naturally tends to reduce both capital and operating costs per kWh. Turning to the question of tariff, it is not at all clear why Mr. Clark should have taken 0·8 power factor as his basis, whereas Mr. Dorey adopted 0·75. I have had experience of a tariff which might be described as a modification of the three-part tariff referred to by Mr. Dorey. The price in this case is based on unity power factor, and is fixed by a sliding scale according to horse-power (or kVA) of plant installed. A sine meter is used in addition to the kilowatt meter, and the units registered by it are charged at a definite fraction ($\frac{1}{8}$) of the price per unit of power. A minimum consumption has to be guaranteed by the consumer, amounting in this case to an average load of 40 per cent of the capacity installed, for 611 hours per quarter (47 hours per week). In case the consumption in any one quarter does not reach this amount, the charge is based on this minimum, but a rebate of 30 per cent is allowed on the units contracted for but not taken. It will be seen that this is, in effect, very similar to the three-part tariff, but does not require a maximum-demand indicator. Fig. A clearly demonstrates the effect of a tariff such as this, at various power factors, and it will be seen that between 0·9 and 0·6 power factor the curve is practically a straight line, but that it rises very rapidly below 0·6. It seems obvious that a tariff such as this, by which a definite extra charge is made, proportional to the extra kVA, is more equitable than the one in which the extra is inversely proportional to the power factor, as the extra cost of generation and distribution are very nearly in direct proportion to the extra kVA required. Any consumer entering into an agreement to take a supply on any such terms as the above should give very careful consideration to the balance of capital charges, for plant to give a high power factor against the extra cost of current at a lower power factor. In this respect it may be taken that to be a paying proposition the yearly saving due to improved power factor must be at least equal to one-fifth of the extra capital cost involved.

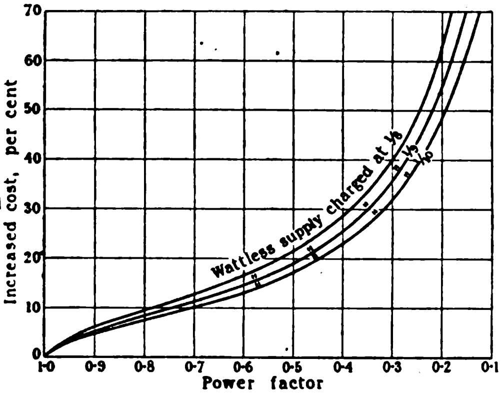

FIG. A.—Curve showing increased cost per kWh at various power factors.

Basis of charge: x pence per kWh + cx pence per kVA-hour of wattless supply, where $c = \frac{1}{8}, \frac{1}{5}$ or $\frac{1}{10}$.

Mr. W. P. Conly: I should like to ask Mr. Dorey's opinion as to the best method of obtaining the desired pressure of 600 volts across the condenser of a power-factor-correcting equipment. In his paper Mr. Dorey advocates two alternatives: (1) To overwind the secondary of the main transformer to carry the wattless component at a line voltage of 600, and (2) to provide an auxiliary auto-transformer stepping up the wattless component from the normal line pressure to 600 volts. In an actual case under my notice it is required to install a 250-kVA transformer at 5 000/440 volts, three-phase, 25 cycles, and at the same time to raise the power factor from 0·7 to 0·92. The former method of the overwound transformer shows a financial advantage of approximately £31. Is this sufficient, in Mr. Dorey's opinion, to justify its use?

Mr. J. Young: I am chiefly interested in this question of power-factor improvement in connection

with small fans taking from 50 to 150 watts. The standard practice with these fans is to fit a small condenser with each either on the down rod of a ceiling fan, or combined with the fan regulator. These condensers have a capacity of from 4 to 12 μF, and I should like to ask Mr. Dorey whether in his opinion there is any loss in capacity either if kept in stock or in use. I have made a large number of tests during the past 6 months on these small condensers. Although this time is not long enough to enable any definite opinion to be formed, I have obtained what appear to be rather curious results. I have several times been unable to obtain the same power-factor correction with a condenser after it has been in use or kept for some time. Quite recently I had a very unfortunate instance of this. A fan and a condenser were connected up and gave a power factor of 0·97, the power factor of the fan being 0·61. The fan was then run for some time, being switched off at night, and on repeating the tests next morning for an inspector I could only obtain a power factor of 0·93. Is there any reason for these results ? I do not suggest that the trouble is all due to the condenser; it may be that the connections are at fault, or that the insulation has deteriorated after standing overnight. Is there any simple way of testing the condensers ?

Dr. R. G. Jakeman: A case came to my notice recently in which a condenser and transformer were used for correcting an induction-motor load. It was found that if the condenser was switched on when the motors were out of circuit, a current of about 3 times the normal was taken, which, however, rapidly fell to normal. If, however, the motors were in circuit first, only normal current was taken. I should be glad if Mr. Dorey would give an explanation of this. It appears to me that the ideal method of power-factor correction is to supply a separate condenser for each induction motor, so that the condenser is switched on and off with the motor and the stator winding acts as a discharge resistance. The objection appears to be the cost, but since the method is applied very largely to fans it does not seem unreasonable that it should be extended to larger motors. This method leads to a new tariff system. The condensers could be supplied and maintained by the supply undertaking, remaining their property. The consumer would pay for the energy used and would have a rebate for allowing the supply undertaking to fit the condensers. The power factor could be corrected to any desired figure, without the consumer being required to understand anything about it. The "No Lag" motor mentioned by Mr. Dorey and described in the *Journal* 10 years ago has the great disadvantage that the primary is wound on the rotor, so that the main current has to pass through the slip-rings. The firm with which I am connected has developed a form of compensated motor which has not this disadvantage.

Mr. F. C. Hall: In regard to Mr. Dorey's paper, it is true that both synchronous and auto-synchronous machinery has been previously described in the *Journal* and both classes are serving many useful purposes; I therefore feel that the author has somewhat given this side of the subject the "cold shoulder"—more especially as he singles out the rotary condenser and proceeds to compare it with the static condenser, to the disadvantage of the former. Supply undertakings abroad appear to use rotary condensers to a larger extent than is the case in Great Britain, and they use them in the form of very big units, certainly up to a capacity of 15 000 kVA, despite the fact that this is a less efficient way to make use of the machine. The greatest value can be got out of synchronous machines when they are used both to deliver load and to correct the power factor; and whilst it is not economical to adopt them in all cases, there are certainly many occasions when it is better to use them than any other method for improving the power factor. An important feature about synchronous and auto-synchronous machines is, that, providing they are delivering a fairly high percentage of kW load in proportion to their kVA capacity, they occupy considerably less space than static condensers and the necessary auto-transformers and switchgear for the same, with consequent reduction in capital cost of buildings, floor-space, etc. Furthermore, in these conditions the efficiency—by comparison with the ordinary induction motor or motors which would otherwise be required to deliver the load—is only about 1 per cent lower than that for the latter machines. The author's treatment of the subject of charging consumers of varying power factors brings out many interesting points, and shows clearly that whilst some supply undertakings offer fair and reasonable tariffs, others either offer no inducement whatever or make no discrimination between the biggest offenders and those who only offend in a small degree.

I find myself at variance with Mr. Clark's revolutionary idea to regard low power factor as a useful source of profit. It seems to me that as power factor is linked up with the question of the general efficient running of a system, we, as engineers, should extend our influence towards the improvement of the power factor, rather than accept something which is bad and endeavour to make money out of it. With regard to Mr. Clark's interesting suggestions as to the more complicated methods of charging for electricity, this may be satisfactory in certain cases of large consumers, but the cost of metering equipment is already high in the case of the great army of small consumers, and it seems desirable for supply undertakings to evolve in their case a tariff which is as simple as possible.

Mr. E. W. Dorey (*in reply*): Several of the speakers have suggested that I should have taken the opportunity of making comparisons between the static condenser and other types of plant for power-factor correction, but as each case needs special and individual consideration it is well-nigh impossible to give comparative figures that would be of any real use. A comparison between the cost and efficiency of an auto-synchronous motor of a given output and those of an induction motor of the same output working with a static condenser, does not really give much useful information. The static condenser is essentially an equipment for correcting the power factor of the load as a whole and not

the power factor of individual machines. The auto-synchronous motor and also the static condenser have each its special field of application. When dealing with a load comprising a number of comparatively small motors, the static condenser is almost invariably the best solution.

In considering the use of auto-synchronous motors installed for the power-factor correction of the total load, an important item to be borne in mind is the output of the auto-synchronous motor. There are cases where an auto-synchronous motor has been installed to work at about one-fourth or one-fifth of its full-load output and, consequently, at low efficiency, as the machine had to be so designed as to be able to give the equivalent kVA output required for power-factor correction. Efficiency in such cases is an important factor that should not be overlooked. On the other hand, where auto-synchronous motors of, say, 100 h.p. upwards can be utilized working at three-quarters to full load, they undoubtedly have a good field of application. The auto-synchronous motor certainly has the advantage of ease of regulation of condenser capacity. In the case of a static condenser it is quite a simple matter to arrange that the capacity can be varied to give one-third, two-thirds or full output.

If we take the case of an auto-synchronous motor of, say, 200 h.p. working in conjunction with 200 h.p. of small induction motors, the installation being designed to give a power factor of, say, 97 per cent lagging, the auto-synchronous motor will be excited in such a way as to ensure that the required degree of correction is obtained at maximum load, and will normally remain so set during the whole of the day; the capacity component will therefore, for all practical purposes, remain as fixed as with a static condenser. With a kVA-demand tariff it may not always be safe to correct to unity power factor, as there is always the danger that at the time of maximum demand the load may be less than anticipated and cause a leading power factor, with a penalty similar to that for the equivalent amount of lag. It would undoubtedly be an advantage in most cases if a minority of the consumers of a supply undertaking had a power factor of unity or a leading power factor; but, as time advances, the majority of the consumers may have corrected their power factors, and when the majority are working with unity or leading power factor the conditions on the system may be very objectionable to the supply undertaking and interfere seriously with the voltage regulation. Looking to the future, therefore, it would seem that the most desirable course is to impose a tariff which will not encourage consumers to run with a leading power factor. A lagging power factor of about 95 per cent should in the majority of cases be quite satisfactory both to consumers and to supply undertakings.

My reference to rotary condensers was confined to conditions obtaining in Great Britain where the field of application is very limited. Abroad, the rotary condenser, as referred to by speakers, frequently has to operate with lagging instead of leading power factor. I do not agree with Mr. Hart that on a 25-cycle circuit in Great Britain the rotary condenser is a better proposition than the static condenser, because, if the losses are taken into consideration, the static condenser will undoubtedly have the advantage, although its capital cost will almost invariably be higher.

The President and other speakers have referred to the necessity of switching static condensers off with the load, in order to avoid voltage-rise, and in the majority of cases this is a very necessary precaution. In the case of static condensers installed by the consumer, the condenser is almost invariably switched off with the load. On the other hand, if the condenser is installed by the supply undertaking at, say, an unattended sub-station, some means would have to be devised for automatically disconnecting it as the load falls off, and switching it in again when the load comes on. So far, I know of no cases where this method has been adopted. The tendency nowadays, and rightly so, is for the consumer to be encouraged to install the condensers or other corrective plant, and he may usually be relied upon to switch them out when the load goes off.

Mr. Hart says that there is divided opinion as to whether the supply undertaking or the consumer should be responsible for the improvement of power factor. There may certainly be a difference of opinion, but I suggest that the great majority of engineers are agreed that it is the consumer who is responsible for the low power factor of the load and who should be encouraged and enabled by the provision of suitable apparatus to install plant for power-factor correction. If the supply undertaking itself endeavours to correct the power factor, the difficulty of capacity regulation immediately arises.

There is one interesting case of an important supply undertaking in Great Britain with a day load of about 16 000 kVA at a lagging power factor of 0·50 which is obliged to improve the power factor of the load before linking up with another supply undertaking. A power-factor tariff has not been adopted and it is now found to be quite impossible to effect the correction on the distribution system. The installing of expensive and inefficient rotary condensers at the power station has been considered. Under such conditions the distribution system will still have to operate with double the current and four times the losses which would occur under equivalent conditions with unity power factor. This is the ultimate fate that will await many supply undertakings who neglect the power-factor problem, and with the rapid increase in the number of linking-up schemes it is not surprising that the majority of supply undertakings are now adopting some form of tariff to compel consumers to improve the power factor of their loads.

In reply to the President's remarks regarding voltage regulation with condensers connected direct across transformers of the pole type, I have no definite data as to the installation referred to in the paper, but the remarks of the engineer, that the voltage regulation is improved, are significant. It is important in an installation of this kind to divide the capacity into a large number of small units distributed as widely as possible over the system; and, quite apart from the other advantages which accrue from the installation of condensers in this way, it should, if properly designed, considerably improve the voltage regulation.

Mr. Ellis has referred to the "Maxigraph." This is an instrument of great merit in special cases such as those mentioned, or for special power-factor or kVA-demand tests, but as an ordinary commercial instrument for metering the kVA demand it is unnecessarily elaborate and costly.

Mr. Kapp and Mr. Young have referred to the use of small individual condensers in conjunction with fans. These have now been developed for commercial purposes, the condenser being fixed in the regulator housing. Small alternating-current fans have a notoriously bad power factor, about 60 per cent, so that if a direct-current fan load is being changed over to alternating current the current will increase by something like 60 to 70 per cent at the same voltage, and the introduction of a condenser in an a.c. fan to bring the power factor up to 91 per cent will keep the current increase down to about 10 per cent. Mr. Young refers to the variation in the capacity value of a fan condenser, but the case he instances must be quite an abnormal one, as in the ordinary way the variation of capacity over many years should be quite negligible.

In reply to Mr. Hill, the 3 000-volt outdoor condenser to which reference has been made in the paper was quite a standard product. Mr. Hill regards the voltage of 600 on a condenser as a disadvantage, but it does not seem to be more of a disadvantage than to use, say, a 33 000-volt transmission where it would be possible at considerably greater cost to use 11 000-volt transmission. It is a question entirely of the most economical plant for the job.

In reply to Mr. Carr, I would point out that in my short paper it was impossible to refer more than briefly to certain types of plant for power-factor correction, and to touch only the fringe of the subject.

Coming to the question of tariffs, it is pleasing to hear that Mr. Chattock and Mr. Lamb have instituted at Birmingham and Manchester respectively a power-factor-rebate tariff for a.c. consumers, despite the fact that in both towns they are in a relatively good position from the point of view of power factor. This, in itself, seems justification for the extended application of a power-factor tariff, particularly in the case of undertakings mainly operating with industrial a.c. loads.

In reply to Mr. Lamb, it was not my intention to suggest that for every £6 4s. spent on 50-cycle static condensers there would be a saving of from £40 to £50 in the capital outlay of the undertaking. In the £40 to £50 figure are items amounting to possibly half, or more, quite unaffected by power factor, but my intention was to convey that only £6 4s. per kVA on a 50-cycle undertaking is necessary in order to justify the installation of a condenser, and there must be ample margin between this and the actual capital cost per kVA of such portion of the undertaking as is affected by power factor. In the case of Manchester with its favourable power-factor conditions, the saving may be only a small fraction of the £40 to £50, but it is nevertheless sufficient to justify the offering of quite a substantial power-factor bonus, and I suggest that in the majority of supply undertakings it will be quite a large fraction, possibly 50 per cent or more.

Mr. Howarth suggests that as the distance factor has to be averaged out amongst consumers of a supply undertaking, so should also the power factor be averaged. This does not, however, seem to be logical, as, whilst the consumers have little or no control over the distance factor, they certainly can control the power factor, and the tariffs should give them some opportunity of realizing their responsibility in this respect.

I disagree with those speakers who say that there are not satisfactory meters for putting into effect the power-factor tariff, and that it is not possible to apply such tariffs to small consumers. The North Metropolitan Electric Power Supply Co. has instituted, with every success, a power-factor tariff applying to almost all classes of industrial consumers from the largest to the smallest, in most cases on a kVA-demand basis using the thermal demand indicator and the Hill-Shotter kVA-demand instrument.

In preparing a tariff based on kW demand, some basic power factor must be assumed, and it follows that the loads with power factors above the basic figure must pay for those below it. Is it not therefore quite logical and reasonable to put the tariff on a kVA-demand basis worked out on the basic power factor, and let those consumers below the basic figure be penalized and those above get a bonus? In some cases a two-part tariff—a kW demand and a running charge per unit—provides for varying the charges with the average power factor, but it would surely be a much simpler and more straightforward tariff to alter the kW charge to a kVA charge and leave the running charge entirely unaffected by power factor. The metering would be much simpler.

The whole problem of power factor is linked up essentially with that portion of the tariff charges attributable to so-called fixed charges, the tendency nowadays being to include in the fixed-charge portion of the rates many items that were previously included in the running charge per unit, which has been referred to by Mr. Kapp. The fixed charge or equivalent part of the rate is, I contend, the only portion that should be affected by power factor, and it is difficult to see what justification there is for offering for an improvement of power factor a bonus on the running charge per unit, other than a small fraction due to a reduction in the losses in transmission, which I suggest can quite adequately be taken care of in the fixed-charge portion of the rate.

REPORT OF THE COUNCIL FOR THE YEAR 1925–1926, PRESENTED AT THE ANNUAL GENERAL MEETING OF 27 MAY, 1926.

CONTENTS.

REPORT.

The Council, at the Fifty-fourth Annual General Meeting of the Institution of Electrical Engineers, present to the members their Report for the year 1925–26, covering approximately the period from 1st April, 1925, to 31st March, 1926, and take this opportunity to thank the many members who have so willingly contributed to the Institution's continued progress and prosperity.

(1) Membership of the Institution.

The changes in the membership since the 1st April 1925, are shown in a table given in Appendix A.

The following table shows the growth of membership for the last 10 years :—

Year	Membership	Increase or decrease
1917	6 613	— 63
1918	6 667	+ 54
1919	7 023	+ 356
1920	8 146	+ 1 123
1921	9 449	+ 1 303
1922	10 275	+ 826
1923	10 911	+ 636
1924	11 415	+ 504
1925	11 743	+ 328
1926	12 142	+ 399

As might have been expected, the high rate of increase of membership which followed the war period has gradually come down to a more normal, but still very satisfactory, figure.

(2) Examinations.

The Associate Membership Examination was held in April and October, 1925, in London, Birmingham, Cardiff, Glasgow, Manchester, Newcastle-on-Tyne, Plymouth and Southampton, and also in Australia, Ceylon, India, New Zealand, South Africa and the U.S.A.

A certain number of candidates submitted theses and papers during the year in lieu of the Examination.

(3) Honorary Members.

The Council have pleasure in recording that, as announced at the Ordinary Meeting held on the 5th November, 1925, they have elected Dr. S. Z. de Ferranti, D.Sc., to be an Honorary Member of the Institution.

Dr. Ferranti, who became a Member of the Institution in 1891, was President in 1910 and 1911, and was awarded the Faraday Medal in 1924.

There are now 11 Honorary Members.

(4) Local Honorary Secretary for New Zealand.

The Council have appointed Mr. A. Gibbs, Deputy Chief Engineer of Telegraphs, Wellington, to be Local Honorary Secretary of the Institution for New Zealand, in place of Mr. J. Orchiston, resigned, who had held that office since 1911.

The Council cordially thank Mr. Orchiston for his valuable services over a long period of years.

(5) Faraday Medal.

The fifth award of the Faraday Medal has been made by the Council to Colonel R. E. B. Crompton, C.B., Honorary Member and Past-President of the Institution.

(6) Deaths.

The Council regret to have to record the death of the following 67 members of the Institution during the year :—

Members.

Arnot, W.
Barrett, Sir William F., F.R.S.
Beresford, Colonel C. F. C., R.E.
Bevis, H.
Bradwell, J. D. L.
Cooke, C. W.
Cooper, W. R., M.A., B.Sc.
Corlett, G. S.
Crapper, Professor E. H.
Gray, Prof. A., M.A., LL.D., F.R.S.
Gray, J. Hunter, K.C.
Hillairet, A.
Hird, F.
Jacob, A.
Lundberg, A. P.
Maclean, A. B.
Matthews, H. B.
Mills, A. E., M.A.
Munro, J. M. M.
Myers, E. R.
Pigg, J.
Roberts, M. F.
Salomons, Sir David, Bart., M.A.
Sankey, Captain H. R., C.B., C.B.E., R.E.
Stevenson, G.
Tate, L. G.
Williams, H. L., B.A.
Wise, G. M.
Wyllie, A.

Associate Members.

Angus, J.
Baeza, E. A.
Bailie, J. D.
Billington, J. R.
Chambers, G.
Coates, H. J.
Fruhe-Sutcliffe, Major R.
Giffen, A. E.
Gundry, W. E.
Ingleby, J. C. B.
Jennings, E. J.
Kinsey, A. T.
McKie, J. W. L.
Mills, H. R.
Milnes, W. M.
Minton, R. C., B.Sc.
Moinet, J. V.
Shepherd, G. M. B.
Smith, P. H. F.
Stickland, H. M.
Sutton, G.
Tweedy, G. K.
Wild, A. G.

Graduates.

Blake, G. T.
Colson, G. B.
Hudson, W. J.

Students.

Adbutharaj, R.
Anson, H. St. G.
Bobby, G. E.
Bowers, W. E. H.
Cook, A. E.
Dawbarn, D. I.
Ferens, L.
Harding, E. H.
Harries, D. G.
Karkaria, A. J.

Associates.

Devey, A. C.
Wickenden, A. H.

(7) Institution Building.

Considerable use has again been made of the Lecture Theatre and meeting rooms by allied scientific and technical societies, and the Council have been glad to learn that the hospitality extended by the Institution in this manner is much appreciated by the bodies concerned.

(8) Meetings.

During the past twelve months 374 meetings have been held in London and the Local Centres by the members, the Council and the various Committees. A detailed statement is given in Appendix B.

The Premiums awarded by the Council for papers will be announced about the time of the Annual General Meeting.*

(9) Local Centres and Sub-Centres.

The interest in, and attendance at, the meetings of the Local Centres and Sub-Centres have been well maintained.

The President has attended annual dinners, meetings, or other functions at the Centres at Birmingham, Glasgow, Leeds, Liverpool, Manchester and Newcastle, and at the Sheffield Sub-Centre.

On each occasion, the President addressed the members and was much impressed by the activities of these branches of the Institution and by their inestimable value in contributing to its prestige and extending its influence.

(10) Wireless Section.

Eight meetings have been held, at which nine papers were read and discussed.

In view of the suggested formation of a separate wireless society, a proposal which was based on a serious misconception of the aims and activities of the Wireless Section, the Committee considered it desirable, in August 1925, to publish in the Press a statement strongly deprecating the formation of a new society. Out of a discussion on the subject which took place in the Press, several valuable suggestions emerged. These were carefully considered by the Committee of the Section, and as a result the following Report was presented to, and approved by, the Council with a view to developing and extending the activities of the Section :

Report of Committee of Wireless Section.

The Committee of the Wireless Section have further carefully considered the proposal for a new Institute of Wireless Engineers and are definitely of the opinion that the interests of qualified professional wireless engineers can best be served by the Institution of Electrical Engineers.

It has already been explained that an engineer with adequate wireless qualifications can become a Corporate Member of the Institution, and that other wireless engineers not reaching that standard are eligible as Graduates and, as such, can attend all meetings of the Wireless Section as well as those of the Institution.

The Committee have taken into consideration the suggestions arising out of the previous correspondence

* See "Institution Notes," page 717.

on this subject which appeared in the Press, and with a view to improving and extending the activities of the Wireless Section and making it more definitely representative of professional wireless engineers, put forward the following recommendations :—

(1) While it is essential that the standard of qualifications for membership of the Institution should be maintained, more opportunity should be afforded to the physicist engaged in wireless work to become a member of the Institution. Applications for membership of the Institution based upon the usual general scientific training and wireless professional qualifications should be referred by the Secretary to a Wireless Section Membership Sub-Committee, which will make reports and recommendations for the guidance of the Membership Committee of the Council.

(2) The qualifications for membership of the Wireless Section should remain as at present, viz. "that he is a member of the Institution and is actively engaged in the study, design, manufacture, or operation of wireless or high-frequency engineering apparatus;" and the Wireless Section Membership Sub-Committee should scrutinize all new applications for membership of the Wireless Section and decide who shall be admitted to it. The Sub-Committee should be authorized to call for full particulars as to the nature of the study undertaken by an applicant or for particulars of his work in design, manufacture or operation, in order to satisfy themselves that the applicant is properly qualified in wireless engineering.

(3) The fact should be emphasized and more widely published that the meetings of the Wireless Section are open to all members of the Institution.

(4) The Wireless Section Committee should get into direct touch with the Local Centre Committees, for the purpose of :—

(*a*) Ascertaining the possibility of starting Local Wireless Sections.
(*b*) Stimulating efforts to produce local wireless papers.
(*c*) Suggesting the reading of suitable papers or the giving of lectures at Local Centres.

(5) Each Local Wireless Section, when properly constituted, should be entitled to elect or nominate one member to the Wireless Section Committee. For this purpose, a Local Wireless Section should consist of at least 15 members, who must already be members of the main Wireless Section.

(6) The papers and the discussions of the Wireless Section, and other wireless papers, in addition to appearing in the *Journal* of the Institution, should be issued separately in the form of "Proceedings of the Wireless Section."

(7) As soon as the necessary alterations to the Bye-laws can be made, the Chairman of the Wireless Section Committee should be an *ex-officio* member of Council, in the same way as are the Chairmen of Local Centres (in the meantime he will be invited to attend all meetings of the Council).

(11) Informal Meetings.

Eleven meetings have been held during the session, the average attendance being 65, as against 59 last year.

A new feature was introduced during the Session by holding a meeting at the Rockefeller Building, University College, Gower-street, where Mr. W. C. Clinton, B.Sc., opened a discussion on the electrical installation of the building.

The primary object of the meetings is to encourage the younger members to participate in discussions on technical subjects, and the Council would like to see fuller advantage taken of these fortnightly gatherings.

The précis of the meetings which appear in the technical Press are carefully prepared, and any statements by speakers likely to be questioned or to cause controversy are omitted.

(12) Students' Sections.

There are at present 3 586 Students on the Register of the Institution, and a very full programme of meetings, visits to works, and social functions has been carried out at the eight Students' Sections now in existence, viz. at London, Birmingham, Glasgow, Leeds, Liverpool, Manchester, Newcastle and Sheffield.

Addresses to the London Students' Section were given by the President and Lt.-Col. K. Edgcumbe, R.E. (T.A.), Vice-President. The President also addressed the South Midland Students' Section.

The London Students' Section created an interesting precedent last summer by holding a Summer Meeting in London, and it was attended by, in addition to London Students, some 20 Students from the provinces and Scotland.

The Meeting, which began on Saturday evening, the 25th July, with a Smoking Concert, was continued as follows :—

Sunday.	A trip up the Thames to Chertsey and back, by steam launch.
Monday.	Visit to the Woolwich works of Messrs. Siemens Bros. and Co., Ltd.
Tuesday.	A motor tour through Kent and Surrey.
Wednesday.	Visit to Wembley Exhibition.
Thursday.	Visit to the Marconi stations at Ongar and Brentwood.
Friday.	Visit to the Research Laboratories of the General Electric Co., Ltd., Wembley.
Saturday.	Visit to the Beckton works of the Gas Light and Coke Co., Ltd.

The proceedings were brought to a close on the Saturday evening (the 1st August) by a farewell Dinner at the Holborn Restaurant.

The Council desire to express the thanks of the Institution for the hospitable welcome extended on the occasion of the visits to works, etc.

The meeting was very successful and thanks are due to the then Hon. Secretary (Mr. J. H. Reyner) and the Committee of the London Students' Section for the excellent arrangements made by them.

(13) Faraday Lecture.

The Faraday Lecture this session was given by Mr. A. P. Trotter, who took for his subject "Illumination

and Light," and it was delivered at Cardiff, Dublin, Liverpool and Manchester. The attendances were very satisfactory, and the principal object of the Lecture, namely, to direct the attention of the general public to electrical engineering, was achieved to a marked degree by the presence of many hundreds of non-members.

(14) REVIEWS OF PROGRESS.

The Council decided this session to publish in the *Journal* periodical reviews of progress in electrical engineering, and for this purpose the subject has been divided into the following 13 sections :—

*Electrical Plant and Machinery (including Marine Work).
*Power Stations and their Equipment.
Transmission and Distribution.
Industrial, Agricultural and Domestic Applications (including Illumination and Tariffs).
Electricity in Mining.
Traction.
Electrical Measuring Instruments and Sensitive Controlling Apparatus.
*Telegraphy and Telephony.
Radio-telegraphy and Radio-telephony.
Electro-chemistry and Electro-metallurgy.
*Electro-physics.
*Research.
*Standardization.

Whilst it is hoped eventually to publish each year reviews of all the sections, a beginning has been made this year with the sections marked with an asterisk. A further selection will appear in 1927, and subsequent action will be based on the experience gained during the first two years.

These reviews have been prepared for the purpose of briefly recording recent advances, and they are intended, not so much for the information of experts in the particular subject under review, as for the information of those members of the Institution who wish to follow the trend of progress in branches of electrical engineering other than their own.

The Council will be glad if members will forward to the Secretary of the Institution any criticisms which they may wish to make on the present reviews, and also on the ground to be covered by those to be published in the future, more especially in regard to points of interest which come under their notice and on which they consider comment might usefully be made.

(15) SCHOLARSHIPS.

The following Scholarships have been awarded by the Council :—

A David Hughes Scholarship.

(Value £50 ; tenable for one year.)

G. N. Peel, B.Sc. (Armstrong College, Newcastle-upon-Tyne).

Salomons Scholarships.

(Value £50 each ; tenable for one year.)

R. O. Carter [City and Guilds (Engineering) College, London].

H. S. Leman (East London College, London).

War Thanksgiving Education and Research Fund (No. 1).

A grant of £100 for educational purposes has been made by the Council, under the provisions of the Trust Deed, to F. W. Rudge (Royal Technical College, Glasgow).

(16) ANNUAL CONVERSAZIONE.

The Annual Conversazione was held at the Natural History Museum, South Kensington, London, on the 2nd July, 1925, when about 1 400 members and guests attended.

The Conversazione in 1926 will be held at the Science Museum, South Kensington, instead of the Natural History Museum.

(17) ANNUAL DINNER.

The Annual Dinner was held at the Hotel Cecil, London, on the 11th February, 1926, and was particularly well attended, the members and guests present numbering 575.

An account will be found in the *Journal*, 1926, vol. 64, p. 436.

(18) SUMMER MEETING.

A Summer Meeting attended by some 350 members and ladies was held at Birmingham, from the 9th to the 12th June, 1925, by invitation of the Committee of the South Midland Centre, who had arranged an interesting programme of functions, excursions and visits to works.

The works visited during the Meeting were as follows :—

The Austin Motor Co.'s works, Longbridge.
The Prince's power station of the City of Birmingham at Nechells, and the mercury-arc rectifier substation at Longbridge.
The British Thomson-Houston Co.'s works, Rugby.
The General Electric Co.'s works, Witton.
The Shropshire, Worcestershire and Staffordshire Electric Power Co.'s new power station, under construction at Stourport.

Other places visited were Droitwich, Evesham, Stratford-on-Avon and Warwick.

The visitors enjoyed the hospitality of :—

The Lord Mayor and Lady Mayoress of Birmingham.
The City of Birmingham Electric Supply Department.
The Council and Senate of the University of Birmingham.
The British Thomson-Houston Co., Ltd.
The General Electric Co., Ltd.
The Leamington and Warwick Electrical Co., Ltd.
The Leicestershire and Warwickshire Electric Power Co.
The Midland Electric Light and Power Co., Ltd.
The Shropshire, Worcestershire and Staffordshire Electric Power Co.

The Council have expressed the cordial thanks of the Institution to all those named. They also wish to place on record their high appreciation of the work of the Committee of the South Midland Centre in making the arrangements for the Meeting, and particularly of that of the Chairman of the Centre (Mr. W. Lawson) and the Hon. Secretary (Mr. H. Hooper).

(19) Paris International Conference on Large E.H.T. Supply Systems.

The third session of the above Conference took place in Paris from the 16th to the 25th June, 1925. The number of countries represented was 27, Great Britain being represented by 7 delegates appointed by the Institution, and 21 ordinary members. The Institution's delegates were Mr. W. B. Woodhouse (chief delegate), Mr. A. R. Everest, Mr. P. V. Hunter, C.B.E., Mr. R. B. Matthews, Mr. A. Page, Mr. G. V. Twiss, and Mr. E. B. Wedmore.

The number of papers presented was 98.

(20) New York Meeting of the International Electrotechnical Commission.

A meeting of the International Electrotechnical Commission will be held at New York in April, 1926. Sixteen countries will be represented and there will be some 24 British delegates under the leadership of Sir R. T. Glazebrook, D.Sc., F.R.S. The delegates appointed by the Council to represent the Institution are Mr. C. P. Sparks, C.B.E., Lt.-Col. K. Edgcumbe, R.E. (T.A.), Mr. S. W. Melsom, and the Secretary.

(21) Wireless Telegraphy and Signalling Bill.

The above Bill, in regard to which the Council made certain representations to the Postmaster-General, as mentioned in the last Annual Report, was not proceeded with by the Government.

(22) Engineering Institute of Canada.

Mr. Frank Gill, Past-President, who was on a visit to Canada in June, 1925, was on that occasion the bearer of greetings and of a message of goodwill from the Institution to the Canadian Institute. The following message has since been received in response :—

"The Council of the Engineering Institute of Canada was gratified to receive the kind messages of the Council of the Institution of Electrical Engineers, and was particularly pleased to have the opportunity of welcoming the Institution's Past-President, Mr. Frank Gill. It is the Council's hope that, in the future, more frequent opportunities will occur for the interchange of friendly messages with the Institution."

(23) The Society of Radiographers.

The Council, who took an important part in founding the Society of Radiographers in the year 1920, and who, under that Society's constitution, had until last year nominated six out of the 18 members of the Society's Council, have withdrawn their nominees and terminated the Institution's connection with the Society.

This action was taken because the majority of the Council of the Society of Radiographers resolved upon certain alterations to the Society's Articles, which, in the opinion of the Council of the Institution, were not in the public interest.

(24) The Institution of Municipal and County Engineers.

The Council received in November, 1925, a letter from the Privy Council enclosing a Petition for, and a Draft of, a Charter of Incorporation applied for by the above Institution, together with a copy of a petition of the Institution of Civil Engineers, and asking for any observations the Council might have to offer thereon.

After due consideration the Council intimated to the Privy Council that, in their opinion, so far as Engineering Bodies are concerned, a Charter should be granted only to those which grant diplomas based solely on technical qualifications and not on the holding of a particular type of appointment, and on that ground they are not in favour of a Charter being granted to the Institution of Municipal and County Engineers.

(25) Model General Conditions for Contracts.

The September, 1921, edition of the Model Conditions "A" (Home—With Erection) has been amended to make it clear that the Regulations and Bye-Laws with which the Contractor has to conform are those which the Local or other Authorities are authorized by Statute to make. In Clause 37 of the new edition (revised January, 1926) the words "which they are authorized by Statute to make and" have been inserted after the word "Authorities." The new edition in all other respects conforms with the old edition.

The following sets of Conditions were also issued during the Session :—

B1. Conditions for Export Contracts (Delivery F.O.B.).

B2. Conditions for Export Contracts (including complete erection or supervision of erection).

(26) Technical Committees.

The former five "Sectional Committees," viz.

Electro-chemistry and Electro-metallurgy,
Electricity in Mines,
Lighting and Power,
Telegraphs and Telephones,
Traction,

have been reorganized as nine Committees, to be known in future as "Technical Committees," as follows :—

Electrical Plant and Machinery (including Marine Work).
Power Stations and their Equipment.
Transmission and Distribution.
Industrial, Agricultural and Domestic Applications (including Illumination and Tariffs).
Electrical Measuring Instruments and Sensitive Controlling Apparatus.
Traction.
Electricity in Mines.
Electro-chemistry and Electro-metallurgy.
Telegraphs and Telephones.

The functions of the Committees will be to obtain suitable papers on subjects within their respective fields and to assist the Papers Committee in connection with the Reviews of Progress referred to in par. (14) of this Report.

(27) Gas and Electricity Undertakings.

With the concurrence of the Council of the Institution and of the National Gas Council, a Joint Committee has been set up with the following reference :—

"To consider whether in the national interest an Inquiry might advantageously be held into the

possibility of closer co-operation between Gas and Electricity Undertakings in promoting capital and fuel economy in the supply to the public of energy derived from coal"

with the understanding that no Reports or Discussions of the Committee are to be published without the consent of both Councils.

The Committee is constituted as follows :—

Mr. R. A. Chattock Mr. J. S. Highfield Mr. G. W. Partridge Mr. C. P. Sparks, C.B.E. Mr. W. B. Woodhouse	Nominated by the Council I.E.E.
Mr. D. Milne Watson, D.L. Mr. W. Cash, F.C.A. Sir A. Duckham, K.C.B. Mr. A. W. Smith Mr. C. Wood, O.B.E., F.C.S.	Nominated by the National Gas Council.

(28) Library.

During the year **163** books and pamphlets have been presented to the Reference Library by members and others, and **80** volumes have been purchased. The total number of readers for the year was 3 537, of whom **114** were non-members, as against **2 419** and **108** respectively in 1924–1925.

The Council have pleasure in recording the continued circulation of books from the Lending Library, to which **71** new volumes have been added. During the year, **1 938** books were issued to **857** borrowers, the corresponding numbers for the previous year being **2 184** and **872** respectively.

A new edition of the Lending Library Catalogue with a subject index is now available, and copies will be forwarded to members on application to the Secretary.

(29) Gifts to the Institution.

The Council have pleasure in recording the following gifts to the Institution, and express their cordial thanks to the donors :—

Donor.	*Gift.*
The Eastern Telegraph Co., Ltd.	A Thomson (Lord Kelvin) marine-pattern galvanometer.
Mr. Napier Prentice . .	Lane-Fox lamp.

(30) Electrical Appointments Board.

The number of applicants for posts who were registered on the 31st March, 1926, was 87, against a total of 78 last year.

A classified register of members seeking positions, containing particulars of their training and experience, is available for inspection at the Institution offices, and the Secretary of the Board will gladly put employers in touch with highly qualified electrical engineers.

The Council earnestly hope that members who are in a position to assist will not fail to make use of the register.

(31) The Journal of the Institution.

The net cost of printing and posting the *Journal* in 1925, after allowing for sales and the revenue received from advertisements, was **£4 166**, as compared with **£3 078** in **1924**. This increase was due to the greater size of the volume (**1 180** pages as compared with **1 006** in the previous volume), the larger number of copies printed (**12 500** as against **12 000**) and an appreciable increase in the number of illustrations. The revenue from sales and advertisements was practically the same in the two years.

(32) "Science Abstracts."

The Physics volume of *Science Abstracts* for **1925** contained **195** pages less than for **1924**, and the Electrical Engineering volume contained **39** pages more than in the previous year. The Accounts show that the net cost of the publication to the Institution in **1925** was **£281**, which the Council consider satisfactory.

The Council deeply regret to have to record the death of Mr. W. R. Cooper, M.A., B.Sc., who had so ably edited the publication since October, 1922.

(33) Committee on Electricity in Agriculture.

The Report of the above Committee has been presented to the Council and was published in the *Journal* (1925, vol. 63, p. 838).

On the recommendation of the Committee, the Council have instructed them (1) to prepare a special recommendation to the Government in connection with the provision of financial assistance for rural electrification and (2) to co-operate with agricultural bodies in tests and experimental work.

The Council have also addressed a letter to the Electricity Commissioners urging that, in any schemes of railway electrification, regard should be had to the requirements of rural areas.

(34) National Certificates and Diplomas in Electrical Engineering.

For the final examinations of the year **1925** the Joint Standing Committee representing the Board of Education and the Institution examined at various schools and colleges students from **46** approved courses for the award of Ordinary Certificates in Electrical Engineering, **17** courses for Higher Certificates, **3** courses for Ordinary Diplomas and **1** course for Higher Diplomas.

The final examinations were held during the summer of **1925** and the number of Certificates and Diplomas awarded was as follows :—

229 Ordinary Certificates.
79 Higher Certificates.
8 Ordinary Diplomas.
2 Higher Diplomas.

(35) Regulations for the Electrical Equipment of Ships.

The Council have authorized the publication of a revised edition, the second, of the Regulations.

(36) Regulations for the Electrical Equipment of Buildings.

As a result of comments and suggestions received in connection with the revised edition of the Wiring Regulations, the Wiring Rules Committee recommended the Council last summer to publish a small number of amendments which were considered to be of sufficient importance to justify their immediate publication. Further alterations have been, and some still are, under consideration by the Committee and, if not published separately, will be incorporated in the next revision of the Regulations. The Committee are also conferring with the B.E.A.M.A. and the B.E.S.A. in connection with certain of the Regulations.

(37) Electricity Regulations.

The Council have approved for submission to the Electricity Commissioners a Report from the Electricity (Supply) Regulations Committee containing recommendations on the Electricity Commissioners' Regulations (A) for securing the safety of the Public, and (B) for ensuring a proper and sufficient supply of Electrical Energy.

(38) Proving House.

During the session the Council received and approved the following Report of the Proving House Committee:

"Having in view that there appears to be very little interest in the establishment of a Testing Authority and Proving House, as has been evidenced by the poor attendance at the meetings held, and considering that the purpose of the Authority, viz. to decide whether apparatus complies with some recognized standard or specification, does not meet the whole of the requirements of those desiring the establishment of the Authority and Proving House, and, further, as no adequate financial support is forthcoming, the Committee recommend to the Council that the proposal be dropped.

"The Committee further desire the Council to note that it has been reported that most of the services of such an Authority, so far as testing is concerned, can be obtained on payment from the National Physical Laboratory, the Manchester Corporation, and other public and also several private laboratories."

(39) Status of Engineer Officers, R.N.

In December, 1925, the Council received an invitation from the Institution of Mechanical Engineers to nominate representatives to join a delegation which the First Lord of the Admiralty had consented to receive on the status of Engineer Officers of the Royal Navy, which, it was considered, was detrimentally affected by the new conditions introduced by Fleet Order No. 3241, of the 21st November, 1925.

Representatives were duly appointed and these met in conference delegates of the Institutions of Civil and of Mechanical Engineers and of the Institution of Naval Architects, when a memorandum was prepared for submission to the First Lord.

The deputation was received at the Admiralty on the 14th January, 1926, and laid before the First Lord the objections of the four Institutions to the changes effected by the Fleet Order in question, the principal change being the deprival of Engineer Officers of the executive rank which they had held in common with deck officers since 1915.

A reply has since been received stating that, in the view of the Admiralty, there are no real grounds for grievance and that experience will convince the Engineer Officers of the Navy that there is nothing in the Order derogatory to their position.

The reply is considered by the members of the joint Conference as unsatisfactory and steps are being taken to carry the matter a stage further.

(40) Benevolent Fund.

The Committee of Management of the Benevolent Fund of the Institution report that on the 31st December, 1925, the Capital Account of the Fund stood at £10 004 11s. 3d., and the accumulated income at £2 380 9s. 6d. The donations and subscriptions to the Fund in 1925 amounted to £1 241 3s. 7d.

In the course of 1925, 78 grants were made to 30 persons, amounting to a total of £1 199 5s. 1d. The following table summarizes the operations of the Fund during the last 10 years:—

Year	Subscriptions and donations received	Total grants made during year	No. of cases assisted
	£	£	
1916	239 100 (Legacy)	195	7
1917	194	198	11
1918	259	230	10
1919	537	291	12
1920	821	341	11
1921	616 809 (Hughman collection)	525	14
1922	632 1 768 (Hughman collection)	776	16
1923	637	1 034	21
1924	1 152	1 323	26
1925	1 241	1 199	30

(41) Annual Accounts.

Excess of Income over Expenditure.—After making provision for contingencies, there is a margin to the good on the Revenue Account for 1925 of £1 196 8s. 11d. This amount, which has been carried to the credit of the General Fund, compares with £2 925 0s. 8d. in 1924.

Mortgage.—

	£	s.	d.
In the Accounts for 1924 this stood at	13 721	2	0
Amount of repayments during the year	1 127	5	10
The amount now stands at	£12 593	16	2

Assets.—Taking the Tothill-street property and the investments at cost, and the Institution Building and

lease, the library and furniture, etc., at the values standing in the books after writing off depreciation—

	£	s.	d.
the Assets amount to	145 336	5	0
against Liabilities	8 007	12	10
leaving a surplus of	137 328	12	2
which, in comparison with that of the year 1924, viz.	133 016	0	11
shows an improvement of	£4 312	11	3

The surplus referred to above of £137 328 12s. 2d. is made up as follows :—

Assets.	£	s.	d.	£	s.	d.
Institution Building and Tothill-street Property	92 289	3	11			
Less Mortgage	12 593	16	2			
				79 695	7	9
Investments, Cash, etc.				57 689	8	11
Stock of Paper, Libraries and Furniture ..				7 951	8	4
				£145 336	5	0
Less *Liabilities.*						
Trust Fund Income Accounts	468	11	1			
Sundry Creditors ..	5 344	18	4			
Repairs Suspense Account	1 795	5	8			
Subscriptions received in advance	398	17	9			
				8 007	12	10
				£137 328	12	2

(42) THE INSTITUTION AND BODIES ON WHICH IT IS REPRESENTED.

Appendix C shows in diagram form the organization of the Institution and the bodies on which it is represented.

APPENDIX A.

MEMBERSHIP OF THE INSTITUTION.

The changes in the membership since 1st April, 1925, are shown in the following table :—

	Hon. Mem.	Mem.	Assoc. Mem.	Grad.	Studt.	Assoc.	Total.	TOTAL.

APPENDIX B.

MEETINGS.

The following is a list of the meetings held during the past twelve months :—

Ordinary Meetings ..	15
Wireless Section Meetings	8
Informal Meetings ..	12
Council Meetings ..	18
Local Centres :—	
Irish	6
Mersey and North Wales (Liverpool) ..	7
North-Eastern ..	11
North Midland ..	11
North-Western ..	11
Scottish	7
South Midland ..	10
Western	10
Local Sub-Centres :—	
Dundee	7
East Midland ..	9
Sheffield	7
Tees-side	7
Students' Sections :—	
London	8
South Midland ..	9
North Midland ..	11
Liverpool	8
North-Western ..	9
North-Eastern ..	12
Scottish	9
Sheffield	5
Committees :—	
Benevolent Fund ..	6
Earthing to Water Mains	3
Electricity in Agriculture	1
Electricity (Supply) Bill	2
Electricity (Supply) Regulations ..	16
Examinations (and Sub-Committee) ..	7
Committees (*cont.*) :—	
Finance (and Sub-Committee) ..	8
General Purposes (and Sub-Committee) ..	14
Informal Meetings ..	5
Lighting and Power ..	1
Membership	11
Model General Conditions (and Sub-Committee) ..	3
Model General Conditions (Export) ..	1
Papers	10
Paul Scholarship ..	3
Proving House ..	2
"Science Abstracts"	5
Ship Electrical Equipment (and Sub-Committee) ..	1
Supply Pressures ..	1
Technical Committees : ("Instruments," "Mines," "Power Stations," "Applications," "Telegraphs and Telephones," "Traction," "Transmission")	9
Wireless Section (and Sub-Committee) ..	11
Wireless Telegraphy Bill	1
Wiring Rules (and Sub-Committees) ..	11
Other Committees ..	15
Total	374

APPENDIX C.

THE INSTITUTION OF ELECTRICAL ENGINEERS.

- Ordinary Meetings
- Wireless Section Meetings
- Informal Meetings
- Meetings of London Students' Section

COUNCIL.

Local Centres.
- Argentina
- China
- Irish
- Mersey and North Wales (Liverp'l)
  - †Mersey and North Wales (Liverp'l) S.S.
- North-Eastern
  - *Tees-side S.C.
  - †North-Eastern S.S.
- North Midland
  - †North Midland S.S.
  - *Sheffield S.C.
  - †Sheffield S.S.
- North-Western
  - †North-Western S.S.
- Scottish
  - *Dundee S.C.
  - †Scottish S.S.
- South Midland
  - *East Midland S.C.
  - †South Midland S.S.
- Western

* S.C.=Sub-Centre.

† S.S.=Students Section.

COMMITTEES.
(Standing.)

Benevolent Fund
Electrical Appointments Board
Examinations
Finance
General Purposes
Informal Meetings
Library
Local Centres
Membership
Papers
Paul Scholarship
"Science Abstracts"
Ship Electrical Equipment
Wireless Section
Wiring Rules

Technical Committees.
- Electrical Measuring Instruments and Sensitive Controlling Apparatus
- Electrical Plant and Machinery, including Marine Work
- Electricity in Mines
- Electro-chemistry and Electro-metallurgy
- Industrial Agricultural and Domestic Applications, including Illumination and Tariffs
- Power Stations and their Equipment
- Telegraphs and Telephones
- Traction
- Transmission and Distribution

COMMITTEES.
(Special.)

Earthing to Water Mains
Electricity in Agriculture
Electricity (Supply) Bill
Electricity (Supply) Regulations
Examinations Sub-Committee
Model General Conditions
Proving House
Supply Pressures
Wireless Telegraphy Bill

BODIES ON WHICH THE INSTITUTION IS REPRESENTED.

Alloys of Iron Research (Royal Society)
Association of Teachers in Technical Institutions (Special Committee)
Birmingham Chamber of Commerce
Bradford Public Libraries Committee
Bristol University
British Cast Iron Research Association
British Electrical and Allied Industries Research Association
British Electrical Development Association
British Engineering Standards Association
British National Committee of the International Electrotechnical Commission
British National Illumination Committee of the International Illumination Commission
Conference on Smoke Abatement, 1926
Corrosion Research Committee of Institute of Metals
Electric Vehicle Committee of Great Britain
Engineering Joint Council
Fifth International Road Congress, 1926
Imperial College of Science and Technology, Governing Body
Imperial Mineral Resources Bureau Conference
Institution of Civil Engineers, Engine and Boiler Testing Committee
Institution of Heating and Ventilating Engineers, Committee on Utilization of Exhaust Steam and Waste Heat
International Electrotechnical Commission, U.S.A., 1926
International Scientific Unions
Leeds Civic Society
Leeds Municipal Technical Library Committee
Loughborough Technical College Advisory Committee
Metalliferous Mining (Cornwall) School, Governing Body
Middlesbrough Technical College, Governing Body
National Committee for Physics (Royal Society)
National Committee on Radio Telegraphy (Royal Society)
National Physical Laboratory, General Board
National Register of Electrical Installation Contractors
Professional Classes Aid Council
Royal Engineer Board
Royal Sanitary Institute Jubilee Congress, 1926

(Continued at foot of col. 1.)

(Continued from foot of col. 3.)

Standing Joint Committee on Gas and Electricity
Standing Joint Committee for National Certificates and Diplomas in Electrical Engineering
Union of Lancashire and Cheshire Institutes, Panel for Engineering
Women's Electrical Association
Women's Engineering Society
World Power Conference; British National Committee

THE INSTITUTION OF ELECTRICAL ENGINEERS.

We beg to report that we have audited the Balance Sheet of The Institution of Electrical Engineers, dated 31st December, 1925, and above set forth, together with the annexed Statements of Account. We have obtained all the information and explanations we have required. In our opinion the Statements are correct, and the Balance Sheet is properly drawn up so as to exhibit a true and correct view of the state of the Institution's affairs according to the best of our information and the explanations given to us and as shown by the books of the Institution.

21st April, 1926.

ADDITIONAL APPLICATIONS OF THE MAGNETIC DRUM PRINCIPLE.*

By N. W. McLachlan, D.Sc. (Eng.), Member.

(*Paper first received 20th October, and in final form 15th December, 1925.*)

Summary.

Further applications of the magnetic drum principle using the magneto-cohesion effect described in a former paper are treated in detail. A description is given of a new form of siphon recorder, with a very small transit time, for high-speed reception on commercial circuits (beam stations). The shoe of the recorder is of special construction and the operating force for a current of 4 mA is about 4 lb., which is extremely large for a recording instrument. Owing to the rapidity of motion of the siphon lever it is possible to secure legible tape records when atmospheric disturbances are neither too severe nor too frequent. The procedure adopted in reading and transcribing messages at the central receiving station is given. Other applications of the magnetic drum principle to a delayed-action relay and to the checking of clocks by wireless signals are described. The thermionic valve circuits associated with the various devices are discussed and portrayed diagrammatically.

Table of Contents.

1. Introduction.

The principle underlying the operation of the apparatus described herein has been outlined previously.† Instruments identical in design with that used in the Institution Lecture Theatre to receive high-speed telegraphic signals from Paris (UFP) in April, 1923, are in service at sea and on shore and have proved absolutely reliable. Even after 10 000 hours' running the cast-iron rings on the drum are true to a small fraction of a mil. The life of a shoe is at least 4 000 hours when working at 100 words per min., the corresponding drum speed being about 150 r.p.m. The life is prolonged by having good alignment so that the toe of the shoe is on the crown of the drum when the relay tongue rests on the spacing stop and the line of pull is tangential to or passes slightly above the drum at this point. Under these conditions the tension required on the back spring is very slight and the normal pressure between shoe and rings is almost entirely due to the effect of the magnetizing current. Of course if comparatively large currents are used, say from 5 to 8 mA, or when working double current if the drum is not demagnetized during spacing (due to the polarization exceeding the signal magnetization or vice versa), the life of the shoe will be reduced.

2. Relay Classification.

Electromagnetic relays can be divided broadly into two types: (1) Those in which the energy of the incoming signal is expended, (*a*) in moving the tongue from one stop to another, this being represented by $W = \int mvdv = \int Fdx = \int eidt$, where m = equivalent mass, v = velocity, F = force, x = distance, i = current and e is the back E.M.F. due to the motion of the armature; (*b*) in energizing the magnetic circuit by the current in the coil, this being represented by $\frac{1}{2}Li^2$ + (mutual energy-changes) + (magnetization losses due to hysteresis and eddy currents); * (*c*) in the continuous generation of heat due to the current in the winding, this being $\int i^2rdt$. (2) Those relays in which the incoming signal supplies the energy for (*b*) and (*c*), that for (*a*) being obtained from an external source. Assuming the signal energy to be equal for both types of relay, it is manifestly clear that (*b*) and (*c*) can either individually or collectively be greater for the second than for the first type. Moreover, the degree of magnetization can be greater for the second type. The latter condition is usually concomitant with a larger operating force, so that a relay of the second class will, for the same energy input and equal moving masses, be more rapid in its action and the pressure at the contacts will be firmer than for a relay of the first class. Put in another way, the energy input for equal performance at any given speed of reception is less for a relay of class (2) than for a relay of class (1). Viewing the situation broadly, the second type can be regarded as belonging to the "trigger" denomination.† Taking a case in point, there is the magnetic drum type of relay in which the signal energy is expended entirely in (*b*) and (*c*) [chiefly in dissipation of heat, excepting at high speeds of operation where (*b*) is a larger proportion of the total than at, say, 100 words per min.] to cause a force between the revolving drum and the shoe. There is no back E.M.F. due to the motion of the shoe, excepting that due to hysteresis and eddy currents, which is relatively small, and the magneto-cohesion effect yields a manifold amplification.

The magnetic drum variety possesses the advantage

* The Papers Committee invite written communications (with a view to publication in the *Journal* if approved by the Committee) on papers published in the *Journal* without being read at a meeting. Communications should reach the Secretary of the Institution not later than one month after publication of the paper to which they relate.

† *Journal I.E.E.*, 1923, vol. 61, p. 907.

* In addition to $\frac{1}{2}Li^2$ there are mutual energy variations due to the armature being in the magnetic field of magnet and field coils, just as there are mutual effects between two coupled electrical circuits.

† The Piedfort relay is also in this class (see *Journal I.E.E.*, 1923, vol. 61, p. 926).

that for the same energy input, the ratio (torque/moment of inertia) is much greater than that for a relay of class (1), thereby ensuring a reduced transit time and a sure contact. There is, of course, the question of revolving the drum continuously, but this is a simple matter at a radio or other central station. In some forms of relay in class (1) a large polarizing current is essential for the electromagnet. The energy absorbed by the winding of the electromagnet is usually equal to or greater than that required by the motor which turns the drum.

It is of interest to observe that the sensitivity of both classes of relay would be appreciably augmented if the ohmic resistance of the winding could be reduced to, say, one-tenth of its present value by the aid of wire of higher conductivity. Also the employment of suitable magnetic material of lower hysteresis loss, reluctivity and coercivity would assist admirably in improving relays in general.

3. Small Drum Recorders.

To meet special requirements a new type of recorder with a drum of smaller dimensions than that used on the standard pattern has been developed. This type will be used for high-speed reception in the beam stations of the Marconi Co. The reduced dimensions give a shorter magnetic path through he shoe, and for a fixed number of ampere-turns the pull with a shoe of definite size is a good deal larger than that on the standard,* although in this respect the state and nature of the drum and shoe surfaces play an important part. The peripheral speed of the small drum appreciably exceeds that of the standard, and the surfaces of the cast-iron rings during operation are somewhat different in the two cases. In general there is a brownish deposit on the small drums and this is usually accompanied by large operating forces. The general arrangement is given in Figs. 1A and 1B, the

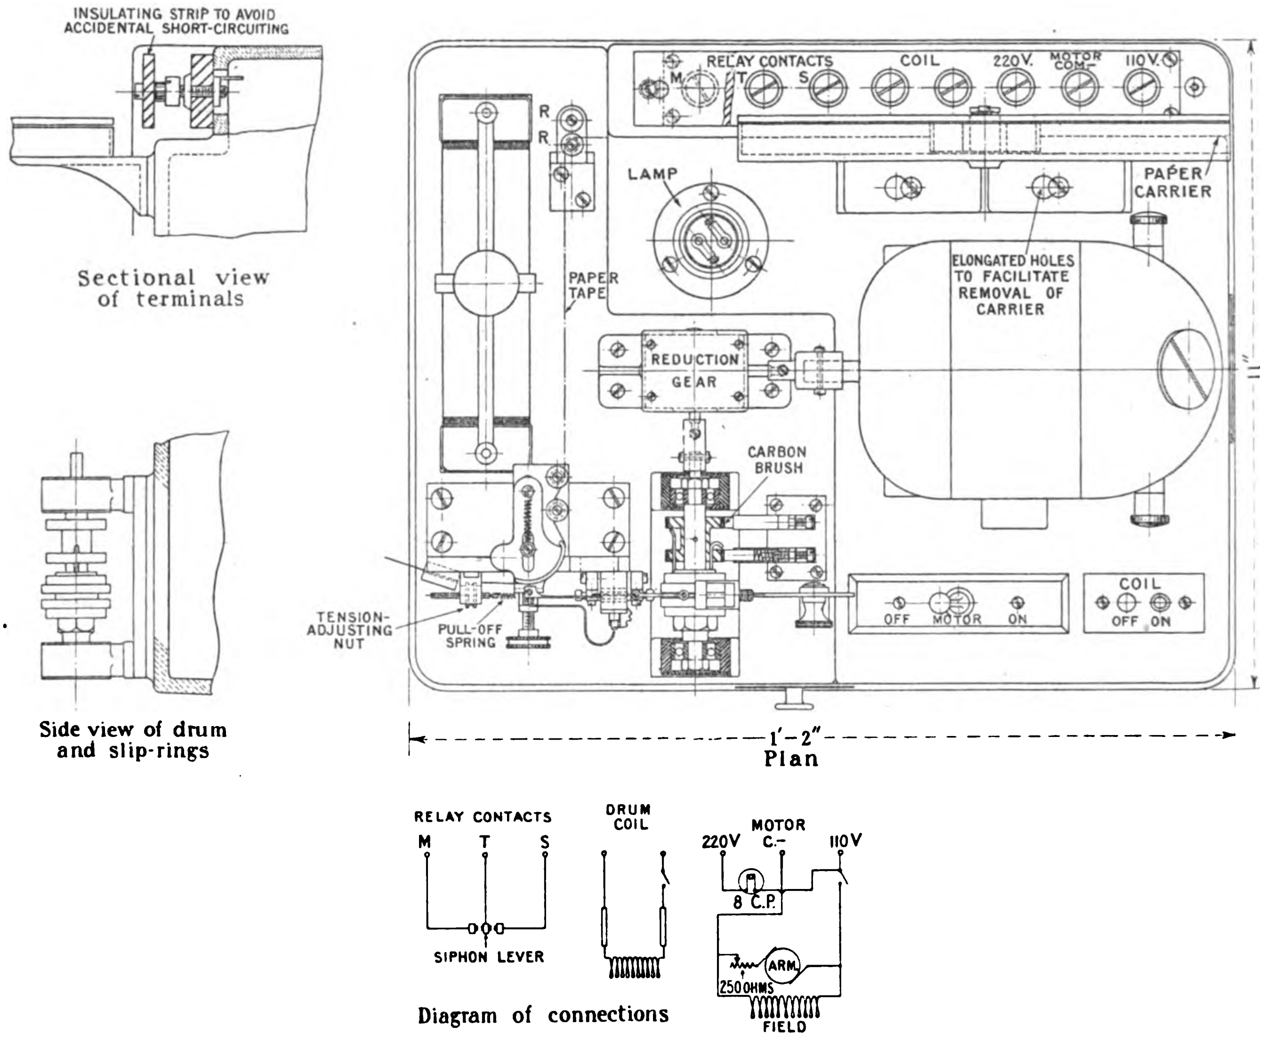

Fig. 1A.—General plan arrangement of magnetic drum recorder (transoceanic pattern) with vertical paper drive. The inkwell is not shown.

former also showing a cross-section of a small drum, from which the construction will be clearly seen. The bobbin is of either ebonite or stabilite wound with about 3 000 turns of either 46 s.s.c. or 48 d.s.c. wire. The larger wire is usually preferable owing to the smaller resistance which measures about 600 ohms, whereas with 48 d.s.c. wire the resistance is double this value. The sensitivity obtained with these windings is ample for recording purposes, but it can be increased by winding the bobbin very carefully with the best quality possibility of short-circuiting of turns the bobbin may be made of bakelite. The bobbin is fixed on a brass former which prevents the flanges from bulging out sideways during winding. The whole is impregnated with fluid bakelite and subjected to the necessary heat treatment. The brass former prevents distortion during the latter process.

The pull and flux curves for the drum of Fig. 1 are given in Fig. 2, and similar curves for the standard recorder have been added for the purpose of com-

No. 48 S.W.G. enamelled wire. The number of turns will now be approximately thrice that with silk-covered wire of the same gauge, so that only one-third the current will be required to produce the same force between drum and shoe. The resistance is augmented considerably so that although the current sensitivity is increased the energy sensitivity is decreased. This, however, may be a requisite feature where valve circuit operation pertains. The insulation between adjacent turns of enamelled wire will not withstand a large voltage, and to ensure reliability and minimize the parison. The small drum is obviously much more sensitive, and care must be exercised in designing small drum recorders that the working forces are not too large. Excessive forces mean considerable wear and tear on the mechanism, and the frequent occurrence of mechanical fractures. When using the circuit depicted in Fig. 3 there is a large initial charging current to the condenser when the tongue meets stop M, and this current may be many times the steady current. The initial rate of rise of this current is E/L, where E = the E.M.F. of the battery and L the inductance of

the drum. With 100 volts and a coil of 3 000 turns the initial magnetization grows at the rate of 60 000 ampere-turns per second. Moreover, the initial force is greater than the steady force and may reach a value of 6 lb.

r = safety resistance (200 ohms).

or more, which is enormous for a recording instrument. Thus the transit time is appreciably smaller than that of the standard recorder, and when the stops are open fairly wide the action of the instrument—with appropriate drum speed—is accompanied by a series of hammer-blows. The steady current which follows the charge to the condenser must be sufficient to prevent the lever arm bouncing off the marking contact. The marking transit time, especially when the amplitude of the siphon point is large, say ¼ in., can be controlled by varying the speed of the drum, and it is interesting to hear the blows weakening and to see the transverse lines becoming more inclined to the vertical as the speed is reduced. A point is usually reached when the motor torque is insufficient to drive the drum. The gear ratio for the drum is 5 : 1 so that with a motor working at 3 000 r.p.m. the drum speed is 600 r.p.m. For an amplitude of 0·0875 in. on the tape the peripheral speed is then just adequate to obtain as large a final velocity of the tracing point as the working force can cause with an operating current of 4 to 5 mA. For continuous operation a drum speed of this magnitude would cause heating and undue wear as well as violent treatment of the recording mechanism. It is arranged, therefore, that the motor speed shall not exceed a certain limit and the speed can be reduced below this limit by means of a rheostat. In this way the marking transit time of the siphon lever is controlled. The siphon mechanism and shoe are designed to give minimum transit time. The condition to be fulfilled is that the moment of inertia of the siphon mechanism* shall be equal to that of the shoe, and that the total moment of inertia shall be as small as is compatible with mechanical strength and reliability.

The small drum instruments are useful for measuring time intervals between successive electrical or other impulses which can be converted to electrical form. Knowing the speed of the travelling paper-tape, the time interval is a function of the distance between vertical marks on the tape. The apparatus is also of value for circuits where atmospherics are troublesome, e.g. long-wave transoceanic circuits. A sample of tape obtained from a long-wave circuit is shown in Fig. 4. This is similar in appearance to that obtained with the standard type of recorder when the drum speed is about 250 r.p.m. and the tape moves slowly. There is little difference in the appearance of the tape from the two types of instrument unless the duration of the disturbance is very short, and the balance is in favour of the small drum. This aspect of the subject is treated below under "Transit times."

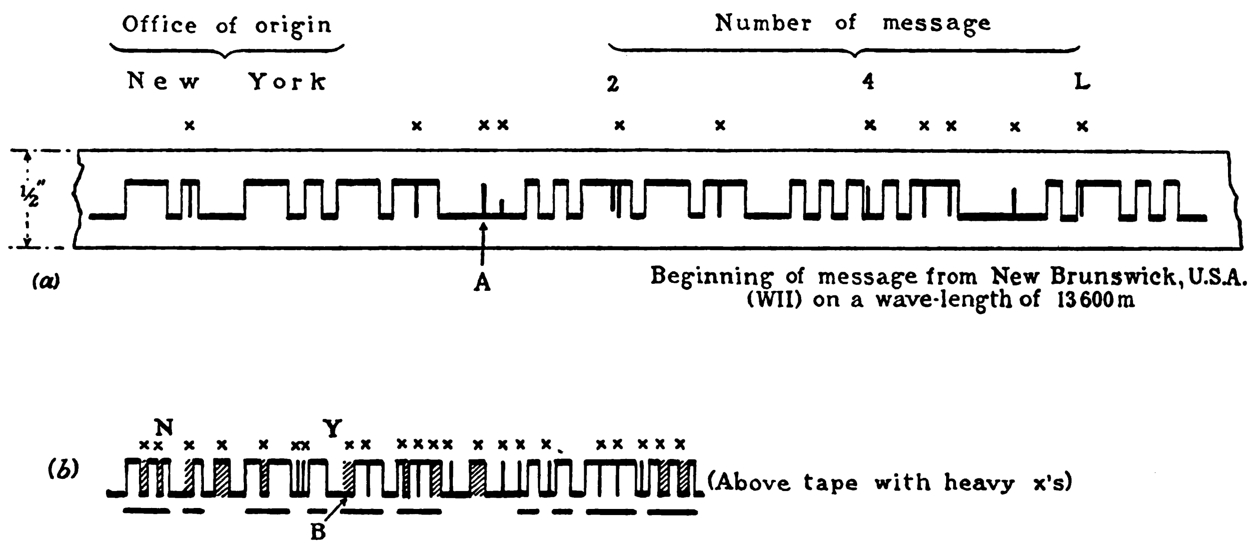

FIG. 4.—Sample of tape taken at Chelmsford (June, 1923) with magnetic drum recorder by the aid of the circuit portrayed in Fig. 6.

The transmission was automatic at from 20 to 30 words per minute. Atmospherics were not severe or many of the thin vertical lines would have resolved themselves into areas as shown in (*b*). Occasionally the end of the siphon did not make a complete transit owing to the short duration of the X in the receiving circuit, i.e. weak X's. The effect during marking and during spacing is clearly exhibited. (*a*) Shows the original tape, whilst (*b*) indicates the effect of severe atmospherics which render the record unreadable.

* *Journal I.E.E.*, 1923, vol. 61, p. 923.

The small drum apparatus is exhibited in Fig. 1. The construction is different from the standard shown in Vol. 61, p. 904 of the *Journal*. Both instruments are mounted on dull black aluminium bases and the finish is gold-lacquer-black. The shoe of the small drum is in two parts held by clamping strips, or preferably cut from a solid ring and spaced at an angle of about 40° to 80°. This construction is imperative owing to the larger curvature of the drum. The natural tendency of a single shoe riding on a drum of large curvature (small diameter) is to move tangentially to the crown. This actually happens after a single shoe has been in use for 15 to 20 minutes. Moreover, the heel of the shoe rides off the drum instead of adhering to it, and the two-part construction was designed to obviate this trouble.

There is no automatic tape feed as on the standard instrument. The paper roll is placed in a vertical position, thus economizing in space, and the framework in which the roll is contained is readily removable either for transport purposes or for the rapid insertion of a new roll. The plane of the tape issuing from the roll is horizontal and this is passed between two vertical rollers RR, which serve to turn it into a vertical plane. It then passes over a curved platen near the crown of which*—assuming the paper to travel from right to left—the siphon point operates, and thence to a vertical slotted guide through which it is drawn by a separate paper puller. The inking arrangement is unique. In order to avoid bending the siphon during operation, the axis of rotation must coincide with that of the siphon lever. To attain this object a cock is let into the base of the inkwell and to the lower end is fixed a gland with a rubber disc as packing. The centre of the gland is coaxial with the siphon. The feed is therefore of a gravitational nature, and during idle periods the cock must be shut to prevent ink flowing over the instrument. For coping with blocked siphons, a special siphon syringe is supplied with both types of magnetic drum instrument. The barrel is filled with methylated spirit and the upper end of the siphon is removed from the gland on the recorder and fitted to an identical gland at the top of the syringe. A gentle pressure on the piston serves to discharge sufficient methylated spirit through the siphon to clean it out thoroughly. Precautions are taken as far as possible to prevent sediment getting into the inkwell, by fitting a strainer. The ink feed is extremely regular and can be controlled in a degree by the pressure of the siphon point on the paper and by closing the ink inlet at the top of the well. The siphon arm is longer than that on the standard, because the mechanical construction required for vertical instead of horizontal motion involves the line of pull of the shoe being further away from the central axis about which the siphon mechanism turns. The lever ratio, however, is still 4 : 1 and the moments of inertia are such as to give the tracing point its maximum velocity for any given force on the shoe, the mechanical strength of the mechanism being adequate to withstand the shocks due to impact on the stops.† These are shown in Fig. 1 and are used where the incoming signals are to be relayed to a land line or to a printing machine. The instrument is fitted with relay contacts if required.

* The siphon point should be about $\frac{1}{16}$ in. to the right of the crown line.
† *Journal I.E.E.*, 1923, vol. 61, p. 923.

The aluminium base which rests on hemispherical rubber feet is apparently rather high, but this is necessitated by the design of tape puller to be used conjointly. Otherwise the height could have been reduced several inches. A drawer for spare parts is situated at the middle of the base and this contains the syringe, spare shoes, springs, siphons, etc., and some small tools. A $\frac{1}{8}$-h.p. motor arranged for 110 or 220 volts d.c. drives the drum through a 5 : 1 acme thread gear. The speed of the motor is controlled by a rheostat and is limited to 2 000 r.p.m.

In transcribing low-speed tape the usual practice is for the operator to sit with telephones on his head in front of a typewriter. The paper tape is drawn past the siphon point of the recorder by a tape puller consisting of a variable-speed shunt-wound motor coupled to pulleys via a worm reducing gear. The operator reads the signals both aurally and optically, and to assist in the latter operation it is preferable to run the tape in a vertical plane. The operator can then get a clear view of the tape from the paper puller to the siphon point, the motion of which can be followed if desired. This procedure is known as the "audio-cum-slip" method. There are in general two tape pullers, (*a*) one immediately before the typewriter, and (*b*) one after the typewriter. This enables the first puller to cause a paper travel suitable for high-speed reception, whilst the second puller is adjusted to a speed suitable for direct transcription on the typewriter. The untranscribed tape accumulates on the operator's right hand and is either dealt with in due course or handed to another transcriber, according to the conditions of reception and service. Under the latter circumstances, i.e. high-speed reception, the audio-cum-slip arrangement is suspended.

The features of small drum recorders are as follows:

(1) For a given current the operating forces are larger than the standard.
(2) They are specially suited for recording on circuits where atmospherics are prevalent, owing to the small transit time and the independent control of the drum and tape speeds.
(3) The transit time can be varied.

4. Transit Times of Recorders.

This is a subject which requires careful consideration on low-speed circuits where atmospherics are prevalent, or on high-speed circuits where characters follow one another in rapid succession. At the moment, atmospherics worry the long-wave circuits most of all. It has been shown elsewhere* how the legibility of recorded signals can be enhanced when atmospherics are neither too strong nor too frequent to upset recording altogether. For this purpose the recorder must move with great rapidity.

In measuring the transit times of the recorders for marking and spacing, the amplitude was adjusted to $\frac{1}{8}$ in. and the recorder actuated in conjunction with a

* N. W. McLachlan: *Journal I.E.E.*, 1924, vol. 62, p. 353.

rapidly responding electric circuit. Dots of known frequency were sent by a local Wheatstone transmitter, the marking and spacing being equal in duration. The paper tape was drawn past the siphon point at a speed concomitant with a record taken at 2 500 words per min. so that a dot at a sending speed of 25 words per min. was about 6 in. long. Care was taken to avoid undue paper friction, and to ensure an adequate supply of ink a gentle air pressure was applied to the feed. A typical dot at a lower paper speed than that cited above is shown in Fig. 5. The initial and final for an a.c.-d.c. converter of the type shown in Fig. 9. The current in each coil was approximately 3 mA. The drum speed was insufficient to give the shoe its greatest velocity and hence the end of the transit curve was linear. The marking transit time with adequate drum velocity is 0·0018 sec.

The recorder was operated under normal valve circuit conditions using 1 coil only with about 4·0 mA (see Fig. 6). The marking transit time with adequate drum speed is 0·0016 sec. By suitable design the time can be reduced below this figure to about 0·0013 sec.,

FIG. 5.—Magnetic drum recorder (transoceanic type). Dot at low speed ; paper speed equivalent to 1 800 words per min.

transit curves are approximately parabolic. If the force on the mechanism and the paper speed are constant, the motion of the tracing point relative to the paper is identical with that of a particle projected horizontally and falling freely under the influence of a constant gravitational attraction. In order to ensure this condition it is essential that the peripheral speed of the drum shall not be less than the speed at which the shoe would move when the mechanism reached the marking stop if acted upon freely by a force equal to that between drum and shoe. When the drum speed is less than this, the end of the transit curve is a straight line, for the shoe is no longer accelerated but is moving at a constant velocity equal to that of the drum.

Data concerning transit times and allied topics are given in Tables 1 to 4.

TABLE 1.

Marking		Spacing	Total
Experiment	Calculation	Experiment	Experiment
2·0	1·9	2·0	4·0

The recorder was operated under normal receiving conditions, being situated in a valve circuit as used, but there is undue impulsive stress on the siphon mechanism.

From Tables 1 and 2 it will be seen that a fair agreement exists between the experimental and calculated values of the *marking* transit time. So far as the spacing transit time is concerned, calculation is out of the question without a knowledge of the time-lag of demagnetization. If this lag were negligible the process of computation would be identical with that for marking. There is reason, based on experimental evidence, to believe that it is not entirely negligible although the condenser-resistance combination can be varied over a fairly wide range without causing alteration in transit time of any practical importance. It will be appreciated that for any given working current the marking and spacing times can be made equal or otherwise by adjusting the pull-off or control spring, and that for a specified tension of the spring the marking

* 200 times the acceleration due to gravity.

transit time can be altered by changing the value of the working current.

In the foregoing remarks the rate of rise of current in the recorder coil has been tacitly ignored. With a comparatively large inductance (several henrys) the time taken for the current to attain a working value must be considered. In the universal or standard type of instrument this amounts to a duration of the order of 0·0004 sec., whilst in the transoceanic or small drum type it is slightly less. Such a value is not of appreciable moment under the present system of ink marking. If, however, an optical arrangement were employed in which the motion of the lever was, say, 1/100th of the figures already quoted, the transit time under the action of the force at full current value would be less than 0·0004 sec. This would necessitate a modification in the design, e.g. a much smaller inductance to enhance the rate of rise of current.

5. Recording through Atmospherics.

When a time/displacement curve of the transmitter modulation is plotted, the result is a series of morse characters in rectangular formation—neglecting of course the initial and final lag due to electromagnetic inertia. In recording incoming signals of this nature it seems a reasonable—but not an exclusive—hypothesis that, apart from atmospheric disturbances and jamming, the time/displacement curve of the transmitter should be reproduced on the paper slip or tape at the receiver. It is known, however, that the signal profile is modified by low-decrement circuits at both transmitter and receiver—principally the latter—and after protracted filtration the curves "enveloping" the oscillations of either radio or audio frequency (according as the filtering is done at radio or audio frequency or both) are no longer of rectangular formation. The shapes of the growth and decay envelopes depend upon the number and the decrements of the circuits in cascade. Prior to recording the incoming signals of audio frequency, it is usual to rectify and smooth the oscillations in order to secure a unidirectional component. The envelope is modified in this conversion process from alternating to direct current, and when the signals are applied to a power or recording valve set to its lower rectifying point an additional alteration in shape is accomplished, especially if the valve is given an unusually large negative grid bias. The latter expedient is a useful artifice in squaring up the signal profile. In what follows it will be assumed, unless otherwise stated, that the envelope of the signal and interfering voltages applied to the recording valve is of rectangular profile, also that the transmission is automatic, thereby preserving uniformity of the characters. This latter is the usual practice in commercial work.

In the preceding Section, incidental reference was made to the influence of atmospherics on the tape record. It is intended to show what conditions must be fulfilled so that atmospherics do not make the record illegible. The visual condition is simply that the area of the marking which represents an atmospheric must be small in comparison with that of a dot, a dash or a space. Also the atmospheric scribings must not be too frequent to fill up the characters. These points are illustrated diagrammatically in Fig. 4. Apart from the signal profile there are two electrical issues with which we are concerned: (1) The rapidity of response of the recorder, and (2) the duration in the receiving circuit of (*a*) the signal, and (*b*) an atmospheric. Firstly, if the time interval between the initial application of the voltage to the grid of the recording valve and the arrival of the siphon point at the marking position is small compared with the duration of a dot; secondly, if the time interval between the initial decaying of the applied voltage and the arrival of the siphon point at the spacing position is small compared with the duration of a dot, the marking on the tape will be of rectangular formation (unless the tape speed be excessive) and the space/time curve of the siphon point will closely resemble that of the voltage/time curve associated with the Wheatstone contacts at the transmitting station. Where atmospherics are concerned the required condition is that the siphon of the recorder shall make a complete to-and-fro transit within a limited time interval, depending on the tape speed and the speed of transmission. There are two salient cases to be examined: (*a*) When atmospherics occur during spacing, and (*b*) when atmospherics occur during marking. During spacing little or no *signal* voltage is applied to the recording valve, but in general there will be a decaying current in the aerial and its associated circuits. The effect of an atmospheric will depend upon the phase of the signal E.M.F. in the aerial at the initiation of the disturbance and also upon its (the X's) wave-form. If the aerial current is adequately augmented the atmospheric will be registered on the tape. The siphon point will make an excursion across the tape and back to the base line or spacing position. This is portrayed at A in Fig. 4. During marking the aerial current will either be growing or decaying or be sensibly constant. The influence of an atmospheric will again depend on its phase and wave-form with reference to the signal. If the aerial current due to the signal is a small fraction of the maximum and the atmospheric is strong enough or suitable as regards phase and intensity, the aerial current will be augmented sufficiently to cause marking on the tape. On the other hand it may practically de-energize the aerial and delay the initiation of the morse character, thus making a prospective dash more like a slightly elongated dot (see B in Fig. 4 (*b*). When the signal current has attained its full working value the same additive and subtractive effects can be obtained from X's. Augmented aerial current during marking due to an atmospheric yields no visible result on an instrument which functions between stops, but an adequate decrease in current is accompanied by a motion of the siphon to the base line and back to the marking position. These remarks are illuminated by the tape record reproduced in Fig. 4. This was secured by aid of the circuit sketched in Fig. 6. The legibility of the tape is enhanced appreciably if the siphon point is oval, the major axis being at 90° to the motion of the tape. This gives thin vertical and thick horizontal strokes.

Passing on to the second point, which concerns the rapidity of response of the complete receiving circuit, the condition to be satisfied is that the duration of the

voltage applied to the grid of the power valve due to an X shall be small compared with that due to incoming characters in the morse code. The maximum value of the voltage is not of material importance, merely its duration above a working value, although in virtue of the receiving circuit the two are usually associated. This necessitates a receiving circuit in which the decay reduced so that the areas will become smaller in proportion to the characters and, furthermore, the speed of the paper tape can be decreased, thus tending to reduce the areas to vertical strokes. In practice this condition generally holds down to a certain minimum speed below which it is more economical and satisfactory to read the messages aurally. Where speeds vary over a wide

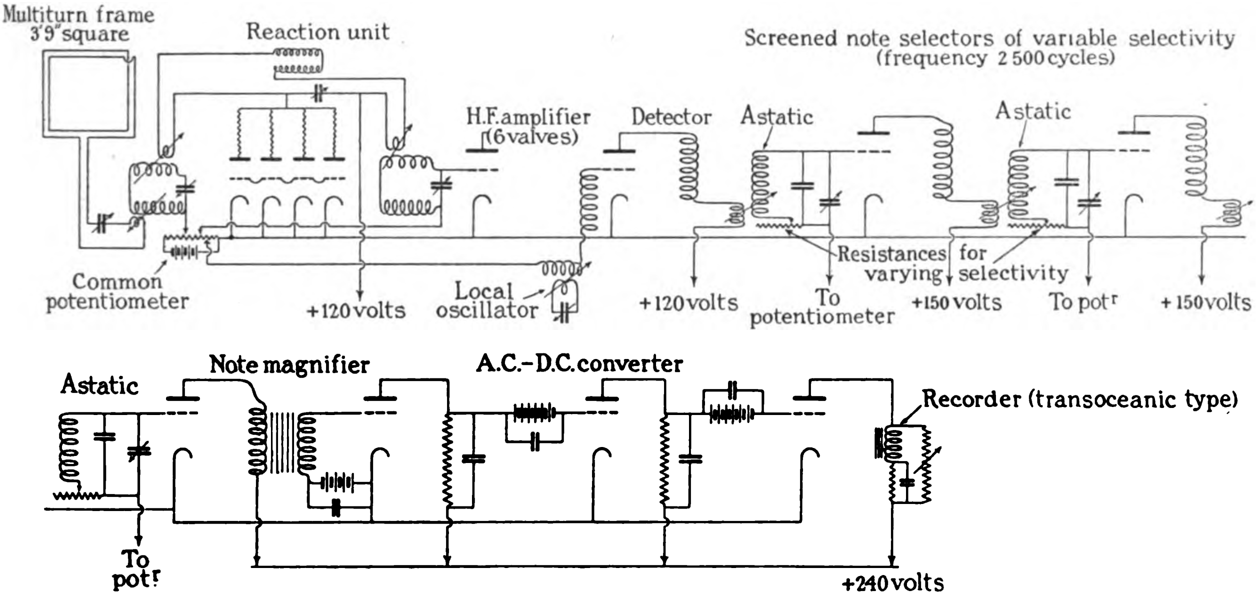

FIG. 6.—Circuit used to obtain tape of Fig. 4 from New Brunswick (WII).

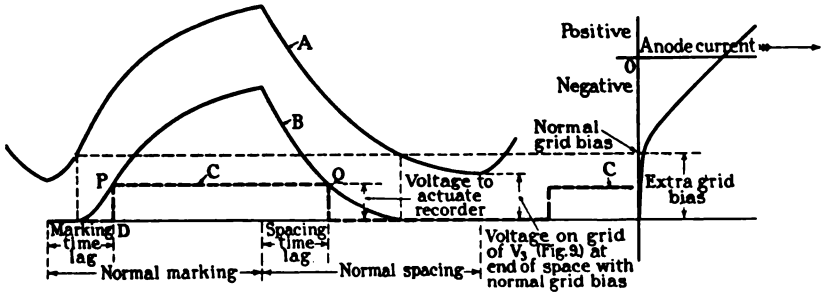

FIG. 7.—Diagram illustrating the effect of using extra grid bias on the recorder valve V_3 of Fig. 9.

A continuous marking is transformed by the recorder into morse characters of rectangular formation, the time displacement curve of which is shifted forward, i.e. lags. In practice the result is legibility, since the profile of the signal is akin to that of Fig. 4 (*a*). No allowance has been made for the influence of grid current at the power valve with strong signals. This in itself tends to round off the points of curves A and B, since it is equivalent to a coupling resistance between V_2 and V_3 which decreases as the signal increases.

A = Voltage applied to grid of V_3 of Fig 9. In the absence of extra grid bias the current through the recorder is determined by this curve. Since the current is always above the working value, the record is a continuous horizontal line, i.e. the morse characters merge together.

B = net voltage applied between grid and filament of V_3, i.e. curve A minus the extra grid bias. This is approximately the same shape as the voltage applied across the recorder and its shunted resistance combination. Owing to the inductance and condenser the current curve is modified. The current to actuate the recorder is determined by the tension of the pull-off spring.

C = representation of marking on the tape.

period is reasonably proportioned with respect to the length of a dot. There is a value of decay period, according to the speed of sending, the number or frequency of occurrence of the atmospherics and their strength relative to the signal, beyond which the tape becomes illegible due to the formation of relatively large areas (due to the X's). In order to secure legibility, the speed of sending can be range, according to the conditions of reception, it is imperative to have a receiving circuit of variable selectivity. When a series of tuned circuits are used, this variation can be secured by altering the couplings or by manipulating variable resistances in the *LC* components (see Fig. 6). A master control operating all circuits simultaneously is obviously preferable.

The problem of recording highly rounded signals due

to low-resistance circuits has been raised elsewhere.* It has been established in practice by having two rectifiers in cascade as in Fig. 9. By giving one or both an extra negative bias, *in the absence of atmospheric and other disturbing factors*, recording can be accomplished when signals are well-nigh aurally unreadable. A third rectifier helps still further and in that case the negative bias on the other two can be reduced. Conditions free from interference are seldom enjoyed, but even so this simple artifice is by no means to be despised.

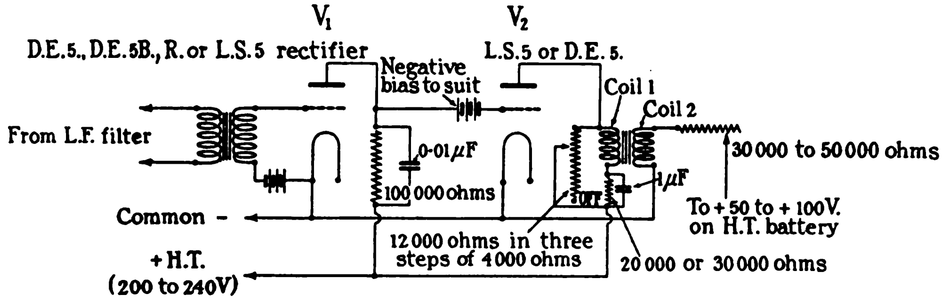

FIG. 8.

The effect of a large negative bias on valve V_3 of Fig. 9 is illustrated clearly in Fig. 7. At P the voltage applied between the grid and filament of V_3 is large enough to actuate the recorder and from P to Q marking is registered, the siphon then falling back to the base line. The profile of curve B between P and Q is immaterial, provided the ordinates exceed PD. So far as the magnetic drum and other fixed-stop instruments are concerned, the behaviour is equivalent to

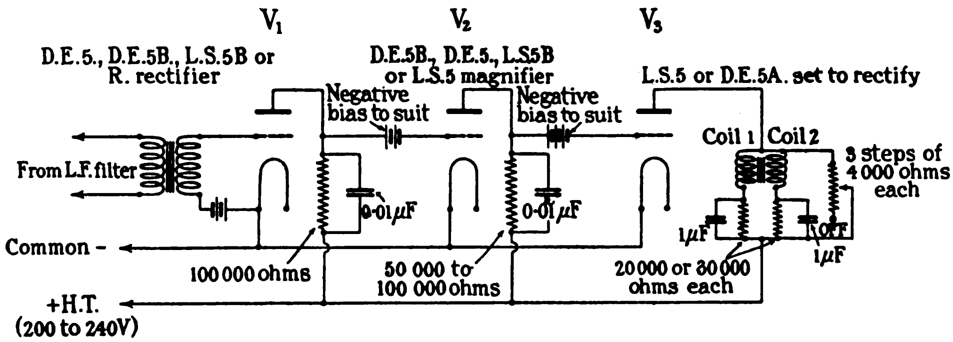

FIG. 9.

that from an input voltage of approximately the rectangular formation of curve C.

6. A.C.-D.C. Converter Circuits.

Several valve circuits used for the direct recording of radio signals were given in the first paper.† For commercial operation it is usually advisable to avoid "trigger" circuits, and moreover the arrangements are devoid of awkward adjustments, being straightforward and affording the desired degree of amplification. There are two main classes into which valve recording circuits may be divided: (*a*) Single current, and (*b*) double current. In general the second class (*b*) has one valve more than the first class, this being required to give the reverse current. The magnetic drum recorder requires a reverse current to cause rapid demagnetization, but it can be obtained automatically by the discharge of a condenser,* thus permitting simplification of the circuits and dispensing with the extra valve for spacing. In general it is preferable to work from common anode and filament current supply sources, and the diagrams cater for this condition to be fulfilled. The function of the recorder circuit is to convert the alternating currents of beat (audio) frequency, usually from 1 500 to 2 500 cycles, into unidirectional pulses whose durations are those of the morse dots and dashes. During the conversion or smoothing process there is usually a certain degree of amplification. For good recording at a speed of 100 words per min. the potential difference between the grid and filament of the power valve during a morse character should not be less than 40 volts. The power valve should have a low internal resistance so that a reasonable proportion of the anode supply voltage is expended on the recorder and its associated apparatus. Suitable valves are D.E.5, D.E.5A, L.S.5, and L.S.5A. The anode supply voltage should not be less than 200.

Fig. 8 shows a simple converter unit consisting of rectifying and power valves. Smoothing is effected by the condenser in the anode circuit of the rectifying valve. During idle periods a current flows through one of the recorder coils via the power valve. The

* *Experimental Wireless*, 1924 vol. 1, p. 623. The diagram on page 625 is not quite correct.
† Loc. cit.

* Loc cit., p. 907

second coil is connected to a tapping point on the anode supply, and the current is adjusted by a variable resistance until it is approximately equal to that in the first coil, but the magnetizations are opposed. Moreover, there is little or no pull on the recording mechanism. When a signal E.M.F. is applied to the rectifier the anode potential falls, and the potential of the grid of the power valve falls by an equal amount, thus reducing the current through coil 1 practically to zero. This leaves the magnetization due to the current in coil 2 free to actuate the recorder. Moreover, the operation of the recorder depends upon a falling current through the power valve.

The next circuit is illustrated in Fig. 9. Here we have a circuit akin to that of Fig. 8, except that there is a valve inserted between the rectifying and recording valves. This valve and its associated condenser-resistance in the anode circuit not only gives additional magnification and smoothing, but serves to make the recorder valve operate on a *rising* current. In this case both coils of the recorder are used, which is an advantage.

Since the transoceanic type of recorder has only one coil it can be used with the circuit of Fig. 9, but not with that of Fig. 8, unless of course the tape is read upside down, there being no polarizing current to invert it automatically as in the universal type.

7. Delayed-Action Relay.

In automatic calling-up or switching devices, which are really a form of remote control, it is sometimes desirable to introduce a peculiarity in the response of the system. This may take the form of a time-lag or delay in the ultimate action of the relay at the distant station where the receiving apparatus is installed. Such an action can be accomplished by the combination of some type of relay with a dashpot, thermostat or like device so that an uninterrupted signal has to be applied for a definite length of time to ring the call bell. As an example we may take the Marconi Company's wireless bell call-up device in which the transmitter is modulated by an audio frequency of about 1 500 cycles, and the selective circuit at the receiver is tuned to this note. Unless a delayed-action combination were installed, any strong nearby jamming station would actuate the call bell.

The magnetic drum principle can be applied readily to fulfil the double function of a relay and a delayed-action device. This is accomplished by passing the signal current through the operating coil on the drum and revolving the latter very slowly, say once every 30 to 60 minutes. In this way, during continuous signalling the shoe and the lever carrying the relay contacts move uniformly but very slowly from the "off" to the "on" position, i.e. from the spacing to the marking contact. With an intermittent signal, for instance morse jamming, the tongue of the relay dallies about the "off" contact. It is essential that this should occur, and the circuit must be arranged to respond rapidly to avoid a cumulative effect which would culminate in an excursion to the marking contact. The drum is identical in dimensions with the universal type, except that the bobbin is slightly deeper to accommodate 30 000 turns of No. 48 enamelled wire. The wire can be wound on a bakelite bobbin and bakelized as described in a preceding Section. No back spring is required for the shoe, since there is no tendency for the rear extremity to lift as in high-speed signalling. The drum is driven by either an electric or a clockwork motor. The advantage of the electric motor needs no comment, but it may be inconvenient in certain cases where an adequate power supply is not available. (A $\frac{1}{40}$ h.p. motor serves the purpose admirably.) Obviously it is necessary to have a large gear reduction to secure the low speed required for the drum motion. It is of interest to note that the drum speed is so low that the signal would require to be applied continuously for *over a century* to cause appreciable wear.

Apart from the fact that this delayed-action relay system is sensitive—the operating current is from

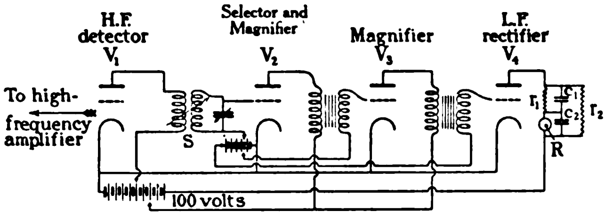

Fig. 10.

V_1 = H.F. detector.
V_2 = note-selector valve.
V_3 = magnifier.
V_4 = low-frequency rectifier.
R = drum relay.
r_1 = resistance (50 000 ohms).
C_1 = condenser (2 μF).
r_2 = resistance (30 000 ohms).
C_2 = condenser (0·02 μF).
S = tuned-note selector (1 000 to 2 000 cycles) loosely coupled.

If the signals are sufficiently strong, V_3 can be omitted. Suitable valves are V_2 = D.E.3, V_3 = D.E.3, V_4 = D.E.3B: to be mounted in shock-absorbing holders. The current supply to the filaments is very small with these valves.

As an alternative to the above circuit, valve V_3 may be coupled resistively to V_4 (V_3 may or may not be set to rectify). A condenser across the resistance is used to smooth the alternating current (the frequency of which is from 1 000 to 2 000 cycles) when V_3 is set to rectify. If V_3 is not set to rectify, the condenser is omitted.

0·3 to 0·5 mA—it possesses the advantage of being extremely flexible, because the time-lag can be varied over a wide range by altering the spacing between the stops and the speed of the drum. The variation depends upon conditions but can easily be arranged for any lag from 1 to 30 seconds. With a single thermostat or a dashpot, a 30 : 1 ratio would be quite impossible.

The relay is operated from any suitable receiving set capable of supplying signals of adequate strength. A satisfactory circuit with a note selector incorporated is portrayed in Fig. 10. This is connected direct to the terminals of any high-frequency amplifier. An air-cored coil of high impedance is connected in the anode circuit of the high-frequency detector valve. This coil is loosely coupled to an oscillatory circuit connected across the grid and filament of the valve V_2. The anode circuit of this valve contains the primary of an iron-cored 4 : 1, 6 : 1 or 8 : 1 transformer, according to the type of valve and the note frequency. The secondary of the transformer is connected to the grid and filament of the relay valve V_4 via valve V_3 and another transformer or a resistance. V_4 is set to the

rectifying point on its anode-current/grid-voltage characteristic. In the anode circuit of V_4 is situated the drum coil shunted by a small smoothing condenser which reduces the impedance of the circuit and thereby enhances the steady current during the signalling dash. The increase in steady current depends upon conditions, but on the average it is doubled due to the condenser across the drum. This will be more readily appreciated when it is realized that the inductance of the drum at 100 cycles is about 600 henrys. Taking a fundamental note frequency of 1 500 cycles, and assuming the drum inductance now to be 200 henrys, the inductive reactance alone is nearly 2 megohms, whereas that of a $0 \cdot 01\ \mu F$ condenser is only 1/200th of this value.

In series with the drum is a shunted condenser combination Cr_1, and the whole arrangement is paralleled by a resistance r_2. It has already been stated that there must be no cumulative effect due to a rapid succession of signals, and the Cr_1 and r_2 units perform the function of demagnetizing the drum at the termination of each separate character, thereby eliminating this effect. Demagnetization is accomplished by the reverse discharge of the condenser through the drum via resistance r_2, as explained in the original paper.* In order that this operation shall be performed with precision, it is advisable that the voltage on the circuit of the last valve shall not be less than 80; 100 volts is a good working value.

In addition to its use in a valve circuit the apparatus can be employed in land line or local circuit work, where it would be provided with a second coil for double or reverse-current operation.† The condenser C_2 and resistance r_2 would then be omitted.

This apparatus has been designed entirely on an economy basis so that valves, batteries, etc., have been reduced to a minimum. The recorder (either type), with its associated circuits, can be used for delay-action work, provided an auxiliary reduction gear is incorporated to slow the drum down. The high tension and the valves would require alteration to get the required operating current.

8. Recording Time Signals for Checking Clocks.

The checking of astronomical clocks by wireless signals is sometimes accomplished by causing the incoming signal to operate a relay from the local contacts of which a marking pen is actuated. This pen scribes on a moving paper tape. The clock pendulum closes a local circuit every second, so that another pen also marks on the paper tape. The horizontal distance between the marks of the two pens is a measure of the accuracy of the clock. In this system there are defects due to (1) the lag of the relay, (2) the difference in lag of the relays actuating the two pens.

By using the magnetic drum recorder these lag defects can be reduced to an inappreciable amount and the apparatus brought down to a very simple and compact character. The seconds signals from the local clock are passed through one coil of the recorder and arranged to give a mark of greater duration than that of the wireless time dot. Through the other coil the wireless signal is passed in opposition so that the siphon comes back to the spacing stop momentarily and then goes to the marking stop. The distance on the tape from the beginning of the upward mark to that of the downward one is a measure of the accuracy of the clock. In these two coil circuits the time-lag is different, but the actual lag is so small as to be of no practical importance, the likely errors of measurement on the tape due to thickness of line, etc., far exceeding them. This will be clear when it is remembered that the siphon point moves $\frac{1}{16}$ inch in less than $0 \cdot 002$ sec. and the (time) accuracy required is not more than 5 times this. If, however, the beginning of the up and down lines is taken, the only error is that due to the difference in electrical lag between the circuits of the two coils. It is possible to eliminate this by making the clock operate on the wireless circuit, but this refinement is unnecessary. It is clear that the instrument can also be used for recording time intervals between different types of impulse, e.g. acoustic.

The author acknowledges his indebtedness to the Marconi Co. for permission to publish the data and information embodied in the paper.

THE RUGBY RADIO STATION OF THE BRITISH POST OFFICE.

By E. H. SHAUGHNESSY, O.B.E., Member.

(*Paper received 16th March, 1926; read before the* WIRELESS SECTION *14th April, and before the* SOUTH MIDLAND CENTRE *28th April,* 1926.)

SUMMARY.

This paper gives a general description of the Post Office high-power radio station erected at Hillmorton near Rugby. The introduction sets out the requirements which the design had to meet.

The paper is divided broadly into three Sections :—Power Plant, High-frequency Generating Valve Plant, and Masts and Aerials.

The first Section deals with the selection and type of power plant employed for converting the e.h.t. alternating-current supply to suitable e.h.t. direct-current and l.t. direct-current and l.t. alternating-current supplies for use on the various parts of the installation, and the precautions necessary in dealing with a wireless load of the magnitude involved. The method of providing lighting for the masts for warning aircraft of obstruction is given.

The high-frequency generating-valve plant Section deals with the design of valve generating plant suitable for full-power transmission or subdivision into two transmitters for use with larger and smaller portions of the whole aerial, and gives the methods adopted for maintaining constant frequency, successive amplification and freedom from harmonics. This Section includes :—The e.h.t. direct-current supply ; the general scheme of circuits ; the filament supply ; the excitation unit ; consideration in regard to the size of power unit ; the power unit ; the paralleling of valves in a power unit ; the paralleling of power units ; safety devices and control circuit ; the control table ; types of coupled circuits ; the design of inductances for high power ; relative positions of amplifiers and aerial circuit ; method of keying and shape of signal.

The masts and aerial Section includes :—A brief general description of the 820-ft. masts ; the method of insulating the masts and the stays ; the method of staying the masts ; tensions on the stays, etc. ; the method of applying test load to top of masts ; the aerial system ; aerial insulation ; aerial spreaders ; earth system ; curves of aerial resistance ; voltage on aerial, etc.

The final Section gives the general results obtained to date, and a brief description of the experimental telephony installation.

INTRODUCTION.

When the Government decided upon the provision in England of a wireless station with a world-wide range, the Post Office Engineering Department was entrusted with the task of its erection. The Wireless Telegraphy Commission which was originally appointed under the chairmanship of the late Lord Milner with Dr. W. H. Eccles (Vice-chairman), Mr. E. H. Shaughnessy and Mr. L. B. Turner as members, undertook the general design of the station. The Post Office engineers in consultation with the Wireless Telegraphy Commission carried out considerable preliminary experimental work and prepared detailed drawings and designs for the station equipment as a whole and for most of the plant; they also prepared the detailed specifications to which manufacturers have designed or made the remainder of the plant.

In the preliminary design of the station it was considered that in order to ensure reliable communication when working on a wave-length of about 18 000 m (16·66 kilocycles) a minimum working current of 500 amperes in an efficient aerial supported on 820-ft. masts would be required. To meet this requirement and provide a safe working margin it was decided that the high-frequency generating valve plant should be capable of dealing with an input of 1 000 kW to provide for a possible necessary low working efficiency of 50 per cent. Such an installation would produce an aerial current of about 700 amperes to meet bad atmospheric conditions.

Originally it was considered that sixteen 820-ft. masts would be required to support a suitable aerial, but to avoid any unnecessary expenditure it was decided to erect in the first instance an aerial having a designed capacity of 0·045 μF on 12 insulated 820-ft. masts and to carry out tests to ascertain the limitations imposed on the aerial power obtainable by such factors as corona, insulation, etc., and to obtain data as regards the range of the station using this maximum power.

In order to keep this description of the Rugby radio station within reasonable limits it is proposed to describe the power plant and the external plant briefly and the radio-telegraph plant in detail.

SITE.

Owing to the large area required, considerable difficulty was experienced in obtaining a site, but ultimately an area of 900 acres (about 1½ miles long by 1 mile wide) bounded on the east side by Watling-street and on the west side by the Oxford canal was obtained at Hillmorton about 4 miles south-east of Rugby. The ground is level and not surrounded by hilly or wooded country, although a fox covert on the site had to be demolished, as it was under the proposed aerial. A water supply is available from a stream running through the site; the nearby railways and the Oxford canal afford transport facilities. The station buildings are erected about the middle of the site (see Fig. 1).

POWER PLANT.

The question of the power supply for the station was one which was very carefully considered and, after a close examination of conditions on the basis of comparative costs and reliability, it was decided to accept a bulk supply from the Leicestershire and Warwickshire Electric Power Co., who are the authorized suppliers in the area.

The company has generating stations at Warwick and

Hinckley, the Rugby area being served by duplicate mains from Warwick, whilst arrangements for linking with Hinckley are in contemplation. The incoming supply is three-phase, 50-cycle alternating current, having an earthed neutral and 12 000 volts between phases.

Duplicate underground cables are provided between the radio station and the company's substation at Rugby, where automatic regulators are installed.

The two feeder cables terminate at the radio station in a separate selector switch cubicle which permits of either or both cables being connected to the e.h.t. alternating-current switchboard.

The radio-station power house consists primarily of a machine room 185 ft. by 47 ft. spanned by an 11-ton overhead travelling crane. The general layout is shown in Fig. 2. One end of the room is partitioned off for work shop and stores to which the crane has access and which can be readily utilized for extensions if this becomes necessary. Parallel with the main room is an annex, the lower portion of which contains a battery room and six trans-

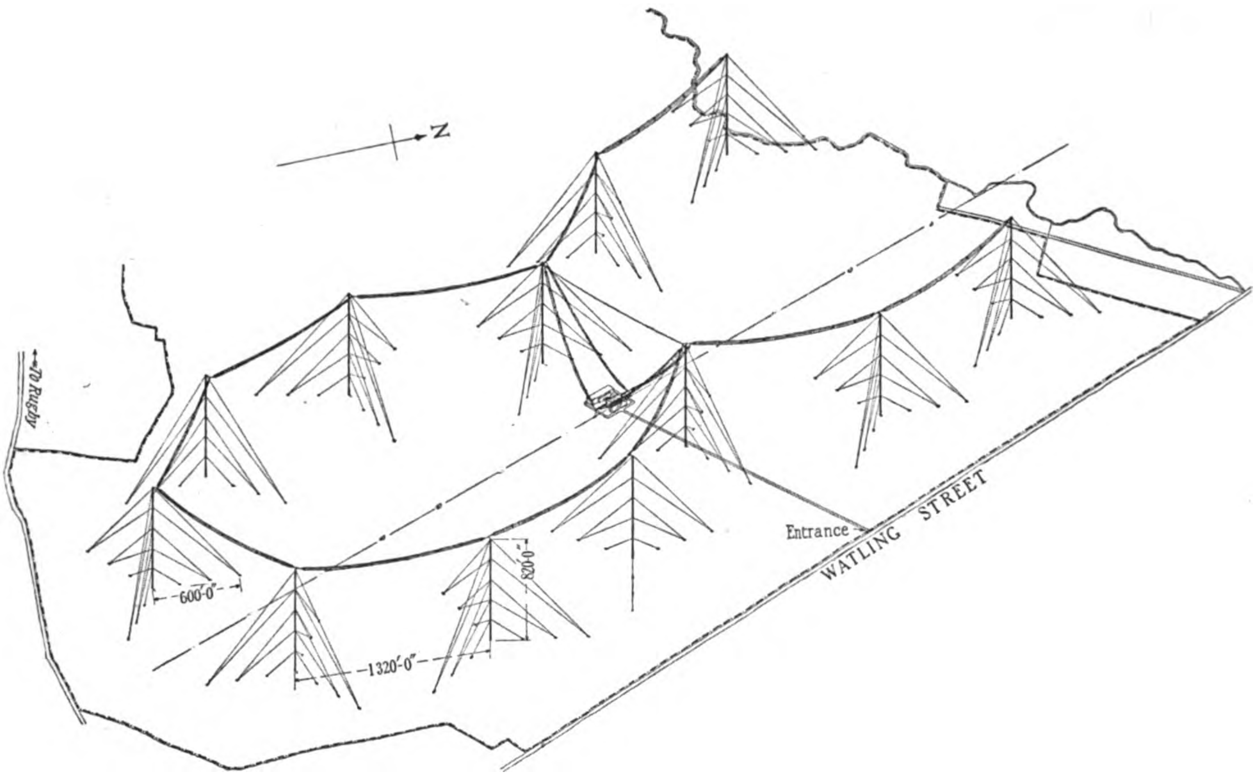

FIG. 1.—Isometric view of station.

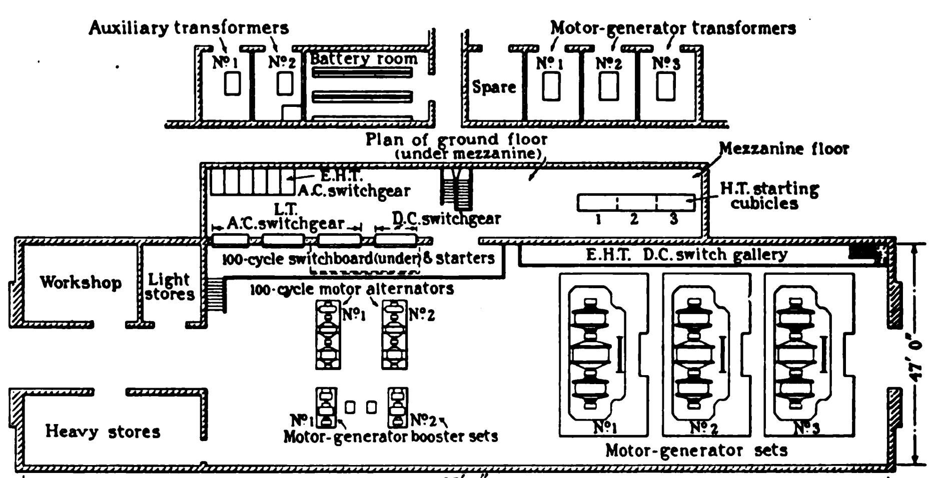

FIG. 2.—Plan of power house (scale $\frac{1}{40}$ in. = 1 foot).

former rooms. A separate room is provided for each power transformer and these rooms can only be entered from outside the building. They are closed by steel doors furnished with ventilating louvres. The upper floor of the annex is a switch gallery open to the machine room. This gallery contains the high- and low-tension a.c. switchboards, high-tension a.c. starting cubicles for the main generators and low-tension d.c. switchboard.

In the machine room are the main motor-generator sets for providing high-tension direct current to the valves, two frequency-converter sets used for heating valve filaments, together with motor starting cubicles and alternator control panels, and lastly two motor-generator and booster sets for battery charging and low-tension d.c. supply.

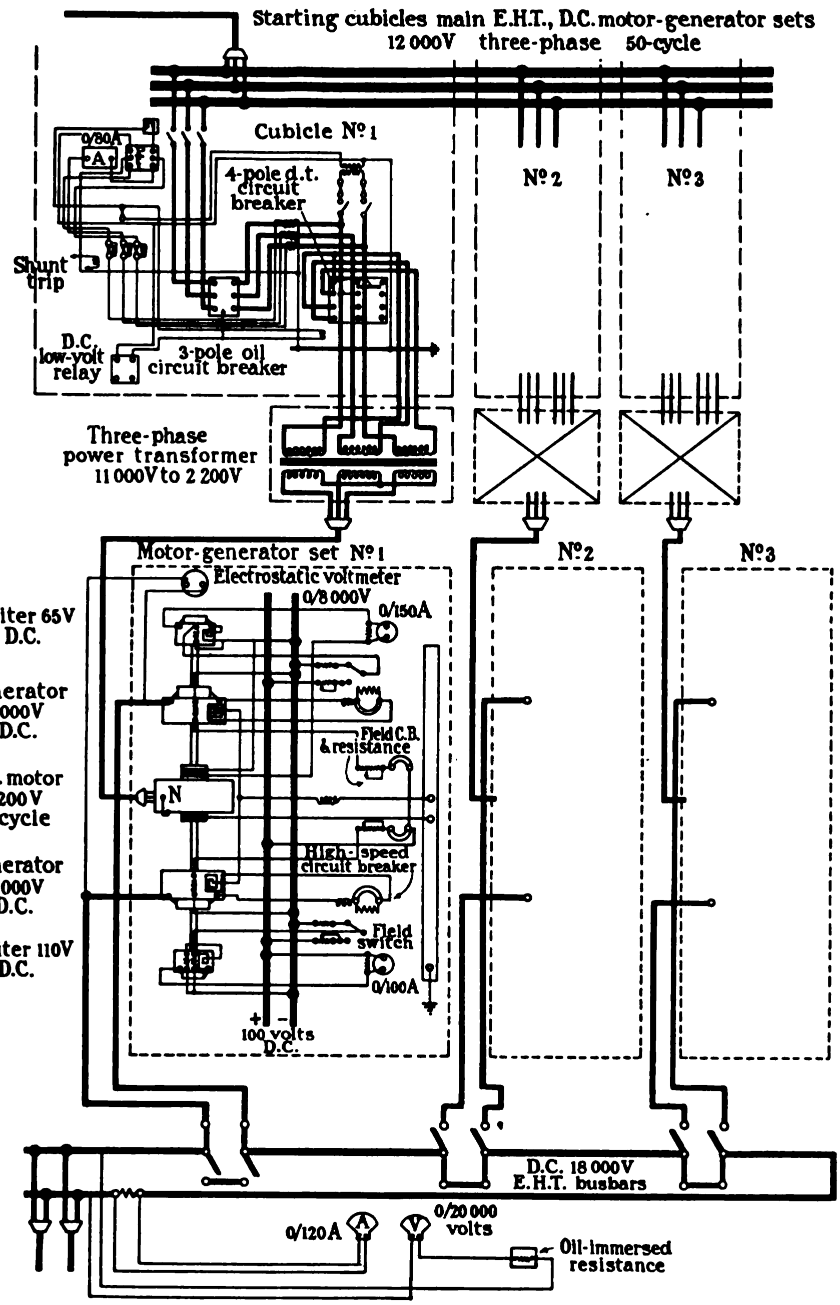

FIG. 3.—Wiring diagram of motor-generator sets.

All power used, other than that required for the main motor-generators, is supplied by two auxiliary step-down (12 000/416 volt) transformers of 450 kVA output through the main low-tension a.c. switchboard. For reasons explained later it was found more convenient to supply

each main motor-generator set through a separate transformer.

The larger motors (i.e. over 100 kW) installed are synchronous machines capable of operating on 0·9 leading power factor, and as a result the station can be operated on unity power factor.

The e.h.t. a.c. switchboard is a 6-panel board consisting of 5 truck cubicles and a metering cubicle. The first truck contains an oil switch controlling the supply to busbars and also contains the company's meters with their respective instrument transformers. The next panel consists of a cubicle containing the Department's check meters and potential transformer.

The four remaining panels are feeder truck cubicles, two being connected to the auxiliary 450-kVA transformers situated immediately below the switchboard, whilst the third, of 2 000 kW capacity, controls the supply to the main motor-generator sets. The fourth truck is at present spare and interchangeable with the remaining three feeder trucks. The low-tension a.c. 416-volt switchboard is of the normal slate pattern containing 16 panels, and controls all auxiliary power inside the station and the outside feeders to mast winches, pumps, etc. These switchboards, together with a number of other switchboards and cabling, were supplied and erected by the General Electric Co., Ltd.

The requirements of the valve transmitter set called for a supply of d.c. power of from 1 000 to 1 500 kW at a potential of from 10 000 to 18 000 volts, with the negative side at earth potential, the higher voltage being provided to cope with probable developments in transmitting valves in the near future.

Owing to the possible failure of valves it was essential that whatever type of plant was installed it would have to be capable of standing a dead short-circuit with impunity. Other special requirements were ability to operate under rapidly fluctuating loads, low self-inductance, and absence of voltage ripple.

The relative merits and suitability of machines, mercury-arc rectifiers and thermionic valve rectifiers for this duty were considered. Tenders were invited for the various types and it was finally decided to install motor-generator sets (see also Report of Wireless Telegraphy Commission, Command Paper 1572–1922).

The machines were manufactured by the British Thomson-Houston Co., Ltd., of Rugby and are an interesting development from machines designed for high-tension d.c. traction work. The Rugby generators, owing to the higher voltage and their operation in series, possess several new features, some particulars of which have already appeared in the technical Press and will only be briefly referred to here. Fig. 3 shows a wiring diagram of these sets. Three sets are provided, each having an output of 500 kW at 6 000 volts d.c., and space is provided for the accommodation of a fourth set. Each set consists of a three-phase self-starting synchronous motor of 640 kVA wound for 2 200 volts between phases, rigidly coupled to two d.c. generators connected in series, and two exciters, one of which is the main exciter and the other the motor field exciter; the main exciter provides field current for both d.c. generators and for the field of the motor exciter.

Each d.c. generator is a bipolar machine having an output of 250 kW at 3 000 volts and provided with interpoles and compensating winding. The magnet frames of cast steel are split diametrically and in order to avoid awkward joints in the pole-face windings the break has been arranged through the centre of the main poles which consist of twin poles, each half carrying its own spool. Another unique feature of the magnetic circuit is a band of laminations incorporated in the yoke to provide an undamped path for the commutating flux under rapidly varying loads. The commutator is of the same diameter as the armature, and all metallic parts in the vicinity of the commutator which are connected to the frame are protected by insulating shields. A series of fan blades mounted between the armature and commutator provide a blast of air across the commutator. The brush gear is completely encased in bronze boxes, the connections to which produce magnetic fields directed to blow out from the machine any arc which may be formed at the brushes.

The bearings are each provided with a thermal relay which, in the event of overheating, rings a bell on the control panel and lights an indicating lamp on the hot bearing.

In order to avoid the use of insulated couplings between motor and generators, each set is supplied with power through a separate transformer. These transformers, manufactured by Messrs. Johnson and Phillips, are wound for 12 000 volts on the primary side and 2 200 volts on the secondary side. The insulation of the secondary winding from the primary winding and core bunched was designed for and subjected to a flash test of 50 000 volts. The secondary side is connected directly to the motor terminals by means of a 3-core paper-insulated cable, and all a.c. switchgear is on the primary side of the transformer.

The d.c. controls of each set are mounted on an auxiliary baseplate which carries generator field rheostats and shunt field rheostats for the main exciter and motor exciter.

The main baseplate of each set and the auxiliary baseplate are insulated from earth by being mounted on groups of porcelain insulators. The neutral point of the motor stator is connected to the baseplate. The mid-point between the d.c. generators is also connected to the base-plate through a leakage relay. In this way the potential of any portion of the set relative to the frames is limited to 3 000 volts d.c.

When working in series each set has a baseplate potential corresponding to its position in the circuit; thus the first baseplate will be at 3 000 volts, the second at 9 000 volts and the third at 15 000 volts above earth in each case.

The wiring diagram of the control panels on the auxiliary baseplate is shown in Fig. 4.

Each main baseplate carries two high-speed circuit breakers each connected in series with a generator armature. The high-speed circuit breaker is set for instantaneous tripping on about 5 times full-load current; it inserts a blocking resistance in circuit and at the same time, by means of auxiliary contacts, trips the generator field contactor. The action of the circuit breaker is extremely rapid, the contacts being fully opened within 0·02 sec., whilst in order to suppress the

generator fields as rapidly as possible the field contactors open the circuit without inserting discharge resistances. Each set is completely surrounded by an earthed metallic screen, and the foundations contain a metallic network which is connected to the earthed screens. All controls are operated by means of insulated spindles from a position outside the screens. The e.h.t. d.c. terminals of each set are connected to a 2-position selector switch mounted on a gallery carrying the busbars. In one position the switch connects the machine in series with the busbars, whilst in the other position the machine is isolated and the gap in the busbars bridged. The screened enclosures and busbar gallery are protected by gates having double electrical interlocks. In addition, it is impossible to enter the machine enclosures without first earthing the baseplate, thus preventing any possi-

delta oil switches, overload and low-voltage trips, ammeter and power-factor meter with current and potential transformers. Each cubicle is located on the switch gallery immediately over its associated transformer, to which it is connected by bare conductors passing through porcelain bushings in the floor. In operation the main oil switch connects one end of the three primary windings of the transformer to the line. The second oil switch is of the 4-pole double-throw type with double escutcheon. On closing the starting-throw the inner ends of the primary windings are connected together, the transformer thus being star-connected to the line and delivering 1 270 volts between phases to the motor. The operation of a sliding interlock bar trips the starting-throw and frees the running-throw which can then be closed to connect the transformer

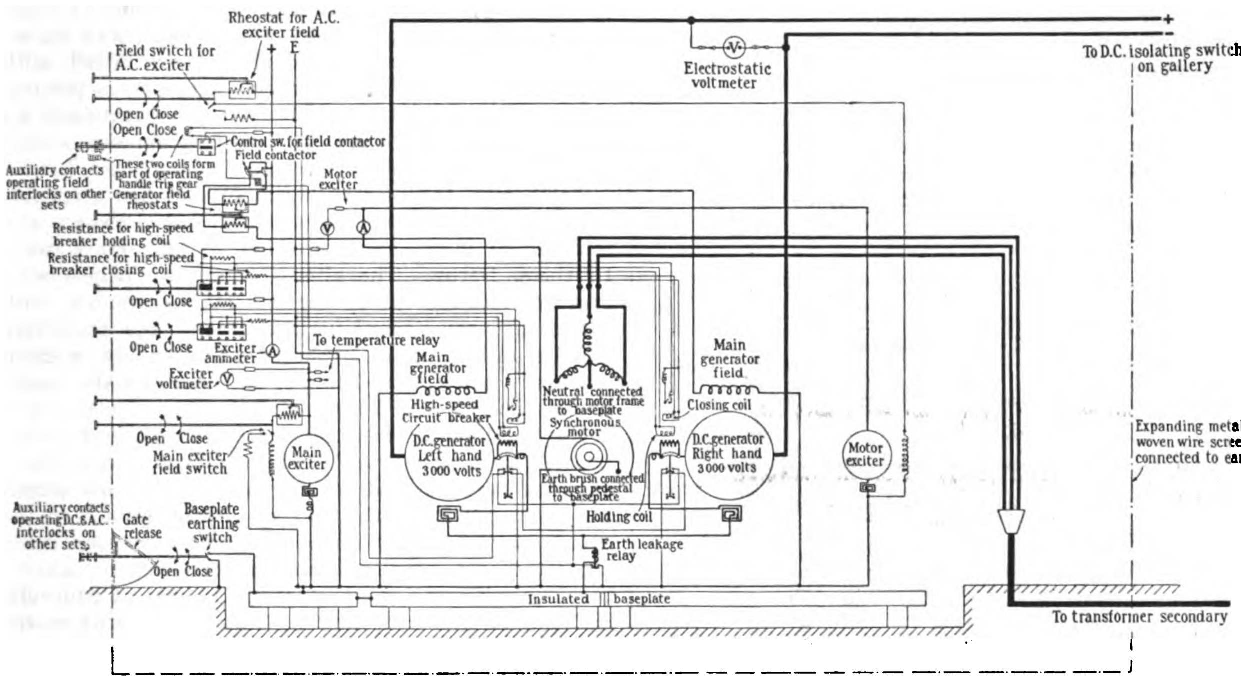

Fig. 4.—Wiring diagram of control panel of 500-kW motor-generator set.

bility of shock from a static charge left on a machine after closing down. A complete system of electrical interlocks external to the machine enclosures is associated with the selector switches, machine controls and a.c. starters. The supply for this interlock system is taken from the 240-volt d.c. battery supply, and no-volt devices are provided to shut down the plant in the event of this supply failing. Any attempt to enter a live enclosure or to operate a selector switch while the busbars are excited will trip the field controls of all running machines. In the event of any generator developing a fault, or in the event of any high-speed circuit breaker opening on overload, means are provided to trip the field controls of all other generators connected to the busbars. As previously mentioned, the motor starting gear for each set is on the 12 000-volt side of the step-down transformer and consists of a steel cubicle containing isolating links, main and star-

primary in delta, giving a normal running voltage of 2 200 volts between phases on the secondary. The switch cubicles were supplied by the British Thomson-Houston Co., Ltd.

In spite of the large dimensions of the machines for their output, necessitated by voltage requirements, the test-results showed an overall efficiency of over 87 per cent.

In addition to the ordinary tests, the machines were subjected to short-circuit tests while fully excited; in the case of one set this test was repeated 20 times, in all cases without flash-over or damage of any kind. A copy of oscillograms taken on a single set by the B.T.H. Co. during the official test is shown in Fig. 5. After installation two short-circuit tests were carried out with all sets in series and fully excited to a total of 18 000 volts d.c. with equally satisfactory results.

The d.c. supply from the busbars is transmitted to the

valve room through duplicate armoured concentric paper-insulated cables, the inner conductor in each case being the high-tension conductor, whilst the outer conductor carries the return current at approximately earth potential. The cables terminate in a steel cubicle

trips. The no-volt trip coil on this switch forms part of a low-tension d.c. circuit and will be referred to subsequently as the "holding coil." One cable terminates in each cubicle, one cubicle being used to supply the main telegraph transmitter, and the other cubicle serving the experimental telephone transmitter. In addition the telegraph cubicle has a selector switch interlocked with the oil switch which connects the e.h.t. d.c. supply to one of two short alternative feeders to the telegraph transmitter, the unused feeder being earthed. The oil circuit-breaker is designed to trip rapidly on interruption of the "holding coil" circuit which is energized from the 240-volt d.c. supply, and during tests the contacts opened 0·18 sec. after interruption of the "holding coil" circuit.

The use of oil circuit-breakers to rupture high-tension d.c. circuits is thought to be a novelty, but tests on short-circuits of 18 000 volts showed that the switch could successfully clear the fault without damage.

The valve filament supply of the station is obtained from two 200-kVA frequency-converter sets each consisting of a 416-volt 50-cycle synchronous motor driving a 200-kVA 354/478-volt 100-cycle three-phase alternator. Each set is provided with a pony motor and exciter. Tirrill regulators are provided on each alternator control panel to limit a.c. voltage fluctuations, and as an additional safeguard the regulators are fitted with excess-voltage cut-outs to provide against the possible failure of the regulator. The voltage maintained by the Tirrill regulators can be varied by remote control from the valve room.

These sets, together with the smaller d.c. generator and other motor-generator sets installed elsewhere and referred to later, were provided by Messrs. Newton Brothers, Derby. The alternator control panels were provided and erected by the General Electric Co., Ltd.

For the operation of various control and protective circuits, and as an emergency lighting supply, a small secondary battery consisting of 120 cells of 200 ampere-hours' capacity has been installed. For charging this battery, 30-kW induction-motor-driven generator and booster sets are provided in duplicate. Automatic switches are provided to short-circuit and disconnect the booster, leaving the battery on the busbars in the event of the motor stopping, the generators being protected by overload and reverse-current circuit breakers. The d.c. busbar voltage is kept at 240 volts and the booster supplies the difference between the battery voltage and this value.

The workshop situated at one end of the power house is provided with a work bench and a number of power-driven machine tools including a 6-in. screw-cutting lathe, 21 in. vertical drilling machine, power hacksaw and shaping machine.

All circuits and machines are provided with protective devices designed to prevent damage from high-frequency currents. On the e.h.t. direct-current generator set, spark-gaps having non-inductive resistances in series are connected across each generator armature. On other machines or feeders straight-filament lamps in cast-iron boxes are shunted across the machine terminals or feeder. In a few cases where the machine current is small a condenser of 2 μF capacity with lamps in series is used.

The switchgear in the valve room consists of the steel cubicles for controlling the e.h.t. direct-current supply and a dead-front board of 20 slate panels carrying all auxiliary supplies for the telegraph transmitter, together with some of the supplies for the telephone sets. A small dead-front slate board of 4 panels supplies all other power required for the experimental telephone set.

The 20-panel board controls the supplies for filaments, grids and anodes of the earlier valve stages and for grid bias of the main valves. The supplies are obtained from duplicate motor-generator sets housed in a small machine room adjoining the valve room.

Other supplies provided by this board are a 240-volt d.c. supply for switch controls and machine excitation, a 50-cycle 416-volt three-phase supply to motors of motor-generator sets and air compressors for keys, a 300-volt d.c. supply for the grid bias of the experimental telephone transmitter, and lastly the 354/478 three-phase 100-cycle supply for heating valve filaments on the telegraph and experimental telephone sets.

Two sets of busbars are provided for the filament supply, one set being associated with each alternator, to which it is connected through a remote-controlled solenoid-operated oil switch. The filament supply to individual valve panels of the telegraph set is taken through a double-throw 3-pole switch on the front of the board and then through a 3-pole contactor mounted behind the board. The double-throw switch enables the valve panel to be connected to either set of busbars, whilst the contactor is in each case remote-controlled from the valve panel where a step-down transformer is situated.

The switchboard and contactors were supplied by the General Electric Co., Ltd.

While on the subject of power supply it may be interesting to mention that a supply of current was required for providing aircraft obstruction lights on certain masts. As the masts are highly insulated from earth it was impracticable to take supply directly from the mains. The difficulty was overcome by mounting a 2-kW 240-volt d.c. dynamo on the mast and driving it by means of a suitable 50-cycle squirrel-cage motor on the ground through the medium of a rubber motor-cycle belt. The motor, which is a totally enclosed weatherproof machine, is provided with automatic starter actuated by a Venner time switch so that the lights are automatically switched on at sunset each evening and switched out at dawn.

High-Frequency Generating Valve Plant.

The high-frequency generating plant was designed to utilize thermionic valves and to be capable of dealing, if necessary, with an output to the aerial of 500 kW continuously under commercial conditions. For the purpose of preliminary calculations the wave-length was taken as 18 000 m, the capacity of the aerial as $0 \cdot 045\ \mu F$, and the total aerial circuit resistance as 1 ohm.

The aerial was designed so that it could be used as one large aerial or be readily divided at the station building into two unequal parts to provide for simultaneous telegraph transmissions on two aerials, and for this purpose two separate down-leads were provided.

The high-frequency generating plant had therefore to be so designed that it could be readily used for such simultaneous transmissions when necessary. However, after the plans had been prepared it was decided to carry out experiments in transatlantic telephony from Rugby in association with the American Telephone and Telegraph Co., and the smaller part of the aerial has been reserved for this purpose for the present and so diverted from its intended function of forming part of a large aerial for the full telegraphic power of the station, or of being used for a second radio-telegraphic channel.

In consequence, the aerial immediately available for the telegraph transmitter is the larger part erected on 8 masts which has a capacity of $0 \cdot 033\ \mu F$. The resistance, as measured after erection, of this aerial at various frequencies in the region of the required transmitting frequency with the masts insulated, is given by curve A of Fig. 7. Curve B of the same figure gives the total resistance of aerial and aerial tuning inductance.

It is essential with the ever-increasing number of transmitting stations that special efforts should be made to maintain constant the frequency of a radio transmitting station and thus reduce the possible interference to a minimum by permitting the use of highly selective receivers.

It was therefore decided to investigate and, if possible, develop the use of the valve-maintained tuning-fork of Eccles and Jordan as a primary source of con-

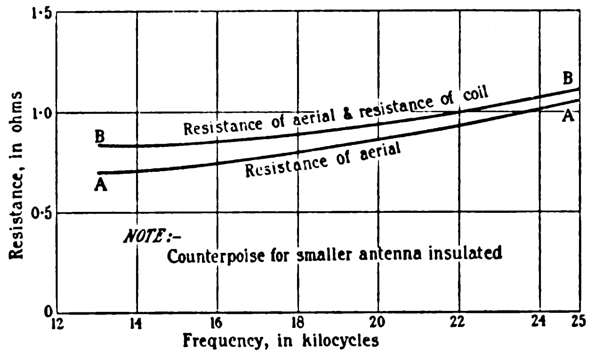

Fig. 7.—Curves of aerial resistance, etc.

Curve AA.—Resistance of telegraphy antenna ($0 \cdot 033\ \mu F$).
Curve BB.—Total resistance of aerial circuit with $0 \cdot 033\ \mu F$ antenna.

stant oscillations. The Post Office research staff produced a suitable combination which was tried out commercially at the Post Office Northolt valve station and proved successful.* The primary source or master oscillator at Rugby is a valve-maintained tuning-fork having a frequency of about 1 800 cycles per second (this frequency being adjustable within small limits), and the high frequency required for controlling the main set is obtained by selecting the 9th harmonic of the tuning-fork frequency.

The frequency produced by this means is remarkably constant, the frequency variation with temperature of the tuning-fork being about 1 cycle in 10 000 per degree C. A small adjustable electric heater is provided to enable the temperature of the box containing the tuning-fork to be kept constant.

The "tuning-fork" stages of amplification may be briefly described as follows. The output from the valve-maintained tuning-fork is of the order of micro-watts, and this is amplified once at low frequency. The 9th harmonic is then selected, filtered and amplified three times with low-voltage valves, giving a final output of 100 watts from the last of these three stages. The tuning fork and all the above stages of amplification

* A. G. Lee: *Electrician*, 1925, vol. 94, p. 510.

are contained in two copper boxes mounted one above the other, the various stages being carefully screened from each other by copper partitions, and this complete unit is termed the "tuning-fork unit." The connections of this unit are shown in Fig. 8.

The output from the tuning-fork unit is amplified three times before it is delivered to the aerial circuit, the various stages being designed to deal with input building and shows the layout of the high-frequency generating plant, etc. The excitation units are seen in duplicate on the right, and the five power units on the left.

The switchboard immediately behind the control table is the 20-panel switchboard, referred to previously, which is associated with the filament supply to the amplifiers and the machines in the auxiliary machine room immediately behind this switchboard which supply

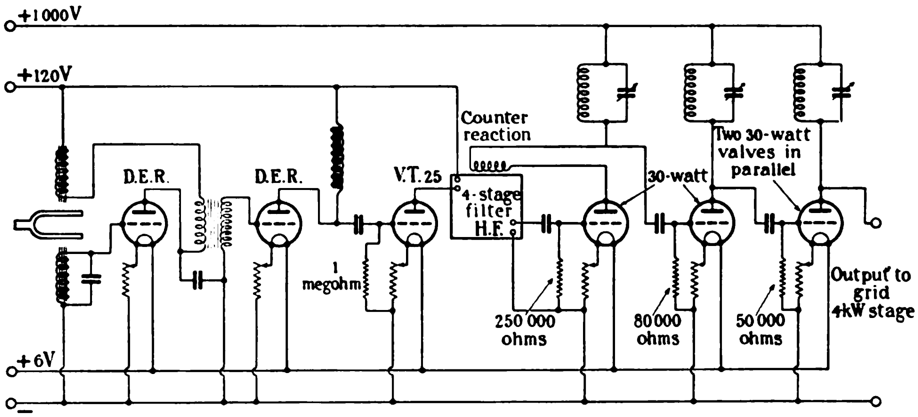

FIG. 8.—Diagram of tuning-fork unit.

powers of the order of 4 kW, 50 kW, and 1 000 kW respectively, and giving output powers of 2 kW, 30 kW and 540 kW respectively. These are referred to as the 4-kW stage, the 50-kW stage and the "power units" respectively. The combination of the 4-kW stage and its associated 50-kW stage forms an "excitation unit." Excitation units and tuning-fork units are provided in duplicate so as to reduce to a minimum the possibility

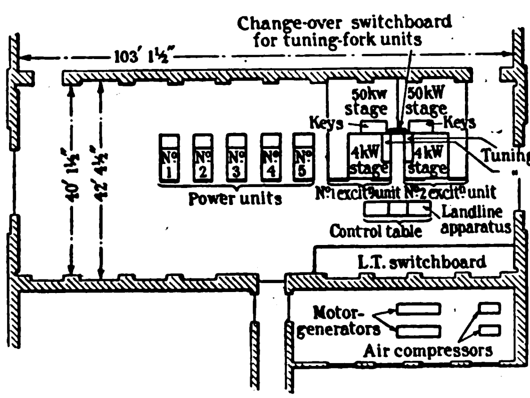

FIG. 9.—Plan of transmitting building.

of delay due to faults, and the arrangement is such that either tuning-fork unit can be used with either excitation unit and either excitation unit can be used to drive the final stage of amplification, which consists of a number of power units.

All the stages and units are contained in high-tension enclosures. The arrangement has been so planned that all meters can be read conveniently, and so that such tuning adjustments as are necessary while the power is on can be made from outside the high-tension enclosures.

Fig. 9 is a plan of the ground floor of the transmitting

the power for the earlier stages of amplification in the tuning-fork unit, the grid bias voltages, compressed-air pump motors, etc.

The main high-tension d.c. switch is remote-controlled from the control table.

The final stage of amplification (i.e. the power units) is not provided in complete duplicate as in the earlier stages. The power-station practice of having a number of units capable of being worked in parallel on common busbars has been adopted. The principal advantages of such a system are :—

(1) It permits an easy flexibility as regards power required for a particular transmission at a particular time of the day, which may be very important from the point of view of not having more valves in use than required and so reducing the consumption of power and also valve replacement costs, which are likely to be a large item in the maintenance costs of the station.

(2) It provides a simple method of repairing a faulty unit or of replacing worn-out or faulty valves while the station is in action.

(3) The installation can be easily adapted to provide either two simultaneous transmission on separate aerials, or a single transmission at larger power on a combined aerial.

(4) It gives facilities for testing different types of valves.

HIGH-TENSION D.C. SUPPLY.

The excitation units and the power units are designed to utilize the same voltage high-tension d.c. supply, and a simple arrangement permits this h.t. supply to be switched on to the 4-kW stage, the 50-kW stage and

whichever power units are in use, by the pressing of a single button on the control table, and ensures at the same time that all accessible units are " dead."

(4) The change-over switch of (1) also makes the necessary transfers in the control wiring of (3) as between the excitation units.

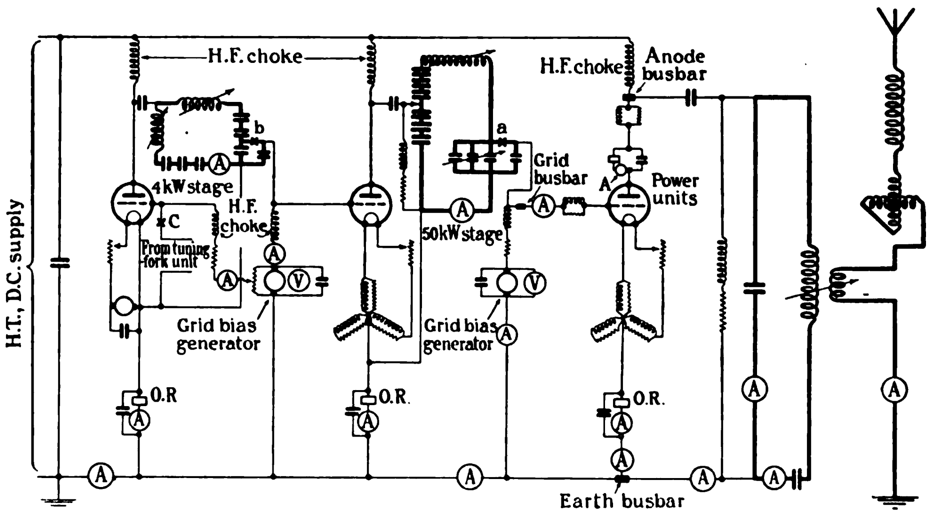

FIG. 10.—Diagram of transmitting circuits.

The general scheme adopted is as follows :—

(1) A change-over switch is provided which connects the h.t. supply to one or other of the excitation units.

(2) The h.t. supply is fed through the excitation unit to the busbar supplying the power units.

(3) All the safety switches and devices form a " series " circuit with the " holding coil " circuit of the high-tension d.c. switch, which is remote-controlled from the control table.

GENERAL SCHEME OF CIRCUITS.

Fig. 10 is a skeleton diagram of the circuit arrangements from the output of the tuning-fork unit to the aerial, showing the circuits between the 4-kW stage and the 50-kW stage, between the 50-kW stage and the power units, and between the power units and the aerial. The tuned high-frequency circuits at the various stages are indicated by the thick lines. A particular characteristic of the circuits is the use of a single tuned circuit between one stage of amplification

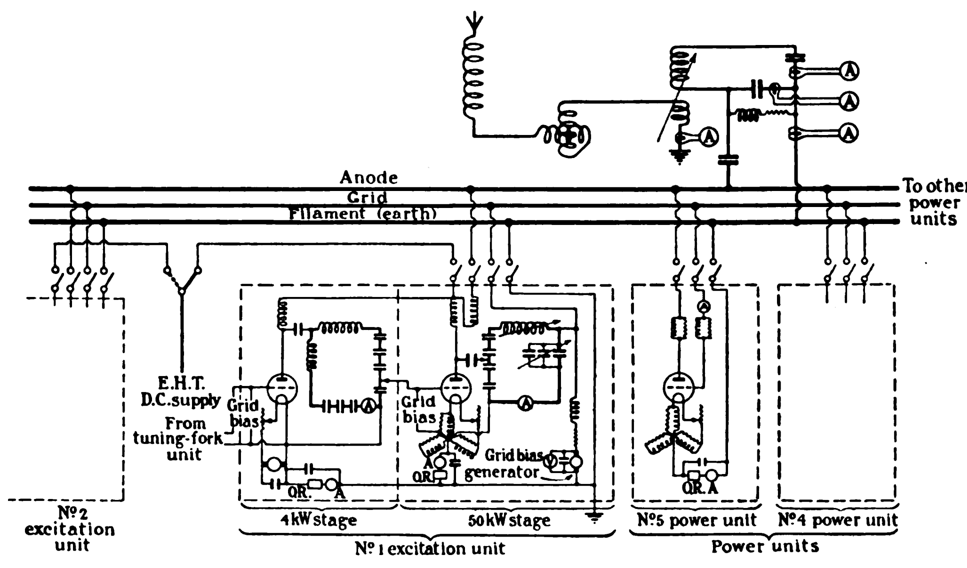

FIG. 11.—Skeleton diagram of arrangement of busbars.

and the next, and the use made of capacitative coupling for giving the necessary voltage variations on both anodes and grids. Some of the advantages of such capacitative couplings are :—

(1) A condenser provides a low-impedance path for the harmonics necessarily generated by a valve transmitter when it is operated as an efficient power amplifier, and thus acts as a desirable harmonic filter.
(2) The actual voltage-swings are easily and accurately calculable both for design and during adjustment.
(3) The power factor of a good condenser being very low, the voltage and current are practically in quadrature.

Fig. 11 is a schematic diagram showing the method of feeding the high-tension d.c. supply through a selected excitation unit to the power units by means of the busbars, and the method of paralleling the power units by means of the same busbars. It will be observed that there are three busbars running the length of the installation for the anode, grid, and filament (earthed) respectively, and that to bring a particular unit into operation in parallel with others it is only necessary to connect it to the busbars by one 3-way switch, and to light the filaments by means of the filament switch for that unit.

In order to simplify this system of paralleling, all apparatus proper to the complete amplifier formed by the power units as a whole, such as anode choke, grid leak, etc., are provided in duplicate and placed inside the respective excitation units.

Filament Supply.

The filament supply for the power units and the 50-kW stage is at 416 volts, three-phase, 100 cycles, transformed down to the required voltage for the filaments (about 20 volts) by transformers in the units themselves. As previously stated, a Tirrill regulator is provided for the 416-volt supply to keep the voltage on the valve filaments constant; this is very important from the point of view of conserving the life of the valves. The filament load of each power unit and each 50-kW stage is balanced between the three phases so as to reduce the effect of any periodic change of emission current due to the use of alternating current for filament heating.

The filament supply for the 4-kW stage is at 15–20 volts d.c. supplied by one of the generators in the auxiliary machine room.

The Excitation Unit.

The 4-kW stage utilizes glass valves of the so-called 600-watt type—i.e. capable of a dissipation of 600 watts—and the panel can be equipped with 1, 2 or 3 of such valves. The valves are mounted on insulators fitted on the back of the slate panel on which the instruments for this stage are mounted.

The 50-kW stage utilizes three water-cooled valves similar to those in the power units, and the manner of mounting, etc., is similar to that of the power units.

The coils forming the inductances of the high-frequency circuits of both stages are constructed of cable of insulated and stranded wires, the cable being wound on a framework of American whitewood in a manner similar to that adopted for the large tuning inductances described later. The cable of the 4-kW stage inductance is 243/36 S.W.G. and that of the 50-kW stage is 729/36 S.W.G. The condensers of these high-frequency circuits are mica condensers in oil.

The safety devices, relays, etc., are similar to those used in connection with the power units.

Associated with each excitation unit is an auxiliary machine unit consisting of one motor driving four generators. These generators have the following ratings and are utilized for the following purposes :—

(1) 500–1 500 volts, ⅓ amp. Anode supply for various amplification stages of tuning-fork unit.
(2) 15–20 volts, 60 amps. Filament supply for 4-kW stage, and also for tuning-fork unit by means of potentiometer.
(3) 40–600 volts, 12 amps. Grid-bias voltage for power units.
(4) 200–600 volts, 1·5 amps. Grid-bias voltage for 50-kW stage and also for 4-kW stage by means of potentiometer.

The motor driving this unit has a remote-controlled starter so that all the various auxiliary powers required are obtained by the pressing of one button at the control table.

With such a chain of amplifiers as that forming this installation one probable difficulty to be combated is the self-oscillation of the system in whole or part due to retroaction from the later to the earlier stages, but this tendency to self-oscillation can be reduced by very careful screening between the various stages. The tuning-fork unit is made up in the form of two copper boxes with copper partitions between the different stages and tight-fitting copper lids to the various compartments. The excitation units and tuning-fork units are placed inside a screened enclosure, the sides and top of which are formed of copper mesh (14 to the inch) mounted on a suitable framework. Internal partitions of similar copper mesh complete the screening between the tuning-fork unit, the 4-kW stage and the 50-kW stage respectively.

Considerations in Regard to the Size of Power Unit.

The number of valves used for a high-power valve transmitter should be reduced to a minimum by using the most powerful valve available as a unit. When the design for Rugby was prepared, the largest power valve commercially available which had been subjected to severe traffic tests was the Western Electric water-cooled valve which is capable of dealing with an input of 20 kW, of giving an output of 10 kW and continuously dissipating 10 kW when operated at a d.c. anode voltage of 10 000 volts—the filament consumption being 41 amperes at 22 volts. This type of valve had been tested to 13 000 volts with an output of 14 kW. The specification stipulated that all valves should be tested at an output of 12 kW with 12 000 volts on the anode. All the valves used in the installation were manufactured by the Western Electric Co. at New Southgate, England.

An efficiency of the order of 95 per cent can be expected from the coupled circuit to the antenna, which means that for an aerial power of 500 kW an output from the valves of about 520–530 kW is required. The determining factors in deciding the size and number of the power units were as follows :—

(1) The number of valves in each unit should be preferably a multiple of 3 in order to permit the balancing of the filaments between the three phases.
(2) The number of units must not be unduly large, in order to avoid complications of wiring and excessive duplication of meters, etc.
(3) The number of units should be sufficient to enable the number of valves in use to be varied in suitable steps (*a*) for the station to work on low power if this proves to be economically desirable, or (*b*) for the utilization of a smaller number of greater power valves as the manufacturing technique of power valves develops.
(4) The number of units should be suitable to provide two transmissions of the order of 300 kW aerial power and still leave a spare unit.

These considerations led to the decision to provide 5 power units, each capable of an output of 180 kW from 18 10-kW output water-cooled valves. With this equipment 3 power units would be required for a 500-kW aerial power transmission, leaving 2 units spare; also two transmissions of over 300 kW aerial power could be undertaken by using 2 power units for each, leaving one unit as a spare in reserve.

The Power Unit.

The power unit consisting of 18 valves is a rectangular enclosure arranged with 9 valves on each side and a front slate panel containing the meters.

The 3 busbars run above the various power units and the excitation units and each power unit can be connected to the busbars by a 3-pole switch. The 3-pole switch for connecting a power unit to these busbars cannot be operated until the Bostwick gates on the sides of the unit have been closed and locked, and the keys locked in the switch itself; the converse holds that the gates of the unit cannot be opened until the keys for opening them have been released by the opening of the switch, which "earths" all parts of the power unit. These interlocking devices render the operation of the power units quite safe.

The front panel of a power unit carries the following :—

(1) Ammeter reading high-frequency feed current from the power unit into the oscillating circuit.
(2) Ammeter reading anode d.c. feed current to power unit from high-tension machines.
(3) Ammeter reading mean d.c. grid current of power unit.
(4) Recording ammeter of filament current, by means of which the actual running time of unit and the life of individual valves can be obtained.
(5) An overload relay for the complete power unit which trips the main high-tension d.c. switch.
(6) An "Electroflo" meter which reads the actual total rate of flow of water through the valve jackets of the unit.
(7) A relay in association with the "Electroflo" meter which operates if the flow of water falls below a certain amount, and trips the main high-tension d.c. switch.

Fig. 12 is a section through a power unit parallel to the front, showing the juxtaposition of the various panels. Slate panels have been used in all cases for mounting the various apparatus and fittings, these slate panels being supported and insulated from the earthed iron framework by suitable porcelain insulators.

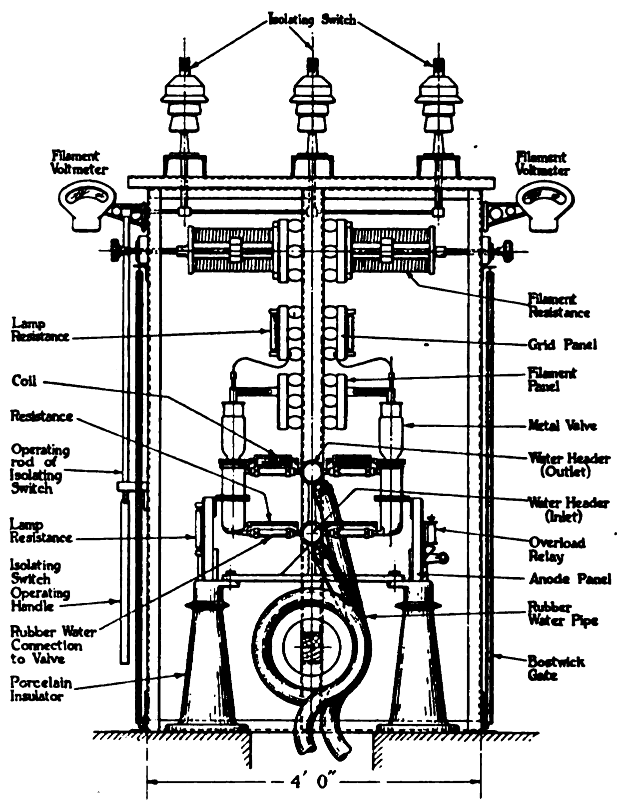

Fig. 12.—Section of power unit.

The two anode panels are supported from the floor by four 18-in. insulators. These insulators also support the copper water pipes between these panels which not only act as headers for the water supply to the anodes but also as the anode busbars for the valves in the panel.

The anode panels carry the valves in their water jackets and the overload relays in the individual anode circuits. In the event of any particular valve taking an excess current due to softness or any other reason, the corresponding relay operates, releasing a hammer normally held up by the armature of the relay, which in turn operates a mechanism that trips the high-tension d.c. switch by breaking the "holding coil" circuit. The arrangement has proved to be very effective, and oscillograms which have been taken show that the h.t. switch is broken in about $\frac{1}{4}$ sec. following an excess of current through the relay.

The water system used for cooling the anodes is a closed system using distilled water which flows by gravity through the valves. The water is pumped from the bottom tank back to the upper supply tank through a "water cooler," where the heat is extracted by an independent circulating-water system.

The distilled water is supplied to the anodes of the power unit through 30 ft. of 2-in. diam. rubber hose wound on a horizontal wooden drum at the bottom of the power units. This rubber hose feeds the 3 in. copper header which passes down through the centre of the unit and which in turn feeds the individual valves on each side through short lengths of rubber tubing to the lower ends of the valve jackets. The outlet water from the upper ends of the valve jackets passes to a similar header which discharges through another length of 2-in. hose similar to that used for the inlet water and wrapped round the same drum. The long length of water in the rubber hose provides the necessary insulation of the anodes from the earthed metal parts of the water cooling system, and the drum carrying this hose is a part of the insulated anode system. The short lengths of rubber tube from the headers to the valves provide the insulation required between valves to permit the insertion of relays, coils, etc., in the individual valve anode circuits. The porcelain floor insulators and the large rubber hose are shown in Fig. 12.

The insulation of the anode system of one power unit under working conditions with water flowing is of the order of 520 000 ohms, giving a leakage current through the water of only 20 mA at 10 000 volts.

Immediately above the anode panels are the filament panels which carry the filament busbars for the unit and the flexible braided leads from these busbars to the separate valve filaments. Above the filament panels are the grid panels, which carry the grid busbar (in the form of a complete loop of copper strip between the panels) and also any "stopper" circuits referred to later.

Above the grid panels are the filament rheostats, one of which is provided for each valve, together with a voltmeter key to enable the actual filament voltage to be read by means of a swinging voltmeter at the end of the panel. This independent variation of the filament voltage in order to obtain the rated value for each valve is very necessary in order to conserve the life of the valves, the life being seriously shortened if the filament is continuously run slightly above its rated voltage.

The Paralleling of Valves in a Unit.

One of the difficulties in designing a large power transmitter using a large number of valves is the tendency of such valves to "self-oscillate," individually or in groups, the inter-electrode capacity of adjoining valves or groups of valves forming the condenser of the oscillating circuit in association with the inductance of the connecting leads, etc. These difficulties are increased with water-cooled valves where the existence of the water jacket increases the intervalve and inter-electrode capacities very considerably. Every such difficulty of this nature must be examined and dealt with separately, and, generally speaking, the oscillations can be suppressed and the system made stable by one or more of the following devices :—

(1) The provision of a small condenser between the grid and filament of each valve, as close to the electrodes as possible, in order to make the grid-filament impedance capacitative.

(2) The use of "stopper" circuits in the individual anode, and/or grid circuits consisting of an inductance in parallel with a resistance high compared with the impedance of the inductance at the transmitted frequency. For undesired oscillations, however, which are of a much higher frequency, the added inductance becomes a large proportion of the inductance of the circuit, and the resistance across it provides sufficient damping for the conditions of self-oscillation of the valves to be unfulfilled (Western Electric Co.).

(3) The insertion of a series resistance in the individual anode or/and grid circuits which act as a damping for self-oscillation but are not of high enough value to cause a large power loss at the transmitted frequency.

The best arrangements for a particular case must be obtained by experiment, and quite a number of combinations of such devices would probably be equally successful. It is generally desirable to allow a factor of safety on such devices by fitting more than the minimum absolutely essential, so as to provide for the contingency of faults which might otherwise permit self-oscillation, with the consequent possible destruction of a number of costly valves.

The arrangements used successfully at Rugby are :—

(1) Two small condensers of 400 $\mu\mu$F each are mounted on each valve between the grid and each end of the filament.

(2) A series non-inductive resistance of 100 ohms between each individual grid and the grid busbar.

(3) The anode feed from the individual valves to the top water header (which acts as the anode busbar) consists of an inductance of 50 μH in parallel with a non-inductive resistance of 60 ohms to the same header and a similar non-inductive resistance to the bottom water header, these two headers being metallically connected at the end of the panel.

Fig. 13 gives the circuit arrangements of a complete power unit.

The Paralleling of Power Units.

The paralleling of the power units themselves also involves consideration as to the method of prevention of inter-oscillation between power units.

At Rugby the combined anode of the power unit is fed to the main anode busbar through a "stopper" circuit consisting of an inductance of 100 μH in parallel with a resistance of Morganite plates of 8·5 ohms. The combined grid of the power unit is fed to the main grid busbar through a "stopper" circuit consisting of an inductance of 50 μH in parallel with a resistance of 300 ohms formed by 6 straight-filament lamps in series. The positions of these in the circuit are shown in Fig. 13.

These "stopper" circuits are fitted at the back of the power unit in the space above the filament transformer and immediately below the 3-pole power unit isolating switch, to two terminals of one side of which they are connected.

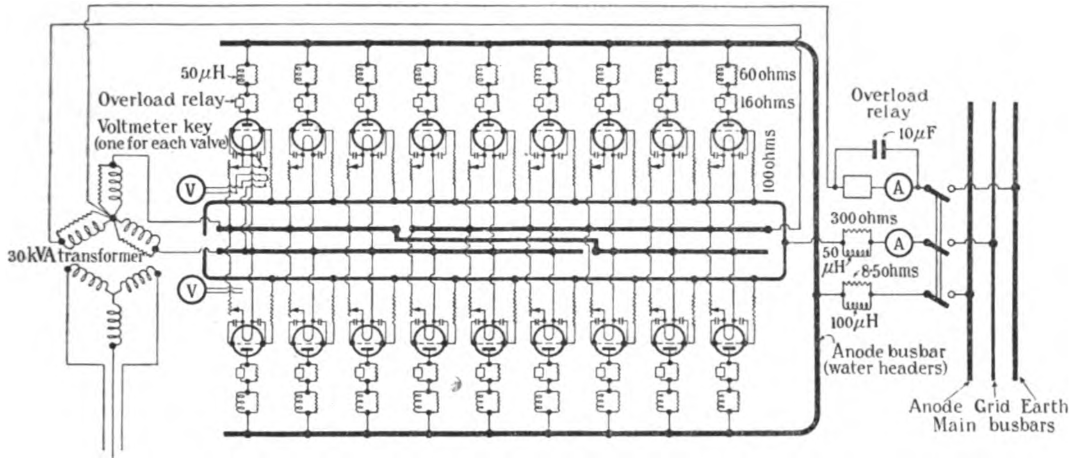

FIG. 13.—Wiring diagram of power unit.

SAFETY DEVICES AND CONTROL CIRCUIT.

The safety devices can be divided into two groups :—

(1) Those for the protection of the personnel.
(2) Those for the protection of plant.

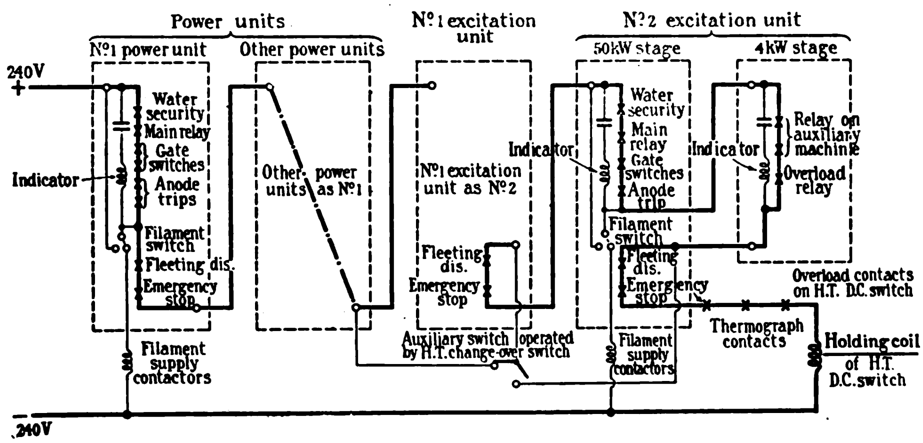

FIG. 14.—Skeleton diagram of control circuit.

For the protection of personnel, the interlocking of the gates of the power units as described previously, and the earthing of the unit when the isolating switch is open, safeguard the station staff from electric shock when working on the power units. A similar arrangement is provided in connection with each excitation unit. The 4-pole isolating switch (see Fig. 11) which connects the high-tension d.c. power to the excitation unit, and the excitation unit to the main busbars is similarly interlocked with the gates of the excitation unit enclosure.

The protection of plant is of special importance when using valves, because, firstly, the closing of the h.t. switch for a very short period under incorrect conditions might result in the destruction of a number of valves, and secondly, there is a possibility of valve failures which amount to a short-circuit of the 10 000-volt d.c. supply. All the safety devices and relays are therefore linked up in one series circuit through the "holding" coil of the high-tension d.c. switch. A disconnection in any one place will then prevent the switch from being closed, and also the breaking of the circuit at any point during transmission due to a fault or an overload will open the high-tension d.c. switch.

Fig. 14 is a skeleton diagram showing the circuit arrangement of this "series" control wiring through the "holding" coil of the high-tension d.c. switch. The main facts to be noticed in connection with it are as follow :—

(1) The series circuit includes one of the two excitation units and whatever power units are in use.

(2) The operation of the hand-operated switch which changes over the h.t. supply from one excitation unit to the other automatically changes over the control wiring and short-circuits that of the excitation unit not in use to permit access for repairs, adjustments, etc.

(3) The placing of the filament switch on a power unit to the " off " position short-circuits the control wiring of that particular unit, and enables work to be done on that unit while the others are in use.

(*d*) Gate switches.

(*e*) A fleeting disconnection during the movement of the power unit isolating switch, to ensure that a unit is not switched on to the busbars while other units are in operation.

(*f*) Emergency push-button.

(2) *On each excitation unit.*

(*a*) Main overload relay for 50-kW stage.

(*b*) Trip operated by individual anode relays of 50-kW stage.

(*c*) Water-flow relay for 50-kW stage.

(*d*) Overload relay for 4-kW stage.

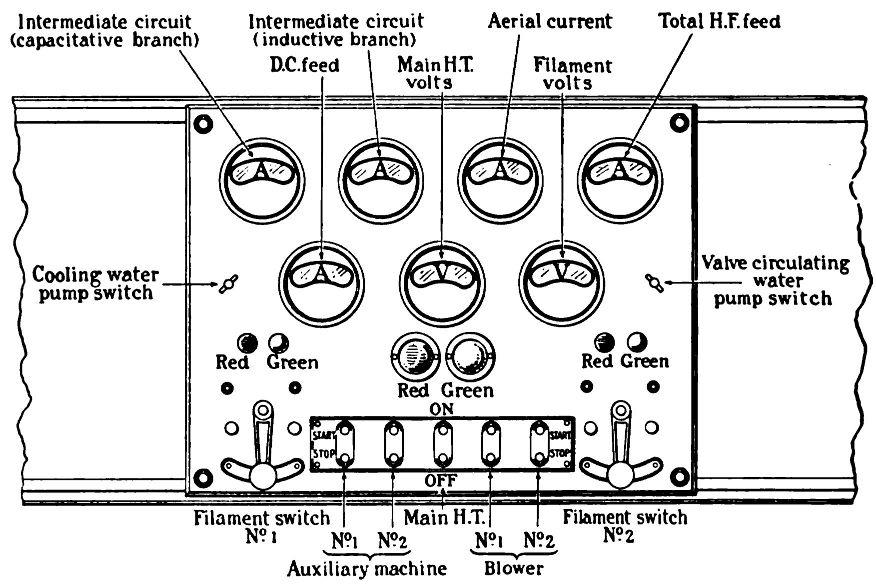

FIG. 15.—Control table.

(4) The placing of the filament switch on a power unit to the " on " position connects the primary of the filament transformer to the filament supply busbars by means of a remote-controlled contactor. The 240-volt supply to operate this contactor is obtained via the control wiring as shown in the diagram, thus ensuring that the filaments cannot be lighted until water flowing through the valve jackets has closed a contact earlier in the circuit.

(5) An indicator is fitted on the front of each power unit panel and placed in series with a condenser across all the contacts of that particular unit. When a break in the control circuit occurs, the charging current from the 240-volt mains into the condenser drops the indicator and gives a visual indication of the particular unit at which the overload or other trouble has occurred.

The operating points of the control circuit may be summarized as follows :—

(1) *On each power unit.*

(*a*) Main overload relay.

(*b*) Trip operated by individual anode relays.

(*c*) Water-flow relay.

(*e*) Gate switches.

(*f*) A fleeting disconnection for the excitation units similar to that of (1*e*) for power units.

(*g*) A polarized relay in association with one of the grid-bias generators to ensure that the auxiliary machine is running and that the bias is of correct polarity.

(*h*) Emergency push-button.

(3) *External to power and excitation units.*

(*a*) A contact in association with a recording thermograph which records the temperature of both the inlet and outlet temperature of the valve-cooling water. This contact is arranged to open if the outlet water exceeds a predetermined temperature.

(*b*) Emergency switch in condenser room.

(*c*) Overload coil of high-tension d.c. switch.

(*d*) Release button on control table.

THE CONTROL TABLE.

The position of the control table in the layout of the transmitting room can be seen from Fig. 9. The slate panel contains all the essential controls and the most important meters of the wireless transmitter. This equipment is shown in Fig. 15 and consists of :—

(1) Press-buttons to start and stop auxiliary machines.
(2) Press-buttons to start and stop air compressor for keys.
(3) Press-buttons to close and open high-tension d.c. switch.
(4) Switch to start distilled-water pump.
(5) Switch to start cooling-water pump.
(6) Switch to close and open main filament supply switch.
(7) Filament supply voltmeter.
(8) High-tension d.c. voltmeter.
(9) High-tension d.c. feed ammeter.
(10) Ammeter reading high-frequency feed current to main oscillating circuit.

(12) Ammeter reading high-frequency current in inductive arm.
(13) Aerial ammeter.

The apparatus terminating the land line from the Central Telegraph Office, London, which controls the transmission from the station, is fitted on the right-hand side of the control panel so that the duty engineer can check the signals passing through the transmitter and also speak to the controlling telegraph office as may be necessary.

On the table on the left-hand side of the control panel is fitted an " engine-room telegraph " operated by push-buttons to enable the power requirements to be signalled to the power house. A loud-speaker and wireless recorder are provided for checking the actual signals transmitted from the aerial. In addition there are fitted on this table, two press-buttons controlling a motor-driven variometer in the aerial circuit to compensate for any changes in the aerial constants due to weather, etc.

The duty engineer, therefore, has full control of the entire station in detail from his position at the control table.

The high-frequency and other electrical measuring instruments fitted in the valve transmitting plant were supplied by Messrs. Everett, Edgcumbe.

Type and Electrical Proportions of Coupled Aerial Circuit.

Any large power valve transmitter should be provided with a coupled circuit, since the use of a valve transmitter at reasonably high efficiency necessitates the production of a certain proportion of harmonics, which should be filtered from the aerial. This involves a consideration of the following points :—

(1) Method to be adopted to produce necessary voltage variation on anode (commonly referred to as " type of anode tap ").
(2) Method of coupling to aerial, i.e. inductive or capacitative.
(3) Coefficient of coupling between aerial and primary circuit.
(4) Proportion of inductance to capacity in primary circuit.

The diagrams of Fig. 16 * indicate various circuit arrangements which are referred to as Types A, B, C, D and E respectively.

For an " anode tap " the use of a capacity rather than inductance brings with it a reduction of the harmonics in the aerial in the ratio of $1/m^2$ for the mth harmonic ; that is, types B and D are m^2 times better than types A and C respectively. For preliminary tuning, the use of capacity rather than inductance brings with it the disadvantage of having to be tapped in relatively big steps instead of being continuously variable

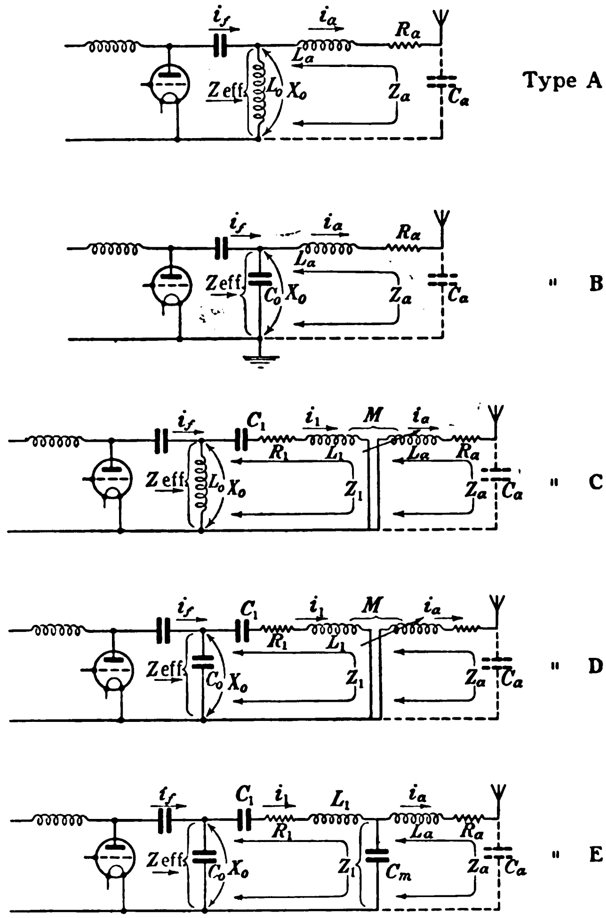

Fig. 16.—Types of output circuits.

as with an inductance ; but, within these steps, variations of coupling between the primary circuit and the antenna circuit will produce equivalent changes in the adjustment of the complete circuit.

Similar arguments apply to the method of coupling the primary circuit to the antenna circuit; that is, as regards the undesirable emission of harmonics, type E circuit is m^2 times better than type D, and therefore m^4 times better than type C. The ideal circuit, therefore, from the point of view of harmonic emissions is that shown as type E with capacitative coupling to both anode and aerial.

In practice, however, when designing a circuit for an

* The author is indebted to Mr. R. V. Hansford and Mr. Faulkner for these diagrams.

aerial not yet erected of which the resistance and capacity are not known accurately, it would be expensive to provide a range of condenser values for both anode and aerial couplings which would cover both all the large and small adjustments required during the experimental period of tuning up the plant. If, however, a type D circuit is used with a condenser having a relatively coarse adjustment for the anode coupling and a continuously variable inductive coupling for the aerial, all necessary adjustments for the preliminary testing can be made with facility; then when the constants of the aerial circuit are known and the preliminary tuning has been completed, if necessary the change from type D to type E can readily be made. It has, however, been found unnecessary to depart from the type D circuit installed.

As regards the emission of harmonics, the improvement obtained by using a coupled circuit of type D instead of a plain aerial circuit is dependent, among other factors, upon the product of the decrements of the primary and aerial circuits. When a low-decrement aerial tuning inductance is provided, the decrement of the aerial circuit at a given frequency is practically fixed, being mainly dependent upon the external part of the circuit.

It is therefore important that the decrement of the primary circuit be made low, and this involves the provision of the most efficient inductance coil and condensers having very low loss. The cost of the primary circuit is roughly proportional to the kVA with which it has to deal, except at the higher voltages where the cost increases rather more rapidly than the kVA.

The efficiency of the coupled circuit and the improvement as regards harmonic emission obtained by using the coupled circuit are both independent of the ratio of inductance to capacity in the primary circuit. Under these circumstances the actual value of the inductance was chosen from a consideration of the following:—

(1) The cost of the coil decreases slightly as its inductance is decreased.

(2) Above a certain working voltage the cost of the condenser increases at a more rapid rate than its capacity.

(3) The cost and difficulty of insulating leads are increased when high working voltages are increased.

This led to the decision to have a primary circuit inductance of the low value of 500 μH. The values of the condensers making up the primary oscillating circuit are given in Fig. 17. The condensers used are mica condensers immersed in oil, made by Messrs. Dubilier to meet the Post Office specification. These have a power factor of 0·00025 at the working frequency. The power factor was tested by an 8-hours' run on each unit on full load and voltage at the maker's works. In addition to the power factor tests each unit of the condenser banks (Fig. 17) was tested at the following voltages:—

Bank A—68 000 volts (R.M.S.) at 50 cycles.
Bank B—25 000 volts (R.M.S.) at 50 cycles.
Bank C—35 000 volts (R.M.S.) at 50 cycles.

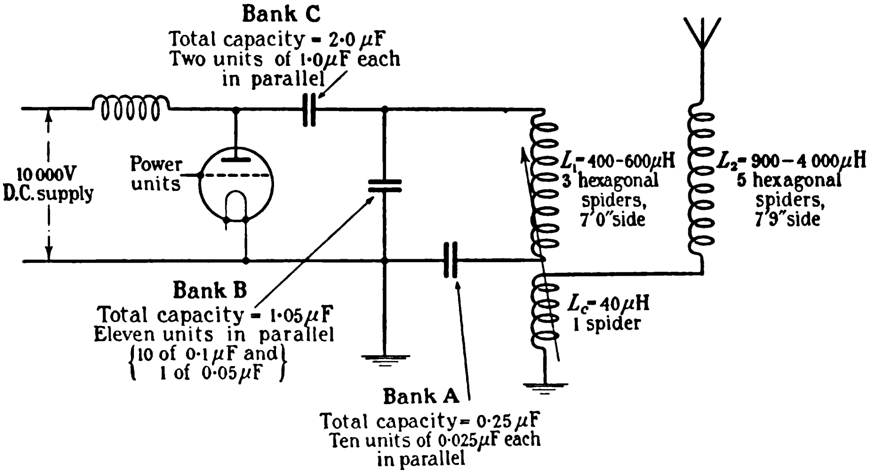

FIG. 17.—Coupled aerial circuit.

The primary circuit is designed to carry a current of 630 amperes, and at this current the value of the R.M.S. voltage applied to the condenser would be 33 000 volts (peak value 46 500 volts) and the kVA 20 800. Actually at present the value of the working primary current is about 300 amperes.

At Leafield the condensers, consisting of aluminium plates immersed in oil and made and erected by the Post Office engineers, have been working for about 2 years with a current of 260 amperes and a voltage of 68 000 (R.M.S.), dealing with 18 000 kVA. The Dubilier type of condenser is much less bulky than the Leafield type and its adoption enabled space to be saved in the Rugby building.

THE DESIGN OF INDUCTANCES FOR HIGH POWERS.

It is essential in a high-power transmitting station that the losses in the primary-circuit and aerial-circuit

inductances should be reduced to a minimum. The losses which add together to form the equivalent resistance of the coil may be divided into the following three groups :—

(1) Losses in the conductor itself.
(2) Losses in surroundings.
(3) Losses in the framework necessary to support the conductor forming the inductance.

The losses in the conductor itself (group 1) have been discussed mathematically in detail by Mr. Butterworth,* and although Mr. Butterworth does not deal with the case of a large coil with widely spaced turns in a deep winding space, the formulæ he has given can be used without serious error *to compare* the efficiency of various designs of coils, etc. At the time the designs were being prepared the practical manufacturing limit as regards number of strands in a cable was 6 561 (= 3^8) and for this number of strands, so far as conductor losses only were concerned, calculations indicated that the diameter of the coil should be as great as the limitations of the space permitted and the diameter of the wire used should be very small and of the order of 0·007 in. It was therefore decided to use a cable of 6 561 strands of No. 36 S.W.G. wire for both the primary and aerial inductances, each strand being insulated by enamel and one covering of cotton or silk. The cables were made to the Post Office specification by Messrs. Henleys Telegraph Works Co., Ltd., and Messrs. Connollys, Ltd. The maximum current-carrying capacity of this cable when wound into an inductance is probably of the order of 1 000 amperes.

With an efficiently designed coil of large dimensions for big powers, the losses in the surroundings and in the inductance framework must necessarily be of the same order as the conductor losses. The losses in the surroundings can only be reduced by having adequate clearances between the inductance and the floors and walls, and by avoiding as far as possible for the construction of the building the use of materials which are likely to absorb energy from the inductances.

A considerable amount of experimental work † has been carried out in the Post Office Engineering Department to ascertain a suitable insulating material for use in the construction of radio transmitting inductances, and it was found that American whitewood was very much better as regards dielectric losses than any other material or any other wood. The method adopted by the Post Office for the construction of transmitting inductances is to mount a cable formed of insulated and stranded wires on a framework of American whitewood. The cable is wound in slots on movable wooden spiders which are supported by rollers on a wooden framework, so that changes of inductance can be obtained by the relative movement of the spiders without the awkward mechanical construction of "tapping points" and the disadvantages of "overhanging" end-turns. The maximum width of the largest inductance coil is 14 ft. 6 in. The particulars and general dimensions of the aerial and primary circuit inductances are as follow :

* *Philosophical Transactions of the Royal Society*, A, 1921, vol. 222, p. 57.
† E. H. Shaughnessy : Chairman's Address to the Wireless Section, *Journal I.E.E.*, 1925, vol. 63, p. 60.

Aerial coil.—This consists of 5 spiders each of 8 turns wound in the form of a hexagon with 7 ft. 9 in. external side (5 ft. 9 in. mean side). Distance between individual turns 6 in. Inductance continuously variable between 900 and 4 000 μH.

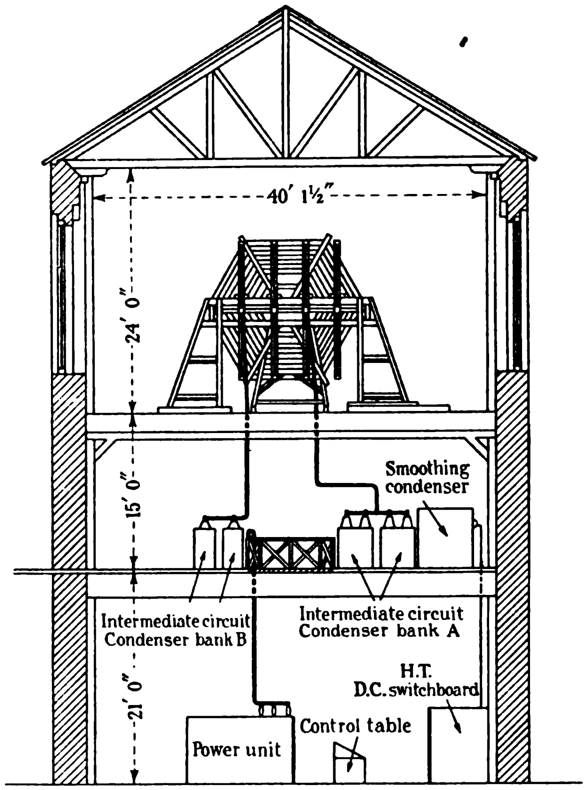

FIG. 18.—Section of transmitting building.

Primary circuit coil.—This consists of 3 spiders each of 4 turns wound in the form of a hexagon with 7 ft. external side (6 ft. 2 in. mean side). Distance between turns 6 in. Inductance continuously variable from 400 to 600 μH.

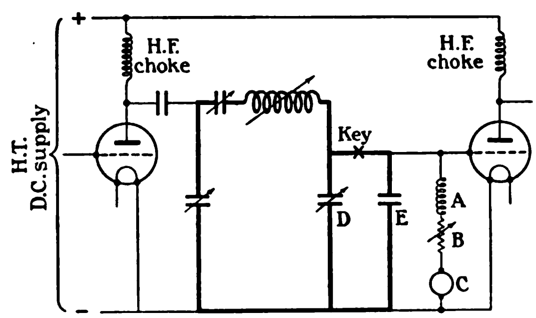

FIG. 19.—Skeleton diagram of inter-stage circuit.

Coupling coil.—One spider wound with 2 turns 6 ft. 5 in. external side. This coil is mounted on the same framework as the intermediate circuit coil and is coupled thereto. Inductance 40 μH.

One outside spider can be moved by a screw in order to get a fine adjustment of tuning. The method of

making a joint in the stranded wire between the spiders is to splay out the strands on a number of insulated flat copper plates and semi-conical copper fittings so as to ensure proper circulation of current through all the strands and to keep a cool joint.

It was estimated at the time of the design, from previous comparisons between actual and calculated decrements of smaller coils, that the decrement of the complete primary circuit would be about 0·003 to 0·005 and that of the aerial tuning inductance would be about 0·002. The actual measured resistance at 16 000 cycles of the entire primary circuit as erected was 0·088 ohm, giving a decrement of 0·0053. The measured resistance of the aerial tuning inductance and coupling coil (2 500 μH) at 16 000 cycles was 0·11 ohm, giving a decrement of 0·00137 for the coils. These values of decrements are very low and the author has not noticed details in the technical Press of any transmitting inductance which is as efficient as these have proved to be.

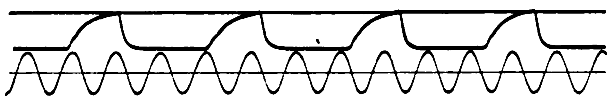

FIG. 20.—Oscillogram of rectified aerial current.
[Aerial current = 515 amps.]

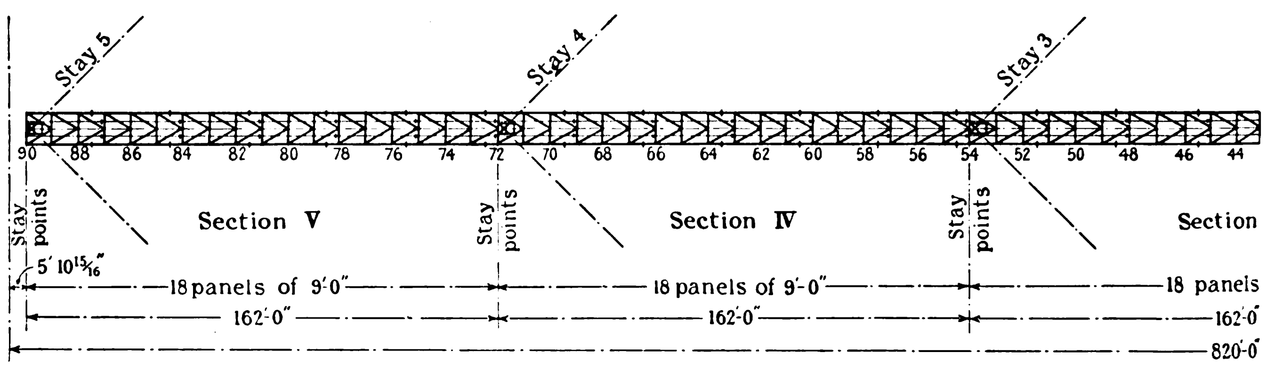

FIG. 21.—Elevation of mast.

RELATIVE POSITIONS OF VARIOUS AMPLIFIERS AND AERIAL CIRCUIT.

Fig. 18 is a section of the transmitting building, showing the relative positions of the power units and their output circuit. It will be noticed that the condensers of the primary circuit and the smoothing condensers on the high-tension d.c. supply are placed on a floor immediately above the power units. A large opening is provided in this floor for light and observation purposes, and the high-frequency leads from the ground floor to upper floors are taken through this.

The inductances for the primary and aerial circuits are mounted on wooden beams above the condenser floor. This arrangement places the inductances as far as possible from the floors, walls, etc. The metal work used in the construction of the building above the condenser floor is reduced to a minimum, and is a negligible quantity.

METHOD OF KEYING AND SHAPE OF SIGNALS.

One of the greatest difficulties experienced in the design of any type of large-power radio transmitter is that of successful keying, and in each case the best method and best adjustment are obtained by experience and experiment. A considerable amount of experimental work on various methods of keying a valve transmitter was carried out with the 50-kW transmitter at the Post Office Northolt radio station, and as a result of those experiments it was decided to provide for the simultaneous operation of a simple "make and break" key at each of the three points in the circuit marked X in Fig. 10. The system has proved to be eminently satisfactory and no difficulties have been experienced up to the highest powers used at present. Creed pneumatic keys are used for points "a" and "b," and a magnetic relay for point "c."

It will be observed that there is no oscillation in the aerial when the key is "up," and that this result is obtained by breaking the feed to the grid from one stage of amplification to the next, as shown in Fig. 19, which is a skeleton diagram of the last inter-stage circuit.

There are two points of particular interest in the arrangement. The first is that the key splits the coupling condenser to the grid and leaves the condenser E between the grid and filament when the key is up. This condenser is of sufficient value to make the impedance from grid to filament capacitative, and this counteracts any tendency that this stage may have to self-oscillate.

The second point of interest is the series circuit A B C from grid to filament. "A" is merely a high-frequency choke, "B" is an adjustable resistance (grid leak) and "C" is a d.c. (grid bias) generator. When the key is down, the mean negative grid potential is the sum of that due to the grid leak and the generator; when the key is up, the only bias is that due to the generator.

By adjusting the proportions of the bias due to grid leak and generator respectively when oscillating, it can be arranged that the generator voltage is sufficient to allow a suitable direct current to pass through the valves when the key is up. The advantages of this are two-fold and are shown below :—

(1) The d.c. load with " key up " reduces the voltage " kick " on the generator with keying.
(2) The conductive path through the valve (due to the small grid bias) increases the damping of the aerial when the key is up, with a corresponding improvement in the shape of the signals.

The latter point is well illustrated by the group of oscillograms in Fig. 20, which shows the shape of the signal in the aerial for a series of dots at about 50 words per minute. The oscillogram of the rectified aerial current obtained from a local circuit shows quite clearly the different rates of change for growth and decay respectively of the aerial current.

From similar oscillograms of the aerial current the decrement of the aerial circuit for the rise of current has been calculated as being 0·0086, whilst for the decay it is as high as 0·024. The advantage of this method

below this are columns of porcelain insulators and a granite cube (5 ft. 6 in. sides), the whole being supported by a steel column the top face of which is 8 ft. 2 in. above ground. The masts are of triangular form with 10 ft. sides, the vertical posts being formed of two channels fastened together at an angle of 60° by a bent bar plate. The bracing is arranged in panels 9 ft. high and is of the K form.

Five sets of stays, 3 per set, are provided and divide the mast into 5 sections.

The mast is not tapered, but the mast sectional members are gradually diminished in size at each stay point from the bottom to the top of the mast.

The principal dimensions of the mast sections are :—

Vertical posts.
Channels—Bottom section, 10 in. × 3½ in. × 28·2 lb.
Top section, 5 in. × 2½ in. × 11 lb.
Bent bar plate—Bottom section, 8 in. × ½ in.
Top section, 6 in. × ⅜ in.
Bracing angles.—Bottom section, 4 in. × 4 in. × ½ in.
Top section, 3½ in. × 3½ in. × ⅜ in.

The masts were designed to withstand a uniform wind load of 60 lb. per sq. ft. of projected surface, and a horizontal antennæ pull of 10 tons at the top. The

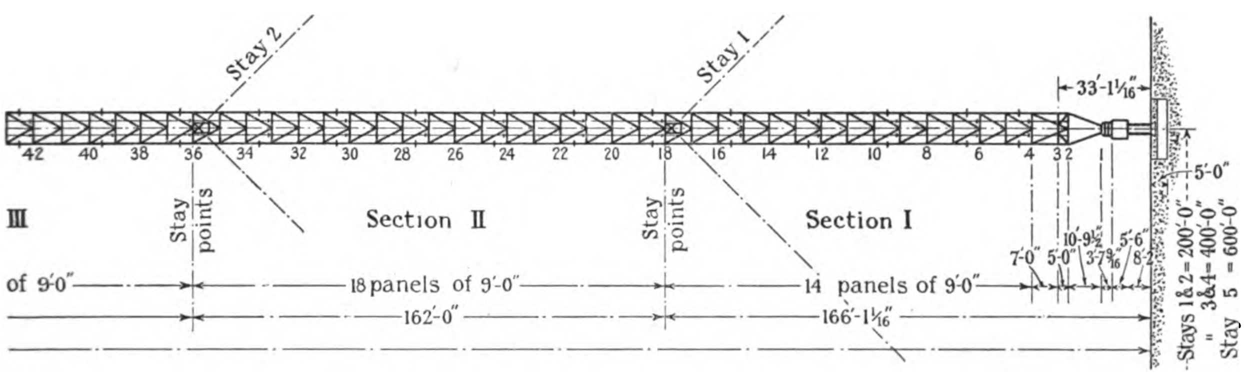

FIG. 21 (*continued*).

of keying as regards shape of signals is therefore quite obvious; the oscillogram indicates that, for higher speeds, advantage should be taken of the quick decay by decreasing the length of the " space " relatively to the " mark," and means for doing this are being developed. This method of keying is due to Messrs. Hansford and Faulkner.

The whole of the work of erecting and assembling the internal wireless plant, including the excitation units, valve panels, power units, oscillating circuits, and the winding and jointing of most of the inductance coils, was done by Post Office workmen under the supervision of, and to the detailed designs of, Post Office engineers. The tuning-fork units were made in the Post Office experimental workshop at Dollis Hill.

Masts.

The masts are 820 ft. in height from ground-level to the top of the antennæ aerial sheave and are of the stayed and pivoted type, insulated at the base (see Fig. 21). The pivot is about 17 ft. above ground-level;

maximum heel or deviation from the vertical allowed under load was 1 per cent, i.e. 8 ft. at the top of the mast. It was specified that the maximum compressive stress in lb. per sq. in. was not to exceed

$$18\,000 - 80\,l/r$$

when l/r is equal to or exceeds 50, and not to exceed 14 000 lb. per sq. in. for ratios of l/r less than 50, where l is the length of the post between bracings, or the distance between stays, and r is the least radius of gyration of post or mast section. Under these conditions the maximum bending moment occurring at any section was 400 tons-ft. and the maximum shear force 15 tons. Throughout the length of the mast below the top stay the compressive load due to the weight of the structure and the vertical component of the stay tensions always exceeds the tensile load due to bending moment, and the posts are therefore always in compression.

The total weight of steelwork in a mast is 170 tons, and the weight of the 15 stays is 28 tons and stay anchorages, etc., 12 tons. Under maximum wind load

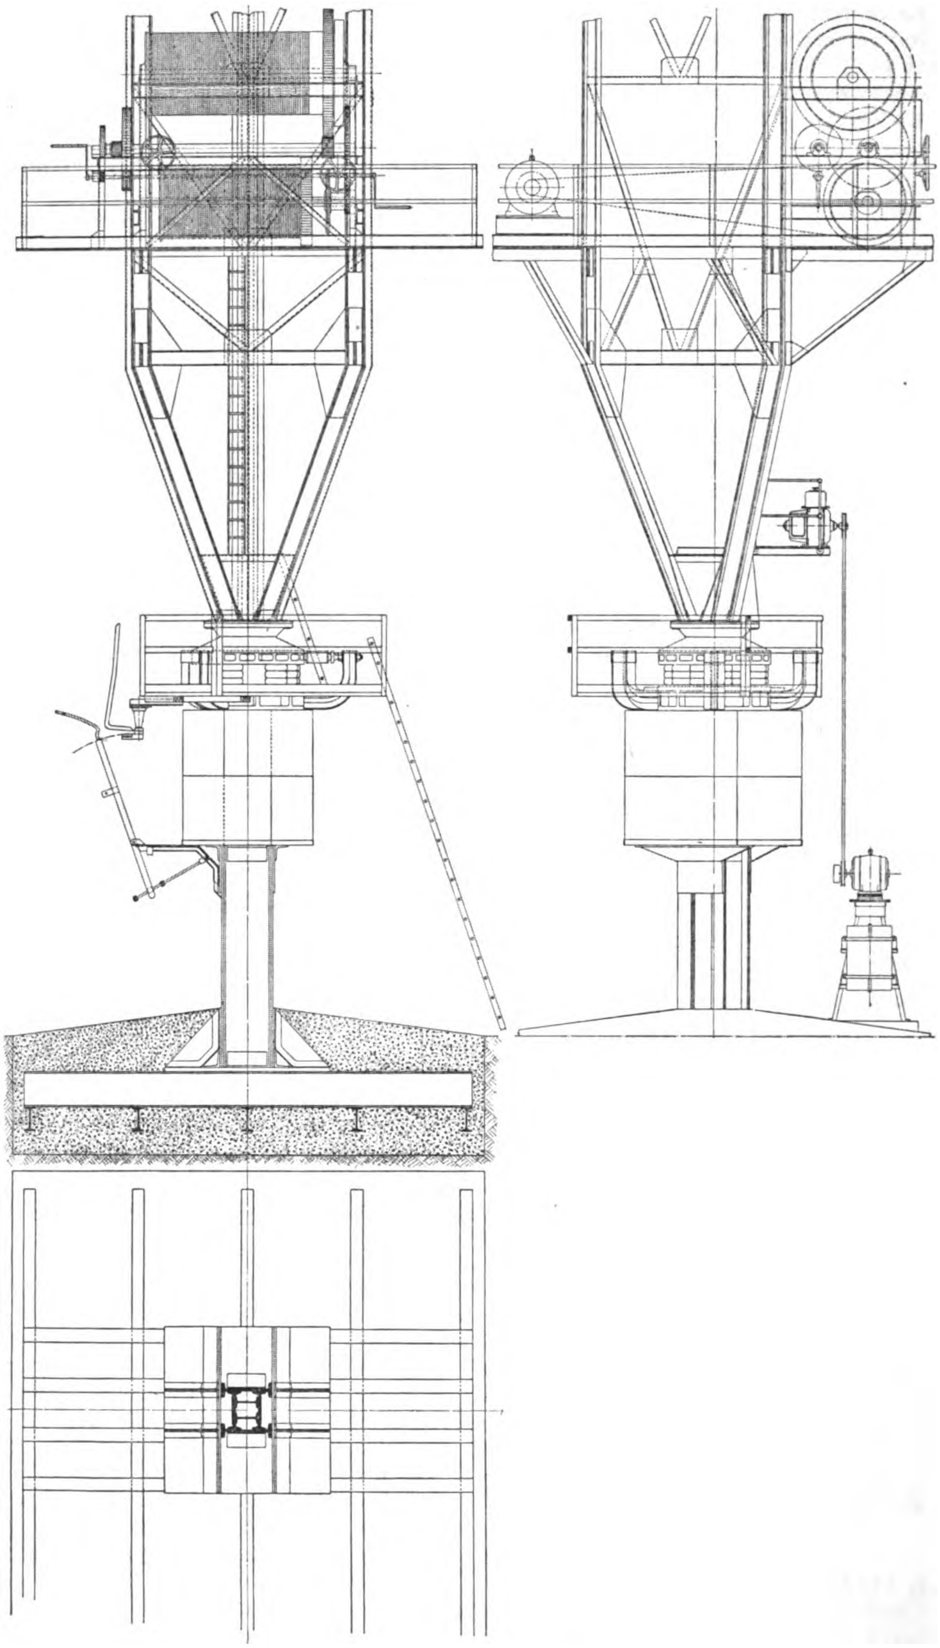

FIG. 22.—Base of mast.

the resultant vertical load on the base of the mast is 400 tons.

The foundations of the mast consist of a reinforced concrete block 20 ft. × 20 ft. × 6 ft. The reinforcement consists of one row of steel joists 18 in. × 7 in. × 75 lb. and a second row of steel joists of 12 in. × 6 in. × 44 lb. placed at right angles to the first row: the steel joists are bolted together and the steel supporting stanchion is bolted to the upper row of joists (Fig. 22).

The maximum load on the earth surface is 1 ton per sq. ft.

Borings were taken at mast positions to depths of about 25 ft. and averaged 1 ft. of soil, 3 ft. to 8 ft. of yellow loam and 12 ft. of soft blue clay, below which was stiff blue clay. In one case only running sand was encountered and the foundations were carried below this to the blue clay.

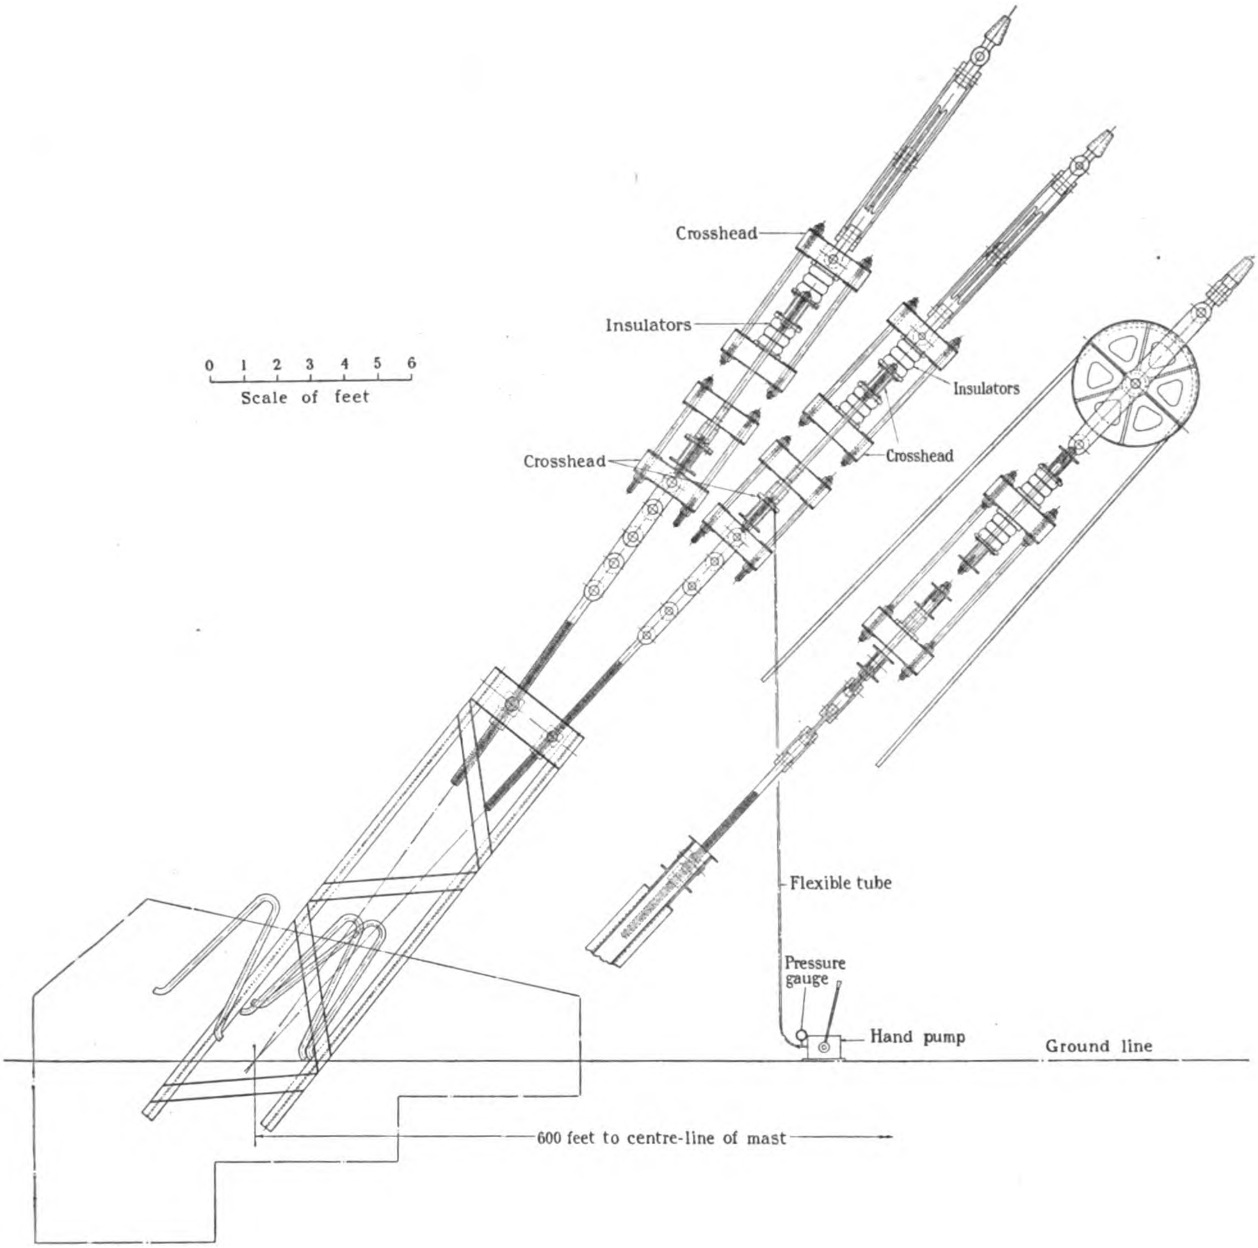

FIG. 23.—Stay arrangement and anchorage.

INSULATION OF THE MASTS.

Two considerations arose in determining the method to be adopted in insulating the masts :—

(1) The choice of a dielectric capable of withstanding a high voltage at high frequency and a considerable compressive load.

(2) Arranging the insulating medium so that the capacity of mast to earth was as low as possible.

The solution arrived at is indicated in Fig. 22. The insulation is primarily provided by 12 columns of porcelain insulators arranged three in each column and placed between steel castings immediately below the pivoted joint. These insulators comply with the specified conditions of withstanding a high-frequency voltage of 25 000 (R.M.S.) at 50 000 cycles per sec. for 6 hours without overheating or breaking, the insulators having first been immersed in water for 2 hours. They were tested mechanically to a compression load of 270 tons, corresponding to a factor of safety of 6.

Each insulator is 9 inches in diameter and 3½ in. thick, with a recessed hole in each face 2½ in. diameter and 1 in. deep.

To ensure uniform distribution of stress between the columns all insulators have ground faces and those in each column were cemented together by a thin layer of Portland cement.

Wooden blocks were used in the place of the insulators during the erection of the masts. To insert the insulators, the mast was raised on hydraulic jacks, the wooden blocks were removed and the columns of insulators inserted with a thin layer of cement at the bottom. The mast was then lowered on the insulators, but the full load was not taken off the jacks until the cement had properly set.

It will be noted (see Fig. 22) that the arrangement of the insulators permits of the insertion of 3 hydraulic jacks to raise the mast and replace any damaged or faulty insulators as required.

The stays are insulated at the base only. The same type of insulator is used as for the mast base, the method of mounting being indicated in Fig. 23. The insulators are in compression, the top column taking the load and the bottom acting as steadying insulators. A hydraulic press is incorporated in the stay-rope attachmen and can be connected to a hydraulic pump and gauge on the ground and used to measure directly the tension of the stay.

The stays are of parallel strand construction and were made on the site. The maximum tensions imposed on the stays under full wind load vary from 30·5 to 37·6 tons in the different stays, the top and bottom sets carrying rather higher loads than the intermediate, and two sizes of stay ropes were adopted. The larger is composed of 151 wires of No. 10 S.W.G. having an area of 1·918 sq. in. and a circumference of 5½ in., and the smaller of 103 No. 10 S.W.G. and 6 No. 8 S.W.G. The factor of safety specified for the stay ropes was 4.

The individual wires of No. 10 S.W.G. have an extension, within the elastic limit, of 0·5 per cent under a stress of 57·7 tons per sq. in., and a breaking load of 3 050 lb.

The aggregate breaking load of the larger ropes, assuming uniform distribution on all the wires, would be about 205 tons. Short lengths of rope with sockets attached were tested in connection with experiments carried out to determine the best type of socket, and the ultimate strength of the rope was greater than 125 tons, the limit of the machine available for the tests. This type of stay has a great advantage over the usual small wire stranded variety in possessing a smaller extension under load. The parallel-strand type has an extension very little in excess of that of the individual wires and, for the longest stay in use on the Rugby masts, this, under maximum load, does not exceed 17 in. irrespective of variations due to temperature, or, allowing for a temperature-rise of 50 deg. F., 21 in. The best results obtained on stranded ropes of special construction and under similar conditions would be equivalent to 35 in. extension for the longest stay at Rugby.

The advantage of the use of the parallel-strand construction is thus evident in limiting the heel of the mast under conditions of load. A further advantage of the use of parallel-wire ropes is that a more exact determination of stay stresses is possible. The masts were manufactured and erected by Messrs. Head Wrightson and Co.

Switches of substantial design are provided for earthing the masts when access to them is required and also for enabling transmission to be carried out at full power with the masts earthed. A spark-gap is also associated

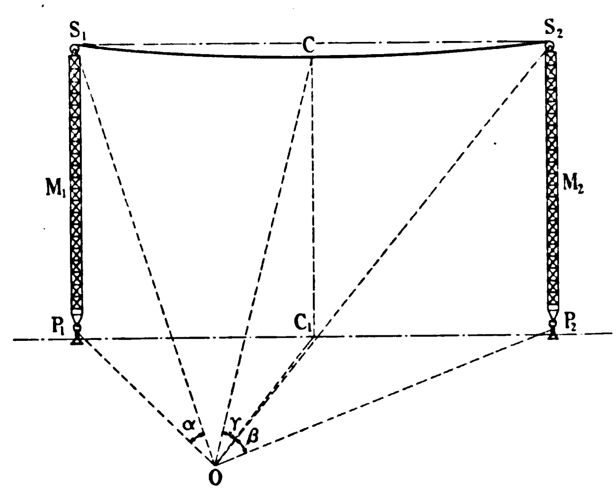

FIG. 24.—Method of load-testing masts.

with the switch as a protective device against abnormal voltages on the masts or aerial.

In order to test the masts with the specified horizontal pull of 10 tons applied at the top, a steel rope was suspended between two masts and hoisted by means of the permanent mast winches until the required tension was reached. Fig. 24 illustrates the method employed. P_1 and P_2 are the vertical projections on the ground of the ends of the rope S_1, S_2, suspended between the masts M_1 and M_2. A theodolite was fixed at O such that the length $OP_1 = OP_2$. The angles of elevation α and β of S_1 and S_2 were measured accurately, and also the angle of elevation γ of the lowest point C of the steel cable. It was then a simple matter to measure the angle P_2OC, in the horizontal plane, C_1 being the vertical projection of C. Also the angle C_1P_2O = angle C_1P_1O being known, and the length OP_2 having been accurately measured, the distance OC_1 was calculated. Thus it was possible to calculate the values of $S_1P_1 = OP_1 \tan \alpha$, $CC_1 = OC_1 \tan \gamma$, and $S_2P_2 = OP_2 \tan \beta$, and so obtain the dip d of the cable. The mass per foot of the steel rope, w,

and l, the distance S_1S_2, being known, the horizontal tension

$$T = \frac{wl^2}{8d}$$

was obtained.

A check on the aerial dip was also made by the same methods. The current taken by the electric motors of the winches, however, was found to give readings consistent with the value of the tension in the aerial suspending halyards and, during the erection of the aerial, reliance was placed upon these readings.

Mast and Aerial System.

The mast and aerial system are arranged so that two separate aerials of different capacities may be used or alternatively the two combined to form one larger aerial (Fig. 1). Two of the masts, spaced symmetrically with regard to the station buildings and 1 320 ft. apart, are common to both aerial systems. The larger of the two aerials is the telegraph aerial and is supported on 8 masts arranged to form an elongated octagonal figure in plan, with sides of 1 320 ft., but with opposite sides on axes at right angles at distances apart of 880 yards and 1 210 yards.

The smaller aerial is supported on 6 masts with the same spacing but forming an aerial with two open arms. This arrangement is designed to permit of the addition of four more masts if necessary, for which purpose sufficient ground is available.

Each aerial system is fed by a lead-up connected to two separate feeders, one attached to each of the masts nearest to the station. When using the whole system as one aerial the leads-up to the two separate aerials are connected together by an internal cable running the whole length of the inductance room.

The aerial insulators are of the porcelain-rod tension type, weighing 6½ cwt. and are shown in Fig. 25. The specified testing pressure which the insulators had to withstand was 120 000 volts at a frequency of 50 000 cycles per second.

Each porcelain tube of the aerial insulator was tested to a load of 10 tons. The complete insulator will thus withstand a pull of over 20 tons. Electrical tests made previous to erection showed that 200 000 volts at 50 000 cycles per second could be applied across the ends without damage. The insulators were made by Messrs. Bullers, Ltd.

Spider spreaders of tubular steel, 12 ft. in diameter, and spaced 140 ft. apart, are used to support the eight 7/14 S.W.G. silicon-bronze wires that form the cage aerial. In order to reduce the dip of the aerial, it was essential to design spreaders having small mass without undue sacrifice of strength. The type decided upon, as best meeting these requirements, is shown in Fig. 26. The split hubs of each spreader are tightly clamped to a central steel supporting cable. All radial arms and circumferential ties are composed of weldless carbon steel, containing about 0·5 per cent of carbon, with a yield point of 30 tons per sq. in. and an ultimate breaking stress of 40 tons per sq. in. In spite of their light structure the spreaders have withstood the severest gales without apparent damage. At each mast the aerial insulator is attached to the steel wire cable at the junction of two spans of the cage aerial, and the aerial is held in space well away from the metal masts.

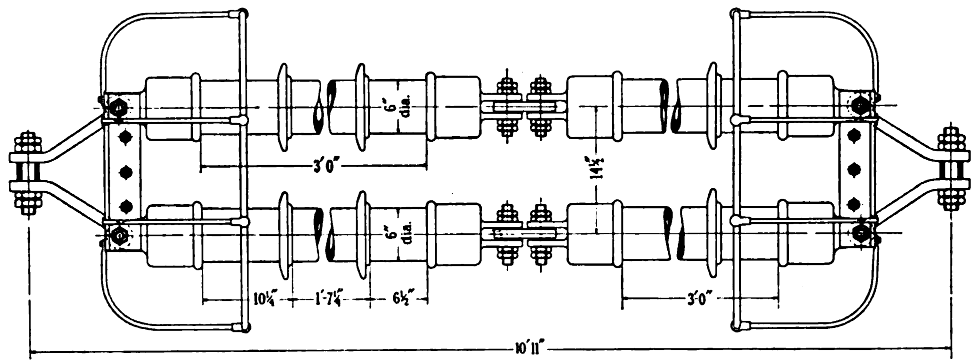

Fig. 25.—Aerial insulator. Scale ⅜ in. = 1 foot.

The two 8-wire feeders are formed on spreaders 6 in. diameter spaced 20 ft. apart. They meet at a point about 400 ft. from the building and are joined to form a single 16-wire lead-up on 6-in. spreaders. The tension of the lead-up wires is taken by six porcelain tubes, similar to those used in the main aerial insulators, suspended on a steel structure near to the building. The six tubes are arranged to form three arms 120° apart, each arm comprising two tubes in series. From these strain insulators, the lead-up wires pass through a copper tube about 19 ft. long that bridges the space between these insulators and the transmission building. At the building the tube carrying the lead-up wires passes through the middle of a double conical porcelain insulator fixed at the centre of a glass plate, 7 ft. square, and the lead-up wires then pass from the tube to the aerial tuning inductance.

In order to avoid either the overloading of the mast or the breaking down of the aerial, the steel rope supporting the aerial insulators passes down the centre of the mast and is attached to a drum fitted with a slipping friction brake so adjusted that the rope is slackened when the load exceeds 10 tons.

The earth system on the telegraph site consists of

copper wire, 100 lb. per mile, buried a few inches below ground. The earth follows the plan of the aerial and extends 800 ft. on either side of the vertical projection of the aerial on the ground, as shown in Fig. 27. Near the buildings the wires leave the ground and converge upon the transmitting room in a fan arrangement.

An insulated counterpoise has been erected under the smaller aerial at an average distance of about 16 ft. from the ground. The counterpoise follows generally the earth system in arrangement, except that the spacing between individual wires is not uniform but varies from 40 ft. immediately below the cage aerial to 80 ft. at the edges.

Observations have been made on the effectiveness of the insulation at the base of the mast by comparative measurements of the aerial resistance and the effective height with the masts insulated and connected to earth.

These observations show that the ratio of the effective height of the aerial with the masts insulated, to the effective height with the masts earthed, is 1·22. The effective height with masts insulated as deduced from measurements made at Wroughton near Swindon is approximately 185 m (607 ft.). The mean geometric height of the top of the aerial at Rugby is 820 ft. – 45 ft. (average dip of aerial) = 775 ft.

The effective height with the mast insulated is therefore 607/775 = 0·785 of the mean geometric height, or 607/820 = 0·74 of the mast height.

Fig. 28 gives the resistances of the aerial with masts insulated and masts earthed respectively. At 19 000 m wave-length the aerial resistances with the masts insulated is 0·7 ohm, and the aerial resistance with the masts earthed is 0·55 ohm.

Fig. 29 shows that the use of inefficient insulators for the masts practically doubles the aerial resistance. Such inefficient insulation is obtained when the porcelain insulators only are short-circuited and the granite blocks alone are used as insulators.

The larger telegraph aerial constants with the mast insulated are: wave-length 7 930 m, capacity 0·0334 μF, and equivalent inductance 530 μH.

To enable overhauls and examination of masts to be made, it is desirable to be able to transmit with a particular mast earthed, as work on an insulated mast is impossible during transmission. The curves in Fig. 30 indicate the effect on the larger telegraph aerial resistance of earthing either No. 1 mast (which is nearest to the station) or No. 6 mast (which is at the end of the aerial).

The d.c. insulation resistance of a mast to earth, including all stay insulators, varies between 1·5 and 3 megohms according to weather conditions.

The insulation resistance of the whole aerial to earth with masts insulated is 8 megohms.

The resistance of each granite block is approximately 20 000 ohms, but the value steadily rises as the granite slowly dries out. The effect of the dielectric current in the granite is to drive out moisture gradually from the interior. This action, combined with absorption by

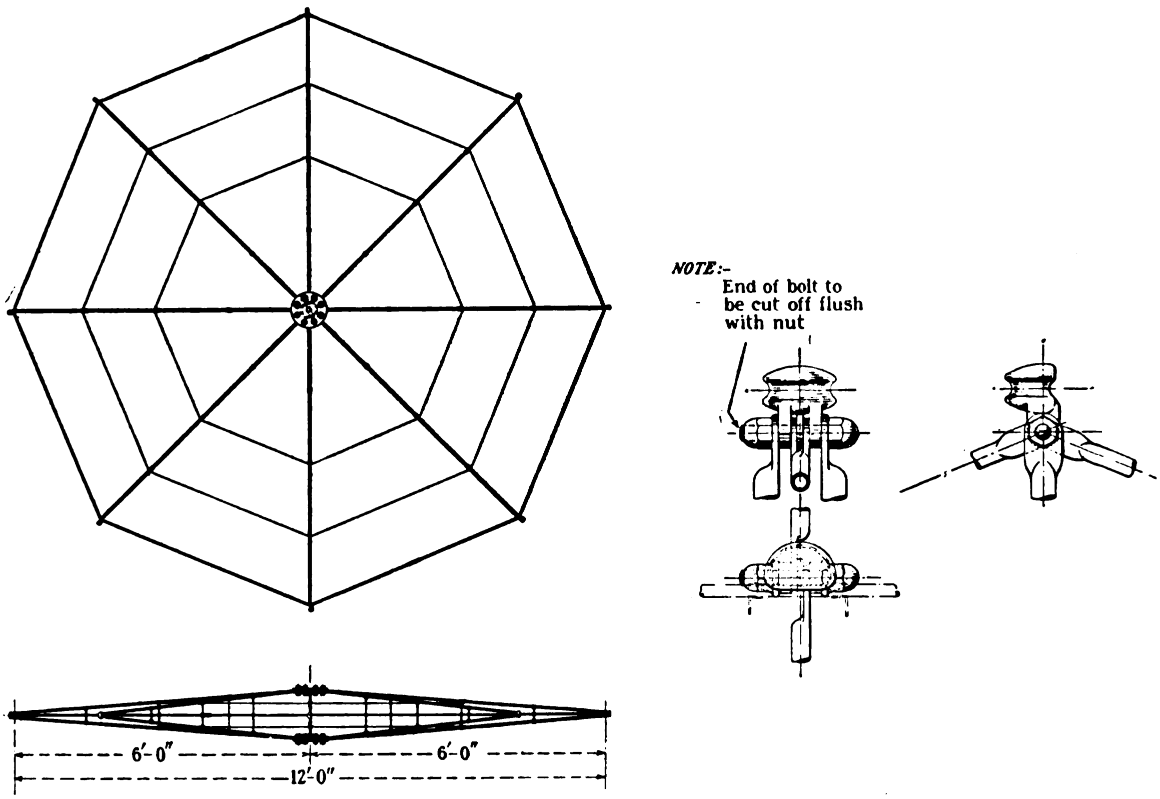

FIG. 26.—Aerial spreader.

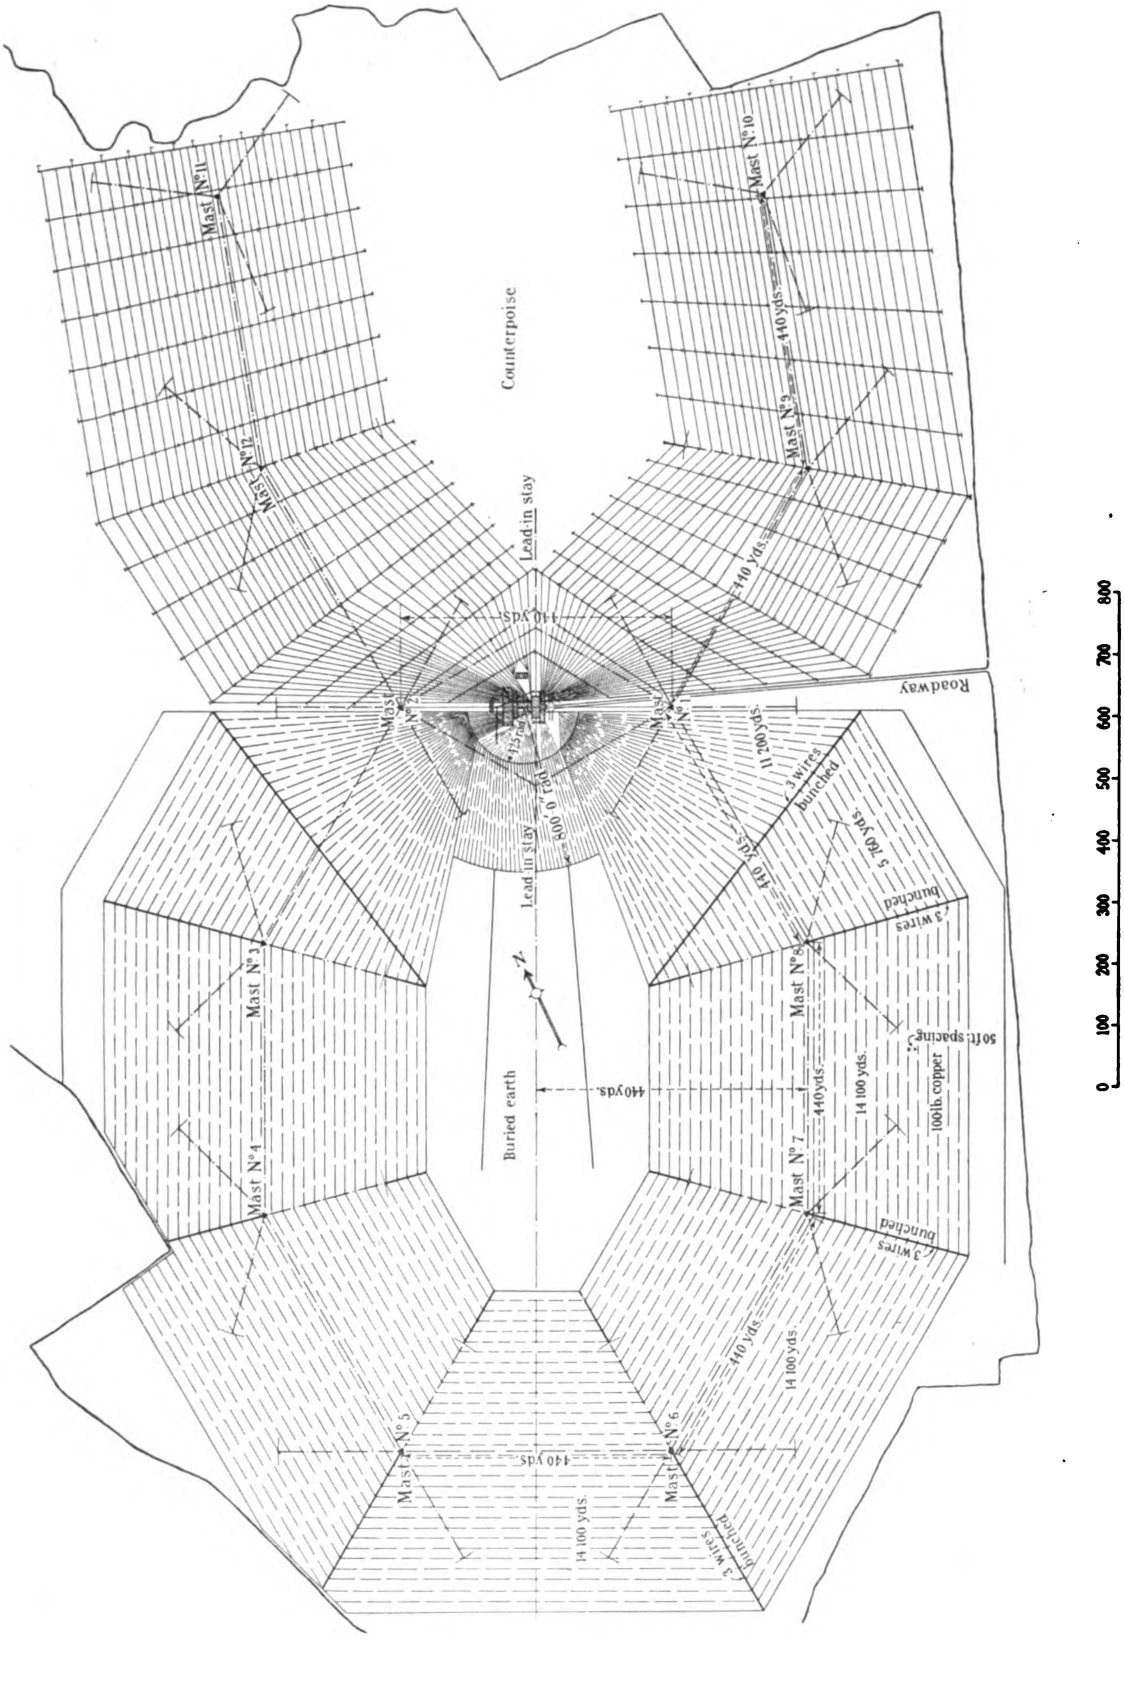

FIG. 27.—Earth system.

the atmosphere in the spring and summer, will raise the insulation to a maximum value and the granite blocks will then be completely coated with bitumastic solution to retain them in a dry state. Bitumastic solution has been tried experimentally for this purpose

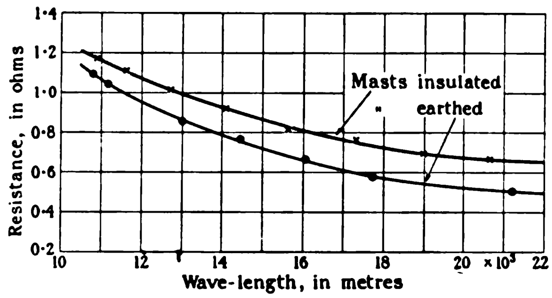

FIG. 28.—Curves of aerial resistance with masts insulated and earthed, respectively.

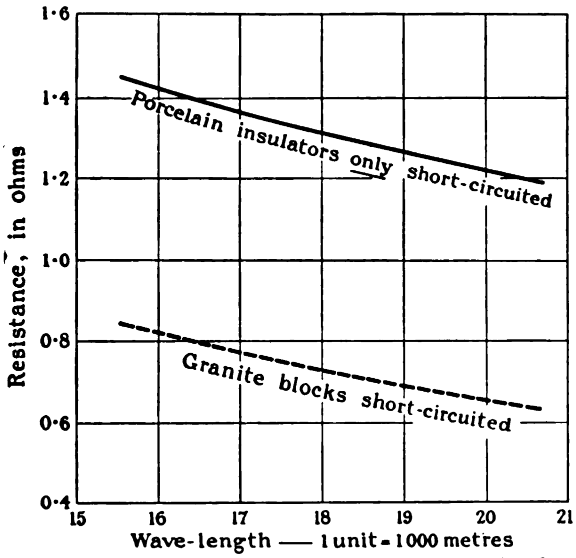

FIG. 29.—Curves of 8-mast aerial resistance with insulators partly short-circuited.

Tests taken first week in November, 1925. Ohmic resistance of each granite block = 12 000 ohms. Ohmic resistance of porcelain insulators under each mast = 3 megohms.

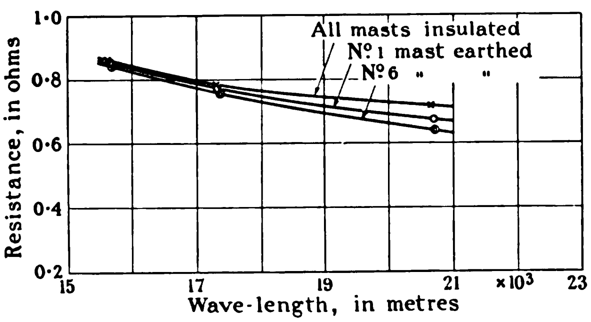

FIG. 30.—Curves of aerial resistance, earthing separate masts.

and proved to be satisfactory. The method outlined for slow drying under working conditions was decided upon as the results of tests made on granite specimens and in order to obviate the risk of moisture remaining in the granite if the blocks were coated with bitumastic solution before erection.

The voltage-drop across the mast insulators was found to be 12 000 volts and the drop across the stay insulators 12 300 volts with an aerial voltage of approximately 165 000, corresponding to an aerial current of 550 amperes.

Curves of the resistance of the smaller telegraph (telephone) aerial and counterpoise are given in Fig. 31. In order to obtain information, measurements were taken both before and after the far ends of all the wires of each arm of the counterpoise were connected together. The smaller telegraph (telephone) aerial constants are: wave-length 4 850 m, capacity 0·0164 μF, and equivalent inductance 394 μH.

Cooling Pond.

A stream running through the site is utilized to supply the cooling water, and a ferro-concrete cooling pond capable of storing 500 000 gallons of water was constructed by direct labour.

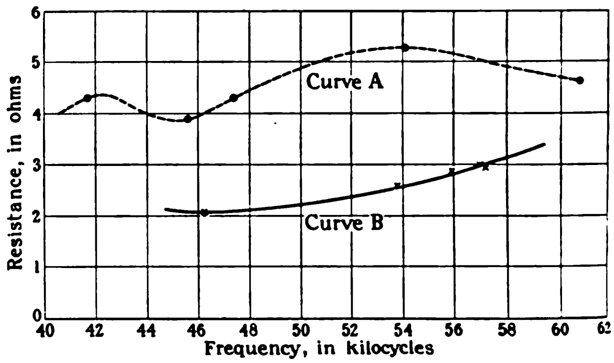

FIG. 31.—Resistance curves of telephony aerial.

Curve B shows the effect of joining together the ends of all the wires of each arm of the counterpoise. Counterpoise insulated in each case. Insulation resistance about 60 000 ohms.

General Results Obtained to Date.

The following schedule gives two typical series of measured values of the more important quantities when working on one portion of the aerial only, viz. that having a capacity of 0·033 μF.

Number of power units in use		3	3
Total number of valves in power units ..		54	54
Aerial circuit	Current	550 amps.	600 amps.
	Power ..	257 kW	306 kW
Primary circuit current		275 amps.	300 amps.
Coefficient of coupling to aerial		0·015	0·015
Efficiency of coupled circuit..		97½ %	97½ %
D.C. Input	Voltage ..	5 820 volts	6 780 volts
	Current ..	61 amps.	64 amps.
	Power ..	355 kW	434 kW
Filament power.. ..		48 kW	48 kW
Efficiency of transmitter	Excluding filament..	72 %	71 %
	Including filament..	64 %	64 %
Voltage on antenna ..		165 000 volts	180 000 volts

These figures are for about two-thirds power of the station, the present limitation being the fact that only a portion of the main aerial is available, which portion is already being used at antenna voltages in excess of **165 000.** With this power, however, the station has been proved to have a world-wide range and only the collection and scrutiny of data over a long period will show to what extent, if any, an increase of power is necessary for a *continuous* world-wide service. From the experience already gained it can be predicted that, if it is proved to be necessary, 3 power units using a d.c. supply of about 9 000 volts will be able to give an antenna current of the order of 750 amperes in the larger antenna of $0 \cdot 045\,\mu$F, with an increased overall efficiency.

It is interesting to note that during the several months that the telegraph station has now been testing and working commercially with type D circuit, not a single complaint has been received in regard to interference with broadcast or other reception by harmonics from the telegraph transmissions, and, moreover, broadcasting stations have been received, without interference, on the site under the aerial.

Experimental Telephony Installation.

The experimental telephony installation is smaller than the telegraphy installation and works with the smaller aerial. It utilizes the American Telephone and Telegraph Co.'s " single side band " system described by the late Dr. H. W. Nichols.* The modulating and filtering circuits and the valve amplifying panels were made and installed by the Western Electric Co., Ltd., in co-operation with the American Telephone and Telegraph Co.

* *Journal I.E.E.*, 1923, vol. 61, p. 812.

From the 31st January to the present time, a period which covers the best radio transmission conditions in this country, experimental week-end tests show that good speech is received in New York during most hours of the day when using an aerial current of about 185 amperes. This installation may form the subject of a separate paper when reliable data has been collected over the period of bad atmospheric conditions.

In addition, two other installations to work with smaller aerials supported on the existing masts are being provided. One will be a medium-wave 50-kW valve set and the other a short-wave 15-kW valve set.

Conclusion.

As liaison member between the Wireless Telegraphy Commission and the Post Office the author would like to remark on the cordial collaboration which existed between the Commission and his engineers throughout the progress of the work, and in conclusion he desires to acknowledge the valuable help received in writing this paper from the Post Office Engineers directly responsible for the various sections of the work, namely Mr. A. J. Gill on the power plant, Mr. R. V. Hansford on the wireless plant, and Col. A. S. Angwin and Mr. T. Walmsley on the masts, aerials and external plant.

Discussion before the Wireless Section, 14 April, 1926.

Sir Guy Wrightson: A description of the masts and the various difficulties we experienced in erecting them was the subject of a recent paper read before the Institution of Civil Engineers by Col. Angwin and Mr. Walmsley. In that paper I think there was only one interesting point omitted, viz. the weather factor. This work took place during an extremely wet and windy season and we were very lucky in having not a single accident in working at those great heights in very windy weather.

Mr. C. F. Elwell: The Post Office engineers have advanced valve practice to such an extent that no other valve station has anything like the power of the Rugby station. In view of the possibility of the erection of further stations of this type and power there are two points to which I should like to draw attention. The first is the question of the number of masts. Is it necessary to erect so many? There are no engineering difficulties in the way of erecting even higher masts, nor are there any difficulties in the way of providing for much greater aerial pulls—for example, 30 tons. In this case probably the masts could have been spaced double the distance apart. This is only an idea for the future. The question of economics has to be studied, but I believe that probably half the masts could have been erected with each one a little higher; this would have compensated for aerial sag, and have enabled a little money to be saved. The other point is the multiplicity of small valves. Personally I believe in the future of single units. Such a unit would no doubt be of a type which would have its own pumping outfit. We are at present in the possession of very little data as to the maintenance of small valves. In the case of a single valve I think it is quite possible to renew its filaments and generally keep it in order at the cost of certain spare parts.

Mr. P. P. Eckersley: I think that any criticism that might be put forward falls to the ground entirely when it is realized that even as far back as 5 years ago the Commission were bold enough to back their preference for valve work, which was then considered, by even the greatest enthusiasts, somewhat dubious for high-power stations. Finally, they have applied real engineering practice and technology to the production of high-frequency currents. I think they are to be congratulated on this account above all others. The tuning-fork drive is, I think, a unique advancement, as everyone must admit that the great aim of the future, both in broadcasting and in telegraphy, must be towards the maintenance of a constant wave-length. It may be of interest to mention that the British Broadcasting Co. also has had some experience of producing harmonics from tuning-forks and using them as independent drives. Starting with a frequency of something like 890 periods per sec., we have been able successfully to drive a particular station at a frequency

of nearly 1 million. Referring to Mr. Elwell's remarks on valves, I suggest that the Post Office engineers have taken the safe course. I should like to ask the author whether the economic gain resulting from insulating the masts could not also have been obtained by employing a somewhat greater power. Apparently the insulating of the masts was an expensive and difficult engineering task involving considerable experimental work, and it would be interesting to hear whether the author is of the opinion that the same result might have been obtained by omitting the mast insulators and providing a larger aerial current to compensate for any reduction of energy actually radiated. We shall all await with great interest the development of the transatlantic telephone experiments.

Mr. G. Shearing: The Rugby radio station represents the most ambitious undertaking in thermionic valve wireless-telegraph transmission up to the present. Its erection must have been a problem of extreme interest, for the task of building complete a high-power valve transmitter such as this, with practically no limitations, is one which comes the way of few radio engineers. The high oscillatory power obtained by the use of thermionic valves is, I venture to think, very gratifying to all who have been engaged in the experimental development of high-power valves. In view of the application of shorter wave-lengths below 100 m at the present time to long-range transmission, and the remarkable results one can obtain with relatively small power supply, it is not easy to say whether the Rugby station is the climax of high-power long-wave valve transmitters; and the trend of wireless telegraph development in the next few years will be a matter of great interest to us all. With regard to the power supply from the substation at Rugby, I should like to know if the line drop to the radio station is negligible or whether the automatic regulators compensate for line drop at varying loads. It would be of interest if the author could give us the load characteristics of the high-tension d.c. generators. Concerning the adoption of motor-generator sets for the high-tension supply by the Wireless Telegraphy Commission in 1922, I am wondering if the author is still of the same opinion, as thermionic rectifying valves can be obtained of good efficiency and on the whole of greater reliability than transmitting valves of the same anode rating. Possibly some economy might result from the adoption of thermionic apparatus for both transmitter and high-tension supply. On the other hand, there is the question of the interposition of the inertia of a mechanical link between the supply undertaking and radio apparatus for the high-tension generator to reduce fluctuation of the supply power during signalling, as opposed to a purely electrical link for the static high-tension transformer and thermionic valve rectifier unit, unless an a.c. generator and motor is introduced also for the h.t. transformer supply. With regard to the adoption of a frequency of 100 for the valve filaments, would not a higher frequency, say of the order of 250, have been better when introducing the motor plant? This would reduce considerably any cyclic temperature fluctuation of the valve filaments as compared with that produced by the small change in frequency from 50 to 100. With reference to the transmitting valves, the designed power dissipation per valve from the figures on page 690 is of the order of 460 kW, or about 8·5 kW per valve, and the test-figures on page 708 correspond to an average anode dissipation of nearly 2·4 kW per valve during marking (I assume the static dissipation is less than this; perhaps the author will say what is its value), so that the valves at present are being operated at a fairly conservative anode power rating as compared with the continuous rating of 10 kW of which each valve is capable. In this connection, is it easy to arrange for the valves to share the load equally? If not, is it possible to correct by filament adjustment alone or are other adjustments necessary; also, have the valves any repair value after breakdown? The inductively coupled circuit of type A (Fig. 16) is undoubtedly inferior to the capacity-coupled arrangements described in the same figure, but for the cases where rapid wave-change over a wide range renders its use desirable, a great reduction of harmonic interference can be obtained by the insertion of a rejector type of circuit between the anode tapping and earth. This is, of course, equivalent in effect to the introduction of a capacity circuit to earth to provide an easy path for the harmonics. The harmonics generated on the Rugby wave-length which may cause interference in general to broadcasting apart from Daventry, are those around the 40th harmonic of the fundamental, and it would be of interest to know whether any radiation has been observed on the lower harmonics such as the 2nd, 3rd, etc. It would also be interesting to obtain an oscillograph curve showing the change of the anode current through the valves during signalling, for comparison with the curve of rectified aerial current given in Fig. 20 of the paper.

Mr. R. N. Vyvyan: The Marconi Co. have been designing high-power stations for Imperial communication on long wave-lengths for a great many years. Actually we designed a station only a short time ago on the valve system to give 875 amperes in an aerial supported by masts approximately as high as those at Rugby. That station was not completed, however, owing to the introduction of the short-wave beam system. I think it is certain that the Rugby station is the last word in high-power wireless stations, in two senses. It is excellently designed in every respect and, in my opinion, reflects great credit on the Post Office engineers, but I do not think that any more super high-power stations will be built, since long-distance communication will, I believe, in future be carried out only by the short-wave beam system. That is also the opinion of my company, but we shall know in a very few weeks whether that opinion is sound or not.

Mr. W. T. Gibson: The author mentions that distilled water is used for cooling the valves. He points out one advantage of this, and I propose to give another. The point he mentions is the very high resistance obtained with the water, giving a leakage current of only 20 mA at 10 000 volts, or 200 watts power loss. With ordinary domestic water the leak would probably be 20 or 30 times as great. That does not matter much in small stations utilizing one or two valves, but with a station of the size of Rugby it becomes very important and there would probably be a loss of 4 or 5 kW in the

hose pipe. The other interesting point in connection with distilled water is that there is no deposit in the anode, whereas it is a matter of experience with ordinary commercial water that quite a considerable deposit is formed on the anode at places where it gets warm. That would become very serious and might create serious maintenance problems in removing the deposit at frequent intervals. The layer is a good insulator and a very bad conductor of heat, steam is formed underneath the anode and possibly overheating of the anode occurs. I agree with Mr. Elwell that in the future there will be a development in the size of valves, but I do not agree with him that the demountable valve is the valve of the future. The great thing is to have a valve of absolutely stable characteristics, and I believe that these are extraordinarily difficult to obtain with a valve that is permanently connected with the pumps. There are always slight traces of gas and the pressure is always fluctuating slightly, and that presents great difficulties in operating a large station. Those difficulties, I think, outweigh any advantage in being able to take the valve apart and re-assemble it.

Prof. J. K. Catterson-Smith: I presume that the aerial constants given on pages 706 and 708 are the fundamental natural wave-length and the equivalent capacity and inductance at this wave-length. The equivalent inductance of the smaller aerial, given in the advance copies of the paper as 994 μH, appears to be wrong. Should not it be 394 μH? There is apt to be some confusion as to the exact meaning of such aerial constants, and therefore it might be helpful to state that for these aerials the electrostatic capacities are 0·0524 μF and 0·0258 μF, and the static inductances 832 μH and 618 μH, for the larger and smaller aerials respectively. I notice that the resistance of the larger aerial is plotted, in Fig. 28, for wave-lengths down to 10 800 m, and I should like to know whether these observations were made with lower values of the aerial tuning inductance than the minimum of 900 μH given in the paper. In the case of this aerial, for which the equivalent inductance is stated to be 530 μH and the capacity 0·0334 μF, the effective inductance is $(1/\sqrt{2}) \times 530 = 375\,\mu$H, and the effective capacity is $\sqrt{2} \times 0{\cdot}0334 = 0{\cdot}0471\,\mu$F, so that the range over which the aerial can be tuned with the 900 to 4 000 μH aerial tuning inductance, and neglecting the coupling coil, should be :—

$$\text{from } \lambda = 59{\cdot}6\,\sqrt{[(375 + 900)\ 47{\cdot}1]} = 14\,500\text{ m}$$
$$\text{to } \lambda = 59{\cdot}6\,\sqrt{[(375 + 4\,000)\ 47{\cdot}1]} = 27\,000\text{ m}.$$

Although efficiencies for the transmitting apparatus are given on page 708, I find no statement of the aerial efficiency, which is an equally important matter. Adopting the value of the effective height given on page 706 (viz. 183·5 m) the radiation resistance of the larger aerial works out as 0·158 ohm at 18 350-m wave-length, for which Fig. 28 gives the measured resistance as 0·72 ohm with the masts insulated. The aerial efficiency is then 0·158/0·72, or 22 per cent, a figure which does not compare too favourably with published values of the efficiency of multiple-feeder aerials. I suppose that aerials of the latter type were considered before the final decision was made to adopt the present form of aerial at Rugby. I should like to take this opportunity of suggesting the sending of special test-signals similar to the "U R S I" transmissions, in order that distant measurements could be made over considerable periods. Such observations would, I am sure, be undertaken by a number of laboratories and the results, when collected, would probably afford matter of interest on this class of transmission. We make daily observations of signal strength at Bangalore and would welcome the possibility of recording and measuring the field strength of systematic signals from Rugby.

Dr. W. H. Eccles (*communicated*): I speak as Vice-Chairman of the Wireless Telegraphy Commission which was instructed by the Government to prepare the general design of the Rugby wireless station and to advise during erection. The author was a member of the Commission and also head of the body of engineers who installed the plant. It is largely due to him that the co-operation between those responsible for the general design and those responsible for the construction was so perfectly cordial. I think it would be hard to find an example of a very big job involving innumerable departures from traditional methods in which the team work has been so good. This has helped to ensure success; a success which could not have been achieved without the aid of the able staff which the author has gathered round him at the Post Office. This staff has been responsible, for example, for the development of the method of controlling the wave-length by a tuning-fork, for the design of the valve panels and safety devices, for the calculation of the unusual form of intermediate circuit and tuning coils, for the erection of the very unusual type of antenna, and for the testing of electrical materials by new methods. But the best testimonial to the efficient work of the erecting engineers is the fact that the station has given magnificent performances during its tests and that its erection was completed without any failure, fault or accident. As may be imagined, the volume of business involved in the purchase of the plant and materials for the station was enormous; and although this side of the work is not described in the paper, I think I may be permitted to say that the author shouldered most of the burden and that the estimates were very closely in accord with the final expenditure.

Mr. E. H. Shaughnessy (*in reply*): Mr. Elwell raises the question of utilizing a smaller number of higher masts. Calculations made at the time the estimate was prepared indicated that the number, height and aerial-pull chosen were the reasonable constructional and economical limits. It cannot be said that a valve with a 10-kW output is a small valve; no reliable larger-powered valve was commercially available at the time the station was designed. The Post Office has very little data as to the maintenance and repair of small valves, and no data at all regarding valves with over 20-kW output. Attention is drawn to sub-paragraph 3 (*b*) in the section headed "Considerations in regard to the size of power units."

I am glad to hear from Mr. Eckersley that the British Broadcasting Company is following the Post Office example of producing constant wave-length from a tuning-fork. With regard to using additional valves

and increased aerial power instead of increasing the effective height of the aerial, owing to corona and voltage limits on the aerial and aerial insulators, the matter is not so simple when dealing with such powers as that used at Rugby.

The various points raised by Mr. Shearing were all considered in the design stage of the Rugby station. The use of 100 cycles for the filament supply was adopted, not for the sake of changing frequency but in order to simplify regulation by the use of a motor-generator and Tirrill regulator. The cyclic temperature-variation effect is overcome by balancing the valve filaments in use over the three phases, as explained in the paper. The choice of 100 cycles was made in order to obtain a standard frequency-changing machine which could be delivered quickly. The rating of the valves is in terms of the anode voltage, output and dissipation, each valve being limited to a maximum output or dissipation of 10 kW. Thus it is not permissible to operate the valves beyond the rated anode voltage, output or dissipation. The figure of 1 000 kW quoted is the machine rating; the input to the power units for 540 kW output when working at 72 per cent efficiency would be considerably below this figure. The present static dissipation on "space" is 1 kW per valve. Provided that the precautions specified (page 694) for the operation of valves in parallel are adopted, the valves share the load equally. It will be appreciated that Rugby is essentially a fixed-wave-length station and, in consequence, the time required to change wave-length does not arise. For this reason a coupled circuit was provided which gives a much more efficient anti-interference arrangement than rejector circuits, etc. Observations so far made on harmonic radiation show that there is no radiation on the lower harmonics. Additional oscillograms showing the rise and fall of the various currents and voltages during keying will probably be published at a later date.

Mr. Vyvyan will be the first to recognize the difference between designing a station to give 875 amperes in the aerial and erecting a station that actually has that aerial current. The absolute need for a high-power station in this country which has a simultaneous broadcasting Empire-wide range has been met by the erection of the Rugby radio station. I think it is too early to conclude that no more high-power stations will be built. Our experience of low-power short-wave stations is that they form valuable adjuncts to high-power stations, being able to work for a limited number of hours per day but not regularly at the same time or for the same periods. As beam stations are directional it would require a large number of these to cover Empire broadcasting, and as no beam station has yet been completed or tested I am quite unable to form any opinion as to its superiority or otherwise over ordinary short-wave stations.

As Mr. Gibson points out, it was with a view to avoiding deposit on the anodes that distilled water was adopted for valve cooling at Rugby. The need for this is emphasized when such a large number of valves are being run in parallel.

I have to thank Dr. Eccles for his generous contribution to the discussion.

With reference to Prof. Catterson-Smith's communication, it is, of course, very difficult to quote definite figures of capacity and inductance for a given aerial without making a large number of reservations as regards frequency, etc., on account of the distributed nature of the capacity and inductance. For practical purposes, the values, C_a, L_a, required are those which will give approximately correct results for a reasonable working range of frequency for the calculation of the wave-length with varying values of loading inductance, L_1, when using the formula $\lambda = 1\,887\sqrt{[C_a(L_a + L_1)]}$. The figures quoted in the paper are the values of C_a, L_a, for the two aerials as defined above, and the figure of 994 μH in the advance copies of the paper was a typographical error for 394 μH, as pointed out by Prof. Catterson-Smith, and has been corrected in the *Journal*. The measurement of the aerial resistance was carried out by means of a specially designed measuring-set which did not utilize the aerial tuning inductance. Multiple-feeder aerials were considered before the final design of the Rugby aerial was adopted. The aerial efficiency is of the order quoted by Prof. Catterson-Smith, and I think that he will find that this does not compare unfavourably with the efficiency of multi-tuned aerials at wave-lengths of the order of the high wave-length quoted by him and used at Rugby.

South Midland Centre, at Birmingham, 28 April, 1926.

Mr. G. Rogers: The author remarked that the ether is becoming overcrowded, with the result that interference takes place between the many high-power stations now working. I do not really think that he means this. It may seem to be so with our present knowledge of the ether, and the means of tuning-in to different wave-lengths. It is inconceivable, however, that the saturation point has been even nearly reached. As the ether is apparently illimitable and pervades all space, its capacity to transmit energy may also prove illimitable. In fact, I venture to suggest that means will be found later to obviate any interference. Also it is quite within the range of possibilities that, in the future, many hundreds of thousands of kilowatts of power will be transmitted through the ether without the saturation point being reached. Was any provision made to protect the huge steel masts and the aerial from lightning? One is familiar with the enormous destructive forces that can be liberated and as, apparently, no protection whatever from lightning has been provided, there would seem to be a possibility that the porcelain base and the granite block at the bottom of each of the insulated masts might be fractured if directly struck by lightning.

Dr. C. C. Garrard: With reference to the question of suppressing the generator fields as quickly as possible, I should like to know whether the author has considered the use of a "suicide" arrangement, as used, for example, on rolling mills, with Ward-Leonard control, to kill the generator field instantaneously. In this connection did the Post Office consider the use of a transverter or the mercury-arc rectifier instead of the high-tension

d.c. machines? The use of the oil circuit-breaker for rupturing the high-tension direct current is interesting, and I should like to know whether it is found necessary periodically to change the oil in this breaker, as I have always understood that direct current carbonizes the oil to a greater extent than does alternating current. What was the diameter of wire used for the aerial? This is of interest from the point of view of corona loss. American whitewood seems to be a very useful kind of timber; has the author had any experience of this for making liquid rheostats? When made of ordinary wood these often suffer from burning due to leakage of current through the wood. It seems to me that American whitewood might be used here. The rise of current on the high-speed breaker seems to be exceptionally large. The normal current is 85 amperes; this rises to 1 400 amperes, which is nearly 17 times full load. High-speed breakers are often used in connection with automatic substations, especially with rotary converters, and the rise of current under these conditions when using high-speed breakers is not nearly so large. What was the time taken for one commutator segment to pass from one brush to the next? I wish to compare this with the time given for the operation of the high-speed breaker, viz. 0·02 sec.

Mr. J. A. Cooper: Why do the Post Office engineers use distilled water for cooling their valves, and why is this cooling water itself cooled by a second water system? Since water is such a bad conductor of heat it would appear that some method of cooling such as spraying would be more efficient, but there is, no doubt, a good reason for the system chosen. The author mentioned, in connection with the valve panels, that if one of the five is not available as a spare when one valve breaks down, it is very easy to locate the faulty valve and replace it. I should like to know what means are adopted for rapidly locating faulty valves. Why is alternating current used for the valve filaments? One might have expected the use of d.c. machines for filament heating as well as for the high-tension supply. One of the amplifying valve units referred to in the paper consisted of a valve having an output of 5 kW; I gather that this valve is not water-cooled. I should like to know why a water-cooled valve was not used; they are generally admitted to be very reliable and should have a long life. One lantern slide showed a very large smoothing condenser. Did the Post Office engineers consider the use of electrolytic condensers in any circuit, and, if so, why did they decide not to use them? In connection with the steel mast stays, it would be interesting to know how the strands are made off to the thimbles. This was not apparent from the lantern slide shown. In connection with the type of aerial shown, I should like to know whether any experiments have been made to discover whether there is any high-frequency loss in the steel wire in the centre of the spreaders and whether, after having had experience of this type of aerial, the Post Office engineers still recommend it as the best type of transmitting aerial.

Mr. T. Plummer: I should be glad of some information in regard to the speed of telegraph signals, and to what extent, if any, distance of reception had an effect on the speed of transmission. In other words, was there any tendency for dots and dashes to run into one another at long distances at high speed? The paper deals entirely with the transmission of signals, and it would be useful to have some information concerning the arrangements of circuits and apparatus which were found to give the best results at the receiving end. Are any weakening effects noticeable due to surface leakage on the various insulators, etc., in wet weather, or is it necessary to compensate for this by an increase of power in the aerial?

Mr. E. H. Shaughnessy (*in reply*): In reply to Mr. Rogers it is not the capacity of the ether for carrying energy that is involved, but congestion is due to the fact that the number of frequencies suitable for long-distance long-wave communications and already utilized is very near to the comparatively limited number available. With regard to lightning, the masts act as lightning conductors and are provided with spark-gaps across the base insulation. The aerial is permanently earthed through the aerial tuning inductance.

With reference to Dr. Garrard's remarks, we have not considered the "suicide" arrangement as the present arrangement is very satisfactory. When it is understood that the short-circuit is straight across the machines the rise of current is not abnormal—with rotary converters in automatic substations any short-circuit usually occurs outside the station. The speed of the machine is 750 r.p.m. and the time taken for a commutator segment to pass from one brush to the next brush is 0·04 second. The chief advantage of whitewood is the low energy loss when placed in a high-frequency electric field—we have no experience with it for making liquid rheostats. The oil in the high-tension d.c. oil switch does carbonize after a number of short-circuits and has to be cleaned, but little or no inconvenience results from this at Rugby.

In reply to Mr. Cooper, distilled water prevents the formation of a deposit on the anodes, and with 54 valves in parallel it offers a higher leakage resistance. Spraying involves a large loss of water due to evaporation. The anode trip-gear and indicating devices are shown in Figs. 13 and 14 and described in the paper, from which it will be seen that the overload relay attached to an individual faulty valve provides a visual indication and trips the control circuit, the tripping of the latter actuating an indicator on the panel containing the faulty valves. The use of alternating current for valve-heating is a more convenient and suitable arrangement where a large number of valves arranged in panels are used. The 5-kW glass valve unit is much cheaper than, and quite as reliable as, a water-cooled valve. Electrolytic condensers were considered, but no commercial type suitable for high-voltage use was available. So far as we have been able to determine, the steel rope does not involve loss; and our experience with this type of aerial shows it to be eminently satisfactory.

Mr. Plummer may take it that distance has no effect upon the shape of the transmitted signal; the prolongation and retardation commonly associated with long land lines are entirely absent. Wet weather has no perceptible effect upon the power required to give the required aerial current.

DISCUSSION ON
"ELECTRICITY SUPPLY TARIFFS." *

SCOTTISH CENTRE, AT EDINBURGH, 12 JANUARY, 1926.

Prof. F. G. Baily: The problem of the scientific tariff has troubled supply engineers ever since Dr. John Hopkinson pointed out that the problem existed, and we are as far from an agreed tariff to-day as at any time in the past 30 years. The difficulty lies in the fact that the true tariff should depend on the additional cost in generating station and network of delivering at each moment an additional load. As this has only a remote relationship to the demand of any one consumer, there is small chance of any practicable tariff accurately assessing the proper charge for his meter reading. At the best one can suppose a range of average consumers and assess each class, however varied the real people are in any one class. The whole lesson to be derived from a scientific analysis of total costs, however, reduces to the simple requirement of increasing the total load, the load per square mile of supply area, the load factor, and the uniformity of the load curve. The question shifts therefore to the consumer, for all these quantities depend solely on the consumer, and the best tariff is one which induces him to use electricity so as to bring about the above results. It is a matter of psychology rather than of science. At the same time, papers such as the present one are beneficial in showing which parts of the total cost are most in need of reduction, and what modification of the tariff will be helpful in this way. It points out that the network is the least satisfactory part, and the cure lies in load density and load factor—more consumers per square mile and each using electric current for more purposes, with special attention to night time and summer. A low tariff for summer may induce the use of electric fires and electric cooking among people who argue that they want coal fires in winter and may as well cook and heat water by them. There is insufficient appreciation of the advantage of subsidising new applications. The suppliers will lay down a network in a new area, and offer current at a price which initially does not pay them, and in the same way every extension into a new use for electricity requires similar support. The consumer is naturally reluctant to make experiments at his own expense, and a change in domestic life is one which people are very cautious in adopting. The tariff becomes, therefore, a means of coaxing prospective consumers, with the sole additional feature that its gross amount shall produce the necessary income for the undertaking. Possibly the variety in tariffs is due to different views as to the psychology of the consumer, and this may vary in different localities.

Mr. F. H. Whysall: There is very good reason for bringing up the question of tariffs and considering what form they should take, for, as Prof. Baily says, it is a constantly varying problem owing to the new loads we are acquiring and the altering shape of our load curves. The author raised a point with regard to the relative values of loads and their effect on load factor. He attributed good load factor to a very large percentage of traction load. Some factories, like sugar refineries and works which are taking current over a 24-hour day, have a much more beneficial effect on load factor than the traction load. The analysis of distribution costs really is the important note in the paper, and I thoroughly agree with him that if supply engineers will turn attention to the analysis of distribution costs, in the same way that they have given their attention to the generating costs in power stations, we are bound to make some very substantial progress in understanding what charges should be made for any particular class of business. If one wishes to do anything with the greatest possible accuracy, one must be able to see very clearly what the circumstances are. There is no doubt that the ideal tariff is such as the author has indicated, and he expresses a preference for the two-part tariff which ensures that the undertaking gets paid for standing charges with a small profit, together with a profit on the running charges. The general impression obtained from reading the paper is that we must be doing business at a loss with the charges that we know to be in force. The danger in trying to analyse costs to arrive at the proper charge for any particular service is that they are invariably misleading, and my experience is that they are misleading in always indicating a charge much higher than would be necessary. As illustrating that point, some time ago the manager of a large company told me that he had carried out an extensive investigation into the costs of supplying individual consumers, and he found that a very substantial loss was made on every one of them, and it was very difficult to explain how the company made its profit. If the author can help us to analyse our costs in some way that will give us a reliable indication of what our charges ought to be, instead of being invariably very much higher than they will have to be to get the business, he will be doing a very great service.

Mr. A. Mears: The author has developed an aspect of the costs to supply electric energy which has probably been overlooked in the past to a large extent, and he shows how distribution costs are affected by the "form factor" of the load on a particular main or set of mains. Unfortunately it is not possible for a supply undertaking to refuse to supply consumers because of the particular manner in which the load is taken—omitting of course very exceptional cases—and the bad have to be taken with the good. From this it follows that the bad effect of some types of consumers must be counterbalanced by inducing good types of consumers to take a supply, and this is best attained by offering an attractive tariff. Diversity of types of consumers with suitable proportions of each type

* Paper by Mr. H. M. Sayers (see vol. 63, p. 850).

should be the aim of every undertaking, and if this is attained I think that the difficulty with the undue costs of distribution owing to form factor will disappear. In Edinburgh we have a good power load with very diverse types of consumers, and a lighting load which is well divided between business and domestic consumers. The domestic heating load is increasing and, in addition, we have a good tramway load. The author refers to places where the units sold to consumers are only about 55–60 per cent of the units at the station bus-bars, but this is surely very exceptional. It is also stated that distribution charges are 2 to 4 times the cost of generation, and I presume from this that the interest and sinking fund together with working expense are included under each heading, and, in addition, the value of the units lost in distribution. In Edinburgh this figure is about one half instead of double. There must be some very exceptional conditions prevailing where the distribution costs are so high, and the question of devising a suitable tariff to remedy this state of matters would be most urgent. The author considers that the principle of charging on what the service will bear cannot be followed very far, but this is probably more idealistic than what usually obtains in practice. A high lighting rate is very frequently charged so as to foster increased consumption at the heating rate with many domestic tariffs. Again, it is the exception to charge meter rentals. The author points out that a rental to cover meter and service charges is equitable and in this I agree, but in practice it is very advisable to avoid it. The business aspects of selling electricity and how a tariff appeals to the ordinary consumer, must also be kept in view. In this connection it is very advisable to have a simple tariff, and probably the method of grouping consumers and charging each group at different rates is the most practical. Too many groups are not to be desired, and I do not think that domestic consumers can very well be divided. In connection with group charging, allowance is made for the diversity factor obtaining in the group itself, and also the relation of the group peak to the principal peak of the station. A study of the general tariffs in use indicates that the grouping of consumers and charging according to their group is very prevalent. The author recommends the grouping method and shows by an example how ice and refrigerating companies can be debited with a small proportion of the kilowatt charges owing to the nature of their load, but we find it better to arrange these consumers on a flat rate, and they keep off the peak during the winter months. The domestic load is now being exploited as representing a new type of load with a different character from other loads, and consequently improving the general demand factor and load factor. Load factor is obviously of the utmost importance and, taking conditions as they are, the best way of improving it is to develop the most diverse types of loads in suitable proportions.

Mr. C. W. Marshall: I do not consider that the author's domestic tariff is at all practicable. I believe that the key-note of the situation lies in simplicity, and I would remind him that the use of Kelvin's law in the old days, led to the erection of power stations on the top of a hill in the middle of the town. My view is that supply undertakings should demand a fixed service charge and a flat rate now; that will be the best thing possible for improving the load factor. It can bring about, too, the further simplification that the meter can be calibrated in money—in shillings if required—and the apparatus can be rated in pence or shillings per hour. On the psychological aspect of analysis I cannot agree with the author at all.

Mr. E. Seddon: The author has approached the subject of tariffs from a new viewpoint, and his observations on the cost of the distribution system as affecting the selling prices are interesting from a scientific point of view. We must, however, have regard to public opinion in these matters. We are a comparatively young industry, and in order to compete with other forms of light, heat and power we must make our commodity popular and attractive in price, and any tendency to multiplicity in tariffs can only have the effect of retarding the progress we desire. It is quite safe to say that no supply engineer would dare to make a statement that his tariffs provide for an equal percentage of profit from all consumers. It is the old tale of making up on the swings what is lost on the roundabouts. Given an equal load factor from two consumers, one near the generating station, the other on the fringe of the system, it is obviously unjust to make the same rates of charge to both consumers, but if a truly scientific basis of cost were taken the price would vary from house to house. I am convinced that it would be intolerable to charge varying flat rates in the same area of supply, and I submit that a common form of tariff must be applied whatever the distribution costs amount to. This principle is accepted in the postal and other services. In my opinion the method of fixing the standing charge of a two-part tariff on the assessment or floor area of property is wrong in principle, and such methods of charge only expose our inability to frame suitable rates based on the cost of providing a supply of electricity. The chaos in tariffs creates suspicion in the minds of potential consumers, and each one imagines that by negotiation he can get an advantage over his fellows. I am glad to know that the question of tariffs is being taken up seriously on a national basis, and I hope that a universal system of charge will follow as a result of these investigations. Load factors of individual consumers are apt to be misleading, as it is quite possible for a lower load factor to be more economical than a higher load factor, depending on the period of maximum load. Diversity is, I think, the more important factor, but I do not think we need trouble ourselves too much about these matters, as I am convinced that the load factor at the generating stations will improve automatically with the general application of electricity for all purposes. We in Edinburgh have been criticized in some quarters for selling current for lighting at too low a rate, namely $3\frac{3}{4}$d. per unit with discounts, but I submit that such criticism is only fair if these rates were made at the expense of other users. In consequence of the fact that our domestic heating rate is practically $\frac{3}{4}$d., and that low-tension power supply varies from $1\frac{1}{2}$d. to $\frac{3}{4}$d., I do not think

that anyone can justly state that we are showing undue preference to the lighting consumers. In addition to our flat rates, we have followed the lead of Glasgow in adopting the combined-rate method of charge to allow of a small amount of heating and power being connected to the lighting circuits.

Mr. W. K. Fleming (*communicated*): The subject of electricity supply tariffs seems to be a perennial one, yet it is well to pause periodically to renew our efforts to elucidate the ideal tariff, by the presentation and discussion of a paper such as the present one. The ideal tariff is one that (*a*) ensures to the supply undertaking a fixed sum per annum (plus a reasonable profit) in respect of the standing charges incurred in supplying the consumer, with all units used charged at running cost (plus a reasonable profit); (*b*) reduces the average price per unit as the load factor and diversity factor increase; (*c*) requires only one meter; and (*d*) is easily understood by the consumer and appeals to his sense of equity. The analytical examination of the subject made by the author is extremely valuable, especially the Section dealing with distribution economy. The domestic load is progressing rapidly just now and it is certain that the next few years will witness a tremendous development. The problem of distribution design will be one of great import, for who can foretell with any degree of accuracy to what extent and at what rate the demand from the vast domestic field will grow? The tariff put forward by the author covers, in the main, the conditions stated for the ideal tariff, although the law of averages is used in so far that the basis of calculation is for classes of consumers and not individual consumers. One might expect in connection with the suggested new tariff that some addition to the accountancy and clerical work would be experienced in view of fairly frequent changes of consumers from one class to another. The question of whether the rate should be levied as a flat rate or as a periodic fixed charge with a low running charge is one that will be influenced by local conditions. In general, large consumers do not mind a high fixed charge, but for small consumers who have many other fixed periodic payments to meet, the fixed charge must be reasonable, otherwise the flat rate is preferable. One benefit of the flat rate is that prepayment meters may be used. This method of payment, using 1d. and 1s. slot meters, has been very successful in Greenock, where it has been in operation for 5 years. Reference is made in the paper to the fact that the lighting load will probably cease to be a predominant feature of the peak load as the use of electricity for other purposes increases. Whilst it is true that the influence of the lighting load is not now so great in districts where the heating and cooking load has been intensively cultivated, yet it is well to keep in mind that in the future it is to be expected that the lighting load in the home will also increase. Most engineers will be aware of the general campaign in favour of "more and better light" which has been proceeding with the co-operation of the Electric Lamp Manufacturers' Association of Great Britain. During the present winter, attention has been concentrated on shop-window and shop interior lighting. Due to the active educative propaganda which has been carried on, we have experienced in Greenock during the past months a very large increase in the shop-lighting load, the intensities of illumination in many cases being doubled. Even now, higher standards of illumination in the home are being advocated, and it is to be expected that when the subject is tackled thoroughly and systematically in the same way as shop lighting, the lighting load will reassert itself to some extent at the time of peak load. The author states that for the immediate future it may be advisable to limit the maximum lighting demand of domestic consumers under the tariff he proposes. However desirable this may be from the supply undertaking's point of view, it is a mistake in policy to restrict the user. The consumer should be at liberty to use the electric service as it suits him to do so. It is permissible, of course, to restrict the hours of use for an electrical hot-water storage tank, for then the commodity that the consumer wants to use—the hot water—is available at any time of the day.

Mr. H. M. Sayers (*in reply*): Prof. Baily is quite right in laying stress on the relation between tariffs and the psychology of the consumer. That is why I advocate classified flat rates as the simplest to understand and apply. The consumer in one of the higher-rated classes may grumble at being charged, say, 3d., whilst a neighbour is charged 1½d. per unit, but the answer is that if he uses the same proportion of lighting, heating and cooking, he will get the same rate; and this should show him that the difference is not arbitrary, but is an endeavour to be fair.

Mr. Whysall says that the analysis of costs for any particular service always indicates a much higher charge than is proved to be necessary. This experience suggests that insufficient credit is given for the diversity effects. I did not attribute the high load factor of certain stations to their traction load, but mentioned that all the stations with published load factors of 30 per cent and over have traction loads. The traction (tramway) load is an instructive example of the value of diversity. Though a tramway load by itself may show a load factor of only 20 to 25 per cent, yet it fits in with other loads in a highly beneficial way. In an industrial town the tramway peaks occur in moving workers to and from their work just before and just after the factory and office loads come on and go off, including the midday break in many cases, and on Saturday afternoons when there is no factory load. Load diagrams and log sheets of Mr. Whysall's own system, which I have examined, show this effect clearly. The few works which run 24 hours per day have by themselves a very high load factor. They require for their supply the full-load amount of plant, plus spares; whilst a tramway load does not add to the plant requirements up to its peak loads.

Mr. Mears generally agrees with the paper. The cases mentioned of very high losses between units generated and units sold are where original local direct-current stations have been displaced by more distant three-phase stations, with direct-current distribution retained through converting plant. These cases will disappear in time. A remunerative tariff must include the charges for services and meters, as well as the kilowatt

charges; for domestic consumers it is better to consolidate these into flat rates than to make specific charges. The statement that the distribution costs in Edinburgh are only about half the generating costs, shows that the Edinburgh system must be unusually compact and unusually well-designed for its present load. It seems to justify the low rate for lighting mentioned by Mr. Seddon.

I agree with Mr. Marshall that simplicity should be the keynote of tariffs, and I hoped that I had shown one way of achieving it; what can be simpler than a flat rate? I cannot conceive how the use of Kelvin's law led to the erection of stations in unsuitable places.

Mr. Seddon's appreciation of the value of diversity is welcome. The paper advocates methods which will encourage and recognize diversity. If they do that, the rates will be automatically reduced to a small number as domestic electrification becomes general and the proportions of lighting, cooking, heating, etc., become sensibly uniform.

I rather agree with Mr. Fleming's criticism of the suggestion that the maximum lighting demand might be restricted for the immediate future. It was mentioned as a concession to the evident fears of some supply undertakings that a low flat rate may produce an expensive domestic lighting peak. I do not share those fears, and I believe that any such condition would soon prove unnecessary and fall into disuse. All the published statements of load and consumption where heating and cooking services are given support this view.

It is gratifying to find that the subject of distribution-costs as affected by load diversity and form factors was appreciated in the discussion. I would reiterate the suggestions in the paper that a much more general use of measurements on the distribution systems should be adopted. The very complete system of measurements used in modern power stations is amply justified by the economies effected and maintained. Similar results may be expected by similar methods applied to the distribution plant. It is only by the knowledge derived from measurement that efficiency can be raised and maintained.

INSTITUTION NOTES.

Summer Meeting.

On account of the strike and in view of the coal situation, the Summer Meeting at the North-Eastern Centre which was to have been held this month has been postponed to next year (14th–17th June, 1927).

Council's Nominations for Election to the Council.

The following have been nominated by the Council for the vacancies which will occur in the offices of President, Vice-President, Honorary Treasurer, and Ordinary Members of Council on the 30th September, 1926:—

President. (*One Vacancy.*)

W. H. Eccles, D.Sc., F.R.S.

Vice-President. (*One Vacancy.*)

Colonel T. F. Purves, O.B.E.

Honorary Treasurer. (*One Vacancy.*)

Lieut.-Col. F. A. Cortez Leigh, T.D., R.E.

Ordinary Members of Council.

Members. (*Four Vacancies.*)

A. C. Cramb.
A. H. Railing, D.Eng.
Prof. S. Parker Smith, D.Sc.
A. J. Stubbs.

Associate Member. (*One Vacancy.*)

F. W. Crawter.

Premiums.

The following Premiums for papers have been awarded by the Council:—

The Institution Premium (*value* £25).
L. C. Grant. "Developments in High-Power Fusible Cut-Outs."

The Ayrton Premium (*value* £10).
S. Mavor. "The Applications of Machinery at the Coal Face."

The Fahie Premium (*value* £10).
B. S. Cohen, A. J. Aldridge and W. West, B.A. "The Frequency Characteristics of Telephone Systems and Audio-Frequency Apparatus, and their Measurement."

The John Hopkinson Premium (*value* £10).
S. Ferguson. "A General Survey of the High-Tension Switchgear Field."

The Kelvin Premium (*value* £10).
P. Dunsheath, O.B.E., M.A., B.Sc. "Dielectric Problems in High-Voltage Cables."

The Paris Premium (*value* £10).
T. Carter. "The Engineer: his Due and his Duty in Life."

A Premium (*value* £10).
Prof. S. P. Smith, D.Sc. An All-Electric House."

A Premium (*value* £10).

J. L. THOMPSON, M.Sc., and H. WALMSLEY. "Notes on the Testing of Static Transformers."

A Premium (*value* £5).

A. B. WOOD, D.Sc. "The Cathode-Ray Oscillograph."

WIRELESS SECTION PREMIUMS.

A Premium (*value* £10).

R. A. WATSON WATT. "The Directional Recording of Atmospherics."

R. A. WATSON WATT and J. F. HERD. "An Instantaneous Direct-reading Radiogoniometer."

A Premium (*value* £10).

J. HOLLINGWORTH. "The Propagation of Electric Waves."

A Premium (*value* £10).

R. L. SMITH-ROSE, Ph.D., M.Sc., and R. H. BARFIELD, M.Sc. "The Cause and Elimination of Night Errors in Radio Direction-Finding."

The Premiums for papers read before the Students' Sections will be announced later.

Informal Meetings.

77TH INFORMAL MEETING (8TH FEBRUARY, 1926).

Chairman : Mr. G. R. Polgreen.

Subject of Discussion : "Modern Applications of Ball and Roller Bearings" (introduced by Mr. R. J. Mitchell).

Speakers : Messrs. C. H. Smith, W. E. Rogers, A. F. Harmer, H. Brazil, C. Belcher, W. A. Erlebach, W. L. Wreford, C. R. Garrard, C. S. Clarke.

78TH INFORMAL MEETING (22ND FEBRUARY, 1926).

Chairman : Mr. H. T. Young.

Subject of Discussion : "Some Changing Characteristics in the Application of Electricity to Public Supply" (introduced by Mr. A. F. Harmer).

Speakers : Messrs. A. Wright, W. E. Rogers, P. Dunsheath, O.B.E., W. A. Erlebach, S. V. Hook, W. Lunn, M. D. Hart, M.Sc., R. Grierson, H. T. Young.

79TH INFORMAL MEETING (8TH MARCH, 1926).

Chairman : Mr. M. Whitgift.

Subject of Discussion : "A Recent Development in A.C. Apparatus" (introduced by Mr. F. Creedy).

Speakers : Messrs. A. F. Harmer, J. Eck, J. Coxon, M. D. Hart, M.Sc., W. E. Rogers, A. J. Gill, R. J. Mitchell, A. H. E. Tomkinson, A. G. Hilling, J. F. Shipley, C. G. King, J. R. Bedford, J. H. St. H. Mawdsley, F. Pooley, A. H. Allen, W. L. Wreford, W. S. Gearing.

80TH INFORMAL MEETING (22ND MARCH, 1926).

Chairman : Mr. A. H. Allen.

Subject of Discussion : "The Performance of Mercury Arc Rectifiers" (introduced by Mr. G. Rogers).

Speakers : Messrs. A. F. Harmer, S. C. Bartholomew, M. D. Hart, M.Sc., W. E. Rogers, F. Creedy, K. H. Tuson, W. Lang, A. Honeysett, G. H. Fowler, R. Grierson, J. Coxon, A. G. Hilling, J. C. Read, J. F. Perrin, J. R. Bedford, J. F. Shipley, W. W. Hughes, W. S. Hunt, R. V. Hook, A. H. Allen.

81ST INFORMAL MEETING (12TH APRIL, 1926).

Chairman : Mr. J. Coxon.

Subject of Discussion : "The Linking Together of Wireless and Wire Communication Systems" (introduced by Captain P. P. Eckersley).

Speakers : Messrs. J. F. Shipley, N. Ashbridge, H. L. Kirk, W. A. Erlebach, R. Sandeman, E. J. Buckingham, A. C. Brown, E. S. Ritter, W. Day, A. Rosen, Ph.D., G. F. Findley, J. Coxon.

THE SEVENTEENTH KELVIN LECTURE.

"THE MECHANICS OF THE ELECTRIC FIELD."

By Sir J. J. Thomson, O.M., M.A., F.R.S., Honorary Member.

(*Lecture delivered before* The Institution, 22*nd April*, 1926.)

The subject which I have selected for the Kelvin Lecture is one that from the very beginning of his scientific career was never long absent from Lord Kelvin's thoughts. It is one, too, which researches only dawning towards the close of his life have put into quite a new aspect. These researches have given us very definite information as to the structure of the atom, they have taught us that the atom is made up of electrons and positively electrified particles of known masses, they have told us the number of electrons and positive particles present in each atom; they have, in fact, given us a definite specification of the electrical state of the atom. With this in our possession it would seem as if we ought to be able to deduce the properties of the atom, by calculating by means of the laws of electromagnetism the behaviour of this definite electrical system. We find, however, if we do this, that the properties of our mathematical atom are in some respects in contradiction to those of the real atom. It is of course a gigantic extrapolation to pass from any system which we can test by direct experiment, and for which the laws of electromagnetism have been verified, to systems like the atoms, where the times and distances involved are of an entirely different order of magnitude. The extrapolation fails, but the point is that if the usual interpretation of these laws is the right one it ought not to fail. The equations expressing these laws are:

$$\frac{dF}{dt} = c \text{ (curl H)}$$

$$\frac{dH}{dt} = c \text{ (curl F)}$$

where F and H represent the electric and magnetic forces respectively and c is the velocity of light. The only constant which these equations involve is the velocity of light, and extrapolation to any scale of time or space should be valid unless it introduced velocities comparable with those of light.

I propose to discuss the question whether the equations of classical electrodynamics or, for the matter of that, classical dynamics are as fundamental as they have been thought to be; whether, instead of giving us a complete representation of the field of force, they do no more than give us the relations between the average value of the quantities used to define the field. That, in fact, they express statistical and not particle dynamics.

Let me introduce the subject by considering the oldest of the laws of electrical action, Coulomb's law, which states that two oppositely electrified bodies attract each other with a force varying inversely as the square of the distance between them. The interpretation assigned to this law is that if A represents one of these bodies and B the other, then A receives a stream of momentum in the direction A B, while B receives a stream in the direction B A, and that in any small time δt the amount of momentum received by either A or B is equal to $\delta t \,.\, Ee/\mathrm{AB}^2$, where E and e are the electrical charges on A and B respectively. The process by which the momentum is communicated has, I think, always been regarded as a perfectly continuous one: that, however acute our powers of detecting variations in momentum might be, we should never be able to detect any break in the continuity of the supply of momentum, and, moreover, that at each instant the gain of momentum of A would be simultaneous with the loss of the same amount of momentum by B, and also that the rate of communication of momentum is determined without any ambiguity whatever when the positions of A and B are known. We have no direct experimental proof of the continuity in the supply of momentum, for all our experiments are on effects which extend over a finite time, a time which is very long indeed compared, for example, with the time which would be taken by an electron to describe an orbit round a positive charge in the atom. All that direct experiment can teach us is that eE/AB^2 is the average rate at which the momentum is communicated, the average being taken over a time which is very large compared with the times occurring in atomic dynamics. Direct experiment gives us no information as to whether the momentum was supplied in an uninterrupted flow, or whether it was given by a series of separate impulses separated by finite times. Yet the difference is a vital one, for it is only on the first of these suppositions that we are justified in applying the methods and principles of classical dynamics to discuss the dynamics of the atom. I may illustrate my point by a simple case. The engineer treats the pressure of gas on a piston as a perfectly continuous force and gets quite accurate results. Yet we know that this pressure arises from the impacts of the molecules of the gas against the piston, that it resembles a series of blows with a hammer rather than a continuous force. These blows, however, succeed each other so quickly that in ordinary cases we cannot separate the effect of one blow from that of another; all that observation of the piston could tell us is the average amount of momentum communicated to it, taken over a time which is very long compared with the interval between two blows. By merely observing this average we cannot determine whether the blows

succeed each other at regular intervals, or whether they follow each other at intervals occurring quite at random; whether they are very small blows following each other at very small intervals, or larger blows following each other at longer intervals. Let us suppose, however, that we reduce the pressure of the gas; this will lengthen the interval between the collisions, and we may imagine the pressure reduced to such an extent that the interval between the collisions becomes long enough for us to be able to follow in our experiments the effect of each collision. At this stage the effect produced by the gas on the piston cannot even approximately be represented by a constant force. The amount of momentum received by the piston in one of these short intervals will be a matter of chance. We cannot say that in a certain time a definite amount of momentum will be communicated to the piston; all we can say is that in this time t the probability that the piston receives n blows is

$$\left(\frac{t}{T}\right)^n \frac{1}{n!} e^{-\frac{t}{T}}$$

where T is the average interval between the blows. We see that in this stage the results and methods are quite different from those obtaining when our experiments extended over a time long enough to include an immense number of collisions; in the latter case the motion of the piston can be determined without ambiguity by classical dynamics and, given the initial conditions, there is only one solution. In the other case the motion of the piston may be almost anything within certain limits; it is determined far more by the theory of probability than by dynamics. The fact is that we have to deal here with two interacting systems, the piston and the molecules of the gas, and the distribution of the molecules is not fixed by the position and motion of the piston, but has to be determined by the theory of probability. Thus, even for the same position and velocity of the piston, we may have different distributions of molecules; the behaviour of the piston will depend upon the kind of distribution, unless the number of molecules is so large that the distributions which differ from a standard one are insignificant in number compared with those which approximate to it.

It may be urged that though we cannot prove the classical hypothesis of a continuous flow of momentum by direct experiment, and though it apparently leads to results which are not in accordance with the electrical theory of the atom, yet this conception is so much simpler and seems so much more probable than the idea of intermittence that we ought to retain it and seek for some other explanation of the discrepancies to which it seems to lead. Is, however, the idea of a continuous flow of momentum so much simpler and more probable than that of intermittence? No doubt the mathematical analysis is simpler for the continuous than for the intermittent flow, but is the idea simpler from the physical and mechanical point of view? Suppose our senses were so acute that we were able to see the molecules of a gas and watch their effects upon each other, or, to put it another way—Maxwell, as you know, introduced the idea of a molecule endowed with intelligence, and showed that it could upset the second law of thermodynamics. Now let us suppose that Maxwell's "demon" was a mathematician, and that he set to work to develop a system of dynamics. Would not to him the idea of a continuous flow of momentum seem remote and far removed from reality? What he sees going on around him is one big bang after another, and not the halcyon repose of continuous smooth motion without any jerks or breaks. Would it not be more natural for this molecular Newton to take as his fundamental idea not a uniform flow of momentum but collisions which succeeded each other irregularly, the average interval between the two collisions depending on the pressure of the gas.

I want to bring before you some of the consequences of supposing that the electric force is of this nature, that it consists of separate impulses separated by finite times. I must point out that this conception involves the existence in the universe of a structure beyond that represented by electrons and positive particles; if there were no structure of this kind, we could not account for the intervals which elapse between the impulses. This structure must be far finer in texture than the electrons; thus, on this view, the electron does not represent the last word in minuteness and there are still smaller entities awaiting discovery by the physicists. For heuristic purposes, i.e. for the purpose of making our meaning clear, and without committing ourselves to the reality of this particular structure, we may liken it to a sub-atomic and sub-electronic gas, the particles of which are much finer than the electrons. It is in these particles that the energy and momentum of the electric field are stored. We may regard these particles as concentrated round the electric charges, each charge carrying with it an atmosphere of these particles. The particles are crowded together near the centre of the charge, but get more and more widely separated as the distance from the centre increases. To distinguish between the positive and negative charges, we may suppose that the particles rotate round the charges and that the rotation as viewed from the centre of the charge is in one direction for the positive and in the opposite direction for the negative charge.

The particles bombard intermittently the charges round which they are congregated. If there were only one charge in the field the particles would be symmetrically distributed around it and the bombardment would not, on the average, make it move in one direction rather than in another; but when two or more charges are near together the symmetry of the distribution of the particles is disturbed and the bombardment results in the charges acquiring momentum. Let us now consider in some detail the way in which the effects produced by intermittent forces differ from those due to continuous ones. We may represent the intermittent force analytically by saying that the chance of a body on which this force is acting receiving in time δt an increment of momentum is $\delta t/T$, where T is the average time between two increments and is a measure of the fineness of the time structure of the electric field. Let I be the increment of momentum given at each impact; then the expectation of the increase in momentum in time δt is $(I/T)\delta t$. If the

force had been continuous and equal to F, the increase in momentum would have been equal to $F\delta t$ and have had a definite value. On the intermittent view, instead of a certainty we have an expectation, sometimes the results will exceed expectations, sometimes they will fall below them; but on the average, when there are a great many increments, i.e. when δt is large compared with T, they will differ but little from the expectation, so that the increase of momentum will be $(I/T)\delta t$, or the same as the body would receive from a continuous force $F = I/T$. Thus for effects lasting for times long compared with T, the results will be very nearly the same whether the forces are continuous or discontinuous; but for shorter times they will be very different.

For if the chance of an increment is $\delta t/T$, then we can easily show that the chances of certain events happening in the time t are as follows:—

(1) The chance that the body receives no increment at all is $e^{-t/T}$

(2) The chance that it receives one increment and no more is $\frac{t}{T}e^{-t/T}$

(3) The chance that it receives two increments and no more is $\frac{1}{2}\cdot\frac{t^2}{T^2}e^{-t/T}$

(4) The chance that it receives r increments and no more is $\frac{1}{r!}\cdot\frac{t^r}{T^r}e^{-t/T}$

The ratio of the chance that there should be $(r+1)$ increments to the chance that there should be r increments is thus $\frac{1}{r+1}\cdot\frac{t}{T}$

Thus until $(r+1)$ is greater than t/T the chance of a larger number of collisions is greater than that of a smaller one; but when $(r+1)$ is greater than t/T the chances of a larger number rapidly diminish. The number of collisions for which the chance is greatest is t/T; the expectation of increase in momentum is It/T, or Ft if $F = I/T$. Thus on the discontinuous theory the most probable increase in momentum is the increase which would occur on the continuous theory. On the discontinuous theory, however, there is a finite probability that the increase should be either greater or less than this value.

We may illustrate the difference between a continuous and an intermittent force by considering a simple case. Take that of an electron projected horizontally and exposed to the influence of a vertical force for a time t. Whether the force be continuous or intermittent the horizontal velocity will remain constant and the horizontal distance travelled is not affected by the intermittence of the force. When the force is continuous and constant there is only one orbit, the parabola. If the force is intermittent there will be an infinite number of possible orbits. In fact any polygon is a possible orbit, provided the rth side makes an angle with the horizontal such that $\tan\theta_r = kr$, where k is a constant.

Thus a horizontal straight line is a possible orbit, because there is just a chance that the electron may escape a collision for the time t. There is an infinite number of two-sided orbits where the electron makes one collision in the time t. At the end of these orbits all the electrons have the same kinetic energy, but they will not all have suffered the same vertical fall, i.e. they will not all have the same potential energy; this is an illustration that the Conservation of Energy in the ordinary sense does not hold for these intermittent forces. To get the same increase in kinetic energy as they would under the action of a continuous force, some of the electrons under the intermittent force would have lost less, others more, "potential energy" than they would under the continuous force. Again, there is an infinite number of 3-, 4-, 5-sided orbits; there is no limit to the number of sides, and the greater the number of sides the greater the kinetic energy acquired by the electron describing the orbit. All these are possible orbits, but some of them are very improbable. We can calculate the probability of any type of orbit. We have already seen that the most probable number of sides for the orbit is t/T; this makes the final momentum have the same value and direction as it would under the continuous force. But even when the number of sides is given, the individual sides may have very different lengths. We can show that the most probable orbits are those where the impacts are equally spaced over the journey. For divide the space passed over by the orbit into vertical strips, and let the breadth of the first be x_1, that of the second x_2, that of the third x_3 and so on; it is easy to show that the chance that the first collision occurs in the first strip, the second in the second, and so on, is proportional to $x_1 \times x_2 \times x_3 \times x_4$; and, since $x_1 + x_2 + x_3 + x_4 + \ldots$ is constant, this is a maximum when $x_1 = x_2 = x_3 = x_4$, i.e. when the increments of momentum are received at equal intervals. Thus, again, the most probable orbit is the one that approximates most closely to that described under a continuous force. It is, however, only when t/T is a very large number that the chance of orbits departing widely from this becomes inconsiderable.

I have already pointed out that the principle of the conservation of energy in its usual form does not apply when the forces are discontinuous. This is because the energy is stored in the particles which constitute the electric field, and the distribution of these particles and their energy may change, even though the electrons and positive particles do not move; an electron may take energy from these particles or give up energy to them without suffering any change in its potential energy.

Take, for example, the case of an electron starting from an infinite distance from a positive particle, falling close to the particle and then receding from it until it is again at an infinite distance away. The potential energy is the same at the beginning and end, so that if the principle of the conservation of energy holds, the kinetic energy at the end must also be the same as at the beginning. If we suppose that the mass of the positive particle is infinite compared with that of the electron, so that it absorbs no kinetic energy, the velocity of the electron at the end of the journey must be the same as that at the beginning. This need not, however, be the case if the force is discontinuous, for when the electron is falling from aphelion to perihelion the increase in its kinetic energy depends upon the

number of increments of momentum it receives during its journey from aphelion, and when it goes away from perihelion to aphelion its loss of energy depends upon the number of increments of momentum it receives on the return journey. Now, according to the intermittent theory of the force, these numbers are not fixed but are a matter of chance, so that there is a finite probability that the electron on its journey from aphelion to perihelion may receive more than the normal number of increments, whilst on the return journey it would receive less. If this were so, the electron would receive more energy in its approach than it would lose on its return, so that it would have gained by the journey kinetic energy without losing potential. The chance of losing more energy on its return than it gained on the approach is just as great as in the case we have considered, so that some electrons may lose kinetic energy by the journey without gaining potential energy. The fact that it is possible for an electron to gain energy in this way has, I think, an important application to the question of the spontaneous dissociation of atomic systems.

Let us take the case of an electron describing an elongated orbit about a positive centre, and suppose that in going from aphelion to perihelion it receives more than the normal number of increments of momentum; when it gets to perihelion it will have more than the normal amount of kinetic energy. Suppose that the increments in the return journey are not more than normal, then on reaching aphelion again the electron will have more kinetic energy than when it started. If this increase in energy exceeds a certain amount, i.e. if it is so great that when the electron approaches the place from which it started it has sufficient energy to carry it against the attraction of the positive centre from this place to an infinite distance, the electron will break away and separate from the positive centre. Thus in this way the discontinuous character of the force may give rise to a spontaneous dissociation of the system—spontaneous in the sense that it is a consequence of the character of the forces acting between the members of the system, and does not depend upon collisions with other molecules or electrons or on the influence of radiation. The probability of the electron receiving an increment of energy ω by the journey can be shown to vary as $e^{-p\omega^2}$, where p does not depend upon ω. The probability thus diminishes rapidly as ω increases; the probability of acquiring a certain amount of energy is inversely proportional to the average life of the atom, so that this life will increase very rapidly with the amount of work required to dissociate it. An example of this spontaneous dissociation is afforded by the negative ions in gases; these have two phases, one being the electron, the other a complex of the electron and one or more molecules. The first phase is continually passing into the second by the combination of electrons with molecules, and the second into the first by the dissociation of the complex. The rate of this dissociation is independent of the pressure of the gas and there is no evidence that it is affected by radiation. Similar considerations show that when the force is intermittent an electron moving past a positively electrified particle may acquire or lose energy by the collision, even though the mass of the particle is infinitely greater than that of an electron, when, if the force were continuous, there would be no transference of energy to or from the electron. Thus it might be possible for an electron projected with less than the energy required to ionize a gas to acquire by collisions with positive particles enough energy for this purpose.

The dissociation considered is that of an electron describing an elongated orbit, and the argument would not apply to a circular one. Similar results would, however, follow for such orbits if we suppose that a body in a field of electric force receives impulses at right angles to the direction of the electric force as well as along it, but that at right angles to the force there are on the average as many positive as negative impulses. If these impulses are, however, discontinuous, there is a finite chance that the number of positive impulses should differ from that of the negative; in this case the body would gain or lose momentum in a direction at right angles to the electric force. Thus an electron describing a circular orbit would have a finite chance of having its tangential velocity and therefore its energy increased. If this increase in the energy amounted to that required to tear the electron away from the positive charge, the system would dissociate.

Let us now consider more in detail other characteristics due to the intermittence of the electric force: these will naturally occur only when the phenomena involve times short enough to be comparable with the time interval of the electric field. This time interval, we may say in passing, is not constant but varies with the strength of the electric field, diminishing as the strength of the field increases. Now suppose the electric field acts on an element of volume which contains a very large number of systems, be they electrons, atoms, or anything else which can be effected by electric force; and suppose the time t the force acts is small compared with T the time interval of the force. We can easily show that the momentum received by the whole system will be the same as if the force had been continuous and equal to I/T. This will be true whatever the time may be during which the force acts. The distribution of momentum will, however, be very different in the two cases, when the time of action is small compared with T. For when the force is continuous the momentum will be equally distributed among all the members, and each individual will possess a small amount, the same as that of its neighbour. In the case of the intermittent force the vast majority of the systems will not have received any momentum at all, but a few will have received quantities that are enormous compared with those which would have been received if the momentum had been equally divided. When the time t is large compared with T, the distribution of momentum under the intermittent force will approximate very closely to that under the continuous. The energy communicated to the collection of system by the intermittent force can be shown to be greater than that by the continuous one in the proportion of $(T + t)$ to t, so that when the time is small compared with T the system absorbs far more energy from the intermittent field than it would from the continuous field which in the long run is equivalent to it.

The difference between the continuous and the inter-

mittent force is accentuated when the forces are reversed after short intervals. For if the force is continuous and acts for a time t, each of the systems will acquire an amount of energy proportional to $(Ft)^2$. If at the end of this time the force is reversed and acts for an equal time in the opposite direction, the energy will be taken out of these systems and restored to the electric field. If, however, the field is intermittent and t is small compared with T, only a small fraction of the systems will have received any energy. When the field is reversed the chance that any of the few systems previously excited will receive negative momentum and so lose energy is exceedingly small, and the great majority of systems which receive energy in the second interval will not have received any in the first. Thus the systems absorb practically as much energy from the electric field in the second interval as they did in the first; whilst, under the continuous field, instead of absorbing energy, in the second period they gave up all they had got in the first. Thus the intermittence of the field may lead to a great increase in the absorption of energy from alternating fields by systems exposed to the action of the field. The question of the transmission of waves of electric force when the period of the wave is shorter than the time interval of the electric force is therefore one that introduces considerations quite different from those of electrical waves of longer period, and requires special treatment.

In the first place, the equations of the electric field do not, if we take the view of the intermittence of force, represent relations between physical quantities which have an existence at any particular time; they have respect rather to the relations between certain statistical quantities, averages taken over a time which is long compared with the time interval of the electric field; for these equations represent relations between electric and magnetic forces. From the point of view of the intermittent theory, electric and magnetic forces do not represent anything that is happening at any particular instant, but an average taken over a time which is long compared with the time interval of the electric field. Thus these equations are meaningless when the times available are not long enough to allow this average to have a definite value. They would not apply, for example, to the case of electrical waves if the period of the waves were less than the time interval of the electric field. The consideration of what would happen to electrical oscillations whose period is shorter than the time interval of the electric field, is a matter of great interest and importance. The time interval T of the electric force is connected with F the intensity of the force by the relation $F = I/T$, where I is the momentum communicated at each impulse, so that as the intensity of the electric field diminishes I/T diminishes also. Now, whatever view we may take of the origin of the impulses which produce the force, whether, for example, we regard them as due to collisions with a swarm of very minute particles or in any other way, we should expect the interval between the collisions to increase as the field gets weaker. The time interval would be a function of the intensity of the field and would be longer for weak fields than for strong. Now consider an electron oscillating with a definite period T_0. Close to the electrons the electric field may be very intense, and its time interval may be short compared with T_0 the period of the oscillations. In such a region as this the classical theory would apply and electrical waves would travel through it, starting from the source of the oscillations. But as the distance from the source increases, the electrical field gets weaker and the time interval continually increases until when a certain distance is reached the time interval becomes comparable with T_0. When this region is reached it seems clear that the waves must stop, as Maxwell's equations from which the wave motion is deduced do not hold. We have seen too that when T_0, the interval between the reversals of the electric force, is small enough to be comparable with the time interval, the absorption of the energy of the electric field is far greater than when T_0 is long compared with the time interval. We should not therefore expect these waves to travel further away from the source than the place where the time interval of the electric field is equal to the period of the oscillations. For oscillations of very long period the critical place would be one where the time interval is long, i.e. where the field is very weak and thus may be at a very great distance from the source; whilst for oscillations of very short period the critical place would be one where the time interval is short, i.e. where the force is very intense and thus, *ceteris paribus*, much closer to the source of oscillations than for the slow vibrations. We may illustrate this point by an example taken from the propagation of sound waves, which raises the same principle. Suppose that we have sound waves of a definite pitch travelling vertically upwards through the air and so getting into regions where the pressure gets lower and lower. As the pressure diminishes, the free path of the molecules increases and, with it, what is called the time of relaxation of the gas, i.e. the time taken by the gas to return to its normal condition after it has been disturbed from it. Suppose that the pressure gets so low that the time of relaxation is long compared with the period of the sound wave. It is clear, I think, that the sound would no longer be propagated, for if a condensation were to occur it would take so long to die away that it would persist until after a rarefaction was due. As this rarefied air cannot transmit the sound waves they will either be reflected back or converted into heat, and the energy of the sound will be confined to a finite volume instead of being dispersed through space.

As another illustration we may take one often used by Lord Kelvin. This is the case of a tightly stretched long string loaded at equal intervals with equal masses. This system has many periods. If P is the fastest of these, $P = \pi\sqrt{(lm/T)}$, where T is the tension in the string, m the mass of one of the particles loading the string, and l the distance between two adjacent particles. If one end of the string is agitated harmonically with a period p, waves will travel freely along the stretched string as long as P is less than p. If, however, the string is made more sluggish by increasing the mass of the particles or otherwise, so that p becomes less than P, the string will no longer transmit the waves and the energy instead of travelling along the string will be localized close to the extremity which is agitated. The

model would resemble the electrical case more closely if instead of spacing the particles at equal intervals the distance between two adjacent particles increased with the distance from one end A of the string; the value of P would increase with the distance from this end. If the end A were agitated harmonically with a period greater than the value of P close to A, but less than the value of P at some distance from A, the waves would travel along the string until they reached the place where P was equal to the period of agitation. Here they would be reflected back and the further parts of the string would be free from agitation.

To return to the case of the vibrating electron. We see that though it may send out electrical waves, these waves, after travelling through a distance which depends on the period of the vibrations and also upon their amplitude, will reach a region through which they cannot penetrate, and will be reflected back. Thus the energy emitted by the radiator will not travel out into space but will be reflected back and again absorbed by the radiator, and thus there will be no escape of energy.

If the oscillations were due to an electron describing a circular orbit, the reflected waves when they struck the electron and gave up their energy to it would, in general, deflect it and cause it to describe a different orbit. Thus the motion of the electron would not be steady. There may, however, be some orbits where the distance of the boundary at which the reflection takes place from the orbit is such that the reflected waves are in such a phase when they reach the electron that they just compensate for the changes in the motion of the electron produced by the emission of the radiation. For such orbits the uniform circular motion might be a steady state. It is evident that certain conditions have to be fulfilled for this to happen, so that it is only orbits with particular periods which possess this property. Since the application of a strong electric force would diminish the time-constant of the field, these orbits would be displaced by electric force. We may illustrate this point by the case of a piston vibrating at one end of an organ pipe which is closed at the other. In general, the waves reflected from the closed end will influence the motion of the piston, but they will not do so if the period of the piston is such that a loop of the vibrations of the pipe coincides with the position of the piston.

Let us apply similar considerations to light waves. Assuming that light is an electrical effect, we see at once that there can be no unlimited propagation of spherical electrical waves diverging from a source, such as is contemplated in the usual conception of the electromagnetic theory of light; for, on this view, energy in the light is distributed continuously through space and the energy per unit volume diminishes indefinitely as the light travels further and further away from the source. Now we have seen that the condition for the propagation of a periodic disturbance is that the period of the disturbance should be greater than the time interval of the electric field; this interval increases, however, as the energy in the light diminishes, so that when the energy falls below a certain value, which is small for long-period vibrations and large for short-period ones, any further propagation is impossible. Thus the intermittence of electrical force demands a corpuscular theory of light, i.e. a theory where the energy is done up in bundles which do not alter in size as they travel through space. The bundle may consist of a periodic distribution of electric force, like a piece cut out of what on the classical theory represents a beam of light. This piece is prevented from spreading because the energy density at its boundary has the critical value, and this boundary acts, on our view, like a reflecting surface and sends back any disturbance which tries to get outside it.

I picture these units as consisting of two parts: a central core in the form of an anchor ring, the plane of the ring being at right angles to the direction in which the unit is travelling. This ring is the seat of an intense electric field, and the circumference of the ring is equal to the wave-length of the light. This ring corresponds to the quantum of the light. This ring vibrates and emits electrical waves which, after travelling to a certain distance from the centre, get to the limit where the time interval of their electric field is equal to the period of the light. This forms the boundary of the unit, and the space occupied by the waves and the energy in them remain unaltered as the unit travels through space. On this view, light has a dual structure consisting of electrical waves with a quantum as the core. The electrical waves give rise to interference effects, the quanta to the photo-electric ones.

On the view that the force is intermittent the electric field must have a structure, and as electrons and positive particles are the centres of intense electric fields, they are probably much more complex than the usual conception of them and must be regarded as centres of complex systems associated with an electron or a positive particle. If we compare the atom with its electrons to a solar system, we may compare an electron or a positive particle to the centre of a nebula and regard the electron as surrounded by an atmosphere of small particles. This atmosphere can be distorted by the presence in its neighbourhood of other electrons or positive particles with their atmospheres, and will assume a shape appropriate to its surroundings. Thus the atmosphere round an electron, far from other charges, would be symmetrical and, if it were distorted, would vibrate about the symmetrical shape. Thus we could have vibrations associated with single electrons or single positively-charged particles, even though the electron or particle were itself at rest. Thus, for example, without becoming neutralized by the absorption of an electron a positively electrified hydrogen atom might be able to give out radiation. The possibility of vibrations of an electric field apart from any movement of the charges in the field has not, I think, been sufficiently realized.

These considerations suggest that just as matter is made up of molecules, and molecules are made up of electrons and positive particles, this is not the end of the story; there are still other worlds to conquer, the worlds which build up the electrons and positive particles.

THE PROBLEM OF THE SPHERICAL CONDENSER.*

By A. Russell, M.A., D.Sc., LL.D., F.R.S., Past President.

(*Paper first received 17th March, and in final form 14th April, 1926.*)

Summary.

Methods are given of computing to any desired accuracy the capacity of a spherical condenser when the bounding spherical surfaces are not concentric. Methods of calculating the attraction on the inner sphere and the maximum potential gradient in the field between the two shells are given. The results obtained are of use in calculating the capacity coefficients of spherical electrodes. They are directly useful also when measuring by standard methods the inductivity (specific inductive capacity), the thermal conductivity and the electrical conductivity of homogeneous substances.

The problem of the electrostatic condenser formed by two concentric spherical shells is familiar to every electrical engineer. If the radius of the outer shell be a and the radius of the inner shell be b, the capacity of the condenser is $\nu ab/(a - b)$, where ν is the inductivity (specific inductive capacity) of the medium between the two shells. When $(a - b)$ is small compared with b, the capacity of the condenser is large and can be very easily measured. Hence this formula gives us a method of measuring inductivity. It can also be used to measure thermal and electrical conductivities, as the mathematical theory of the problems is the same, the only difference being in the nature of the physical constants.

In practice, however, it is impossible to arrange so that the spherical shells are exactly concentric. As the radii of the spheres are nearly equal, a small error in the adjustment of their centres introduces an appreciable error into the results found by using the formula. For example, when Rosa and Dorsey * made a determination of the ratio of the electromagnetic to the electrostatic unit of charge they found it necessary, although their standard air condenser had been constructed with the greatest possible care, to take into account the fact that it was not quite concentric.

The complete solution of the problem, when the spheres are not concentric, is of practical importance from another point of view. It is proposed to use effective pressures exceeding a million volts in value for testing purposes. It is of importance, therefore, that we should be able to calculate without excessive labour the attractions and repulsions between the spherical electrodes whatever their potentials may be, and also the maximum value of the electric stress in the medium between them. At first sight this seems to have nothing to do with the problem discussed in this paper. The author, however, has shown * that the problem of finding the capacity coefficients of spherical conductors can always be reduced at once to that of finding the capacities of certain spherical condensers. They can, therefore, always be found by the help of the formulæ given in this paper. The author has published in the *Journal* † solutions for the case of equal spherical electrodes. The new methods which he now gives, and further methods which he hopes to give in a subsequent paper on the problem of external spheres, will partly supersede the formulæ previously given.

In certain experiments carried out by the late Mr. Duddell he used for the electrodes of his spark-gap a sphere and a hemispherical shell, the concavity of which was directed towards the sphere, and he asked the author to work out the problem of the maximum potential gradient in the spark-gap in this case. This the author did in the paper communicated to the Royal Society and referred to above. In that paper no proofs of the fundamental theorems are given. It is merely said that the formulæ are obtained by the method of images. Although this was a procedure sometimes adopted by Kelvin, the author thinks that much more rapid progress is made when elementary proofs of new theorems are given. In the following paper it is shown that the numerical values desired by electrical engineers can be computed to any required degree of accuracy by the use of elementary mathematics only. A few more advanced methods are given, however, when they lead to simpler or more accurate formulæ.

The mathematical results obtained by two quite different methods, similar to those used by Poisson and Kelvin for external spheres, both lead to the same system of inverse spheres. This system may possibly have some physical meaning. In any case it is of fundamental importance in making calculations, and so the author thinks that he is justified in giving complete mathematical proofs. He finds that it is unnecessary to introduce theorems taken from the Calculus of Finite Differences.

Concentric Spherical Condenser.

We shall denote a spherical condenser, the radii of the surfaces of which are b_0 and b_1, by (b_0, b_1, c_1), where c_1 is the distance between their centres. Its capacity we shall denote by $K(b_0, b_1, c_1)$, where c_1 is zero for concentric systems.

Let us first consider the case of a concentric spherical condenser (Fig. 1) of inner radius b_1 and outer radius

* The Papers Committee invite written communications (with a view to publication in the *Journal* if approved by the Committee) on papers published in the *Journal* without being read at a meeting. Communications should reach the Secretary of the Institution not later than one month after publication of the paper to which they relate.

b_0. Construct another sphere concentric with both and of radius b_2, where $b_2 = b_1^2/b_0$. This sphere is the inverse of the outer sphere B_0 with respect to the sphere B_1. Similarly let B_3 be the inverse of B_1 with respect to B_2, and let $b_3 = b_2^2/b_1 = b_1^3/b_0^2$, etc. Then we have, when the medium is a vacuum,

$$K(b_0, b_1, 0) = b_0 b_1/(b_0 - b_1) = b_1 + b_1^2/b_0 + b_1^3/b_0^2 + \ldots$$
$$= b_1 + b_2 + b_3 + \ldots \qquad (1)$$

Similarly, $K(b_1, b_2, 0) = b_2 + b_3 + b_4 + \ldots$

and so we have

$$K(b_0, b_1, 0) = b_1 + K(b_1, b_2, 0)$$

and, in general,

$$K(b_{n-1}, b_n, 0) = b_n + K(b_n, b_{n+1}, 0) \qquad (2)$$

The radii of the spheres, $b_1, b_2, b_3 \ldots$ form a series

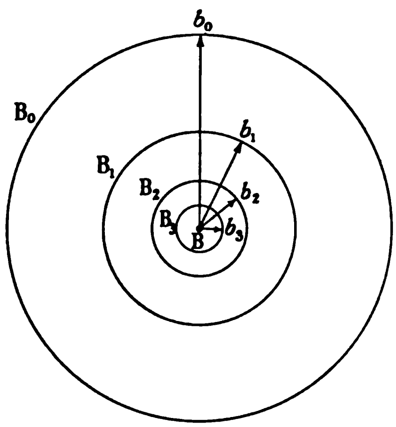

FIG. 1.—Concentric system of inverse spheres.

$$b_n^2 = b_{n-1} b_{n+1}$$
$$K(b_0, b_1, 0) = b_1 + b_2 + b_3 + \ldots = \frac{b_0 b_1}{b_0 - b_1}$$

in geometrical progression, the common ratio of which is b_1/b_0, and if this ratio is small, it is only necessary to compute a few terms of the series given by (1) in order to get a close approximation to its value. When $b_0, b_1, \ldots$ are measured in centimetres the formulæ give the capacity in C.G.S. units. To find the capacity in microfarads we have to divide this answer by 900 000.

If V be the potential difference between B_0 and B_1 (Fig. 1), the maximum value of the potential gradient between them is given by

$$R_{max.} = \frac{VK(b_0, b_1, 0)}{b_1^2}$$
$$= \frac{V}{b_1} + \frac{b_2 V}{b_1^2} + \frac{b_3 V}{b_1^2} + \ldots \qquad (3)$$

If $b_1, b_2, \ldots$ be measured in centimetres and V be in volts, $R_{max.}$ is given by (3) in volts per centimetre.

It will be seen later on that the formula (26) given for the capacity of a condenser when the spheres are not concentric is in agreement with (1), the successive inverse spheres being formed in a similar way but with their centres at definite distances apart. Formulæ (2) and (3) are also particular cases of (27) and (44).

The resultant mechanical force arising from the mutual electrical actions on the inner sphere must obviously be zero when the spheres are concentric, as there is no reason why it should move in one direction rather than another. We shall prove later on that the equilibrium in this case is unstable, as the inner sphere when displaced tends to move towards the outer one.

We shall now give a few geometrical theorems about inverse spheres as these are a great help in electrical problems of the nature under discussion.

The inverse spheres formed from two given spheres, one enclosing the other.—Let B_0 (Fig. 2) be the centre of the outer sphere, B_1 the centre of the inner sphere, and let b_0 and b_1 be their radii. Draw B_1QR cutting the two spheres in Q and R respectively. Join B_0R and produce B_0B_1 to D_0. Choose a point P on B_1R so that

$$B_1P \cdot B_1R = B_1Q^2 = b_1^2 \qquad (4)$$

Then P is the inverse of R with respect to the sphere whose centre is B_1.

We shall now prove that the locus of P is a sphere

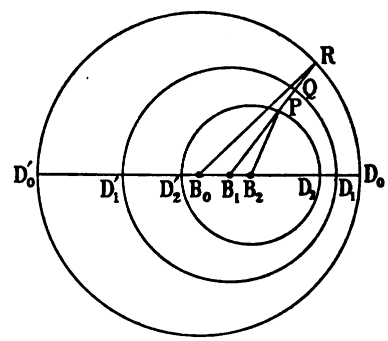

FIG. 2.

$B_1P \cdot B_1R = (B_1Q)^2$. The locus of P is a sphere whose centre is B_2.

of radius $b_0 b_1^2/(b_0^2 - c_1^2)$, where c_1 is the distance B_0B_1 between the centres of the spheres. The centre of this spherical locus is at a point B_2 on B_0B_1 produced, and $B_1B_2 = c_1 b_1^2/(b_0^2 - c_1^2)$.

If the angle PB_1B_2 be θ, we have by trigonometry

$$B_0R^2 = B_1R^2 + B_0B_1^2 + 2B_0B_1 \cdot B_1R \cos\theta$$

and hence $b_0^2 = b_1^4/r^2 + c_1^2 + 2(b_1^2 c_1/r)\cos\theta$

where $B_1P = r$.

Thus $b_0^2 - c_1^2 = b_1^4/r^2 + 2(b_1^2 c_1/r)\cos\theta$

and
$$r^2 = \frac{b_1^4}{b_0^2 - c_1^2} + \frac{2b_1^2 c_1 r\cos\theta}{b_0^2 - c_1^2}$$

and therefore

$$\frac{b_0^2 b_1^4}{(b_0^2 - c_1^2)^2} = r^2 + \frac{c_1^2 b_1^4}{(b_0^2 - c_1^2)^2} - \frac{2b_1^2 c_1 r\cos\theta}{b_0^2 - c_1^2} \qquad (5)$$

In Fig. 2, make $B_1B_2 = \dfrac{c_1 b_1^2}{b_0^2 - c_1^2} = c_2$. Then

$$B_2P^2 = r^2 + c_2^2 - 2rc_2\cos\theta \qquad (6)$$

Comparing (5) and (6) we get

$$B_2P = \frac{b_0 b_1^2}{b_0^2 - c_1^2} = \text{a constant} = b_2 \quad . \quad . \quad (7)$$

and

$$B_1B_2 = \frac{c_1 b_1^2}{b_0^2 - c_1^2} = c_2 \quad . \quad . \quad . \quad . \quad (8)$$

Thus the locus of P is a sphere with its centre at B_2. Since (Fig. 2) $B_1D_0 . B_1D_2 = b_1^2 = B_1D_0' . B_1D_1'$, we get

$$(b_0 - c_1)(b_2 + c_2) = b_1^2 = (b_0 + c_1)(b_2 - c_2) \quad . \quad (9)$$

Similarly we can take the inverse of the sphere D_1D_1' with regard to the sphere D_2D_2'. We shall denote its radius by b_3 and the distance B_2B_3 where B_3 is its centre by c_3. Proceeding in this way we see by (9) that the following relation connects b_n, b_{n-1}, b_{n-2}, c_n and c_{n-1}:

$$(b_{n-2}-c_{n-1})(b_n+c_n)=b_{n-1}^2=(b_{n-2}+c_{n-1})(b_n-c_n) \quad (10)$$

Thus, multiplying out, we get

$$c_n b_{n-2} = b_n c_{n-1} \quad . \quad . \quad . \quad . \quad (11)$$

and hence

$$c_n = \frac{b_n}{b_{n-2}} c_{n-1} = \frac{b_n}{b_{n-2}} \cdot \frac{b_{n-1}}{b_{n-3}} \cdot c_{n-2} = \ldots$$

$$= b_n b_{n-1} \frac{c_1}{b_1 b_0} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (12)$$

From (10) and (11) we also find that

$$b_n b_{n-2} - b_{n-1}^2 = c_n c_{n-1}$$

and from (12)

$$\frac{1}{b_{n-1}^2} - \frac{1}{b_n b_{n-2}} = \left(\frac{c_1}{b_0 b_1}\right)^2 = \text{a constant.}$$

Hence

$$\frac{1}{b_{n-1}^2} - \frac{1}{b_n b_{n-2}} = \frac{1}{b_n^2} - \frac{1}{b_{n+1} b_{n-1}}$$

and

$$\frac{b_n}{b_{n-1}} + \frac{b_n}{b_{n+1}} = \frac{b_{n-1}}{b_{n-2}} + \frac{b_{n-1}}{b_n} = \ldots$$

$$= \frac{b_1}{b_0} + \frac{b_1}{b_2}$$

$$= \frac{b_0^2 + b_1^2 - c_1^2}{b_0 b_1} = \lambda \text{ (say)}$$

Therefore

$$\frac{1}{b_n} = \frac{\lambda}{b_{n-1}} - \frac{1}{b_{n-2}} \quad . \quad . \quad . \quad . \quad (13)$$

By the help of this formula the values of b_3, b_4, ... can be computed very easily in succession.

For example, suppose that $b_0 = 5$, $b_1 = 1$, and $c_1 = 1$. Then we have

$$\lambda = \frac{5^2 + 1^2 - 1^2}{5 \times 1} = 5$$

and thus

$$\frac{1}{b_2} = 5 - \tfrac{1}{5} = 4{\cdot}8, \quad \frac{1}{b_3} = 24 - 1 = 23,$$

$$\frac{1}{b_4} = 5 \times 23 - 4{\cdot}8 = 110{\cdot}2, \quad \frac{1}{b_5} = 551 - 23 = 528, \text{ etc.}$$

Hence, by a table of reciprocals,

$$b_2 = 0{\cdot}2083, \quad b_3 = 0{\cdot}04348,$$
$$b_4 = 0{\cdot}009074, \quad b_5 = 0{\cdot}001894, \text{ etc.}$$

A system of inverse spheres is cut at right angles by another sphere.—Let O (Fig. 3) be the centre of the sphere which cuts the spheres whose centres are B_n and B_{n+1} at right angles. Then if $c_{n+1} = B_nB_{n+1}$, we have

$$c_{n+1} = OB_n - OB_{n+1}$$
$$= \sqrt{(b_n^2 + r^2)} - \sqrt{(b_{n+1}^2 + r^2)} . \quad . \quad (14)$$

where r is the radius of the orthogonal sphere.

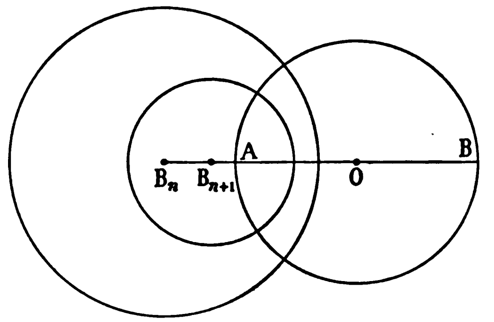

FIG. 3.—The sphere which cuts a given system of inverse spheres at right angles.

Hence by (12)

$$\sqrt{(b_n^2 + r^2)} - \sqrt{(b_{n+1}^2 + r^2)} = \frac{c_1}{b_0 b_1} . b_{n+1} b_n$$

and therefore

$$\sqrt{\left(\frac{1}{b_{n+1}^2} + \frac{r^2}{b_n^2 b_{n+1}^2}\right)} - \sqrt{\left(\frac{1}{b_n^2} + \frac{r^2}{b_n^2 b_{n+1}^2}\right)} = \frac{c_1}{b_0 b_1}$$

The value of the right-hand side of this equation is independent of the value of n. Thus, writing $n + 1$ for n, we get

$$\sqrt{(b_{n+1}^2 + r^2)} - \sqrt{(b_{n+2}^2 + r^2)} = \frac{c_1}{b_1 b_0} b_{n+1} b_{n+2} = c_{n+2} \quad (15)$$

Comparing (14) and (15), we see that r is also the radius of the orthogonal sphere which cuts the spheres whose centres are B_{n+1} and B_{n+2}. Hence it follows that the sphere whose radius is r and whose centre is at O cuts the two original spheres and all the inverse spheres at right angles.

We also have

$$\sqrt{(b_0^2 + r^2)} - \sqrt{(b_1^2 + r^2)} = c_1$$

and therefore

$$2c_1 r = [s(s - b_1)(s - c_1)(b_0 - s)]^{\frac{1}{2}} \quad . \quad . \quad (16)$$

where $2s = b_0 + b_1 + c_1$

The distance of its centre O from B_0 is $(r^2 + b_0^2)^{\frac{1}{2}}$, and the points A and B where it cuts the line of centres are inverse points of all the spheres. The point A gives the limiting position of the system of inverse spheres. We have

$$B_0A = (r^2 + b_0^2)^{\frac{1}{2}} - r$$

The value of B_0B_n.—Let us denote B_0B_n by x_n, then

$$x_n = c_1 + c_2 + \ldots + c_n$$

By (13),
$$1 = \frac{\lambda b_n}{b_{n-1}} - \frac{b_n}{b_{n-2}}$$
$$= \frac{\lambda b_n}{b_{n-1}} - \frac{c_n}{c_{n-1}} \text{ by (11)}$$

Thus
$$\frac{c_n + c_{n-1}}{c_{n-1}} = \lambda \frac{b_n}{b_{n-1}}$$

that is,
$$\frac{x_n - x_{n-2}}{b_n} = \lambda \frac{x_{n-1} - x_{n-2}}{b_{n-1}}$$

and hence by (13),
$$\frac{x_n}{b_n} = \lambda \frac{x_{n-1}}{b_{n-1}} - \frac{x_{n-2}}{b_{n-2}} \quad . \quad . \quad . \quad . \quad (17)$$

To compute the values of x_2, x_3, . . . etc., we first compute b_2, b_3, . . . by (13) and then find x_2, x_3, . . . in succession by (17).

If we put
$$\frac{x_n}{b_n} = \frac{l}{b_n} - \frac{m}{b_{n+1}}$$

where l and m are any constants, we see by (13) that (17) is satisfied. If we now determine l and m so that $x_0 = 0$, and $x_1 = c_1$, x_n will be the required value. Thus

$$0 = \frac{l}{b_0} - \frac{m}{b_1}$$
$$\frac{c_1}{b_1} = \frac{l}{b_1} - \frac{m}{b_2}$$

Thus
$$\frac{x_n}{b_n} = \frac{b_0^2}{c_1 b_n} - \frac{b_0 b_1}{c_1 b_{n+1}}$$

and therefore
$$\frac{b_{n+1}}{b_n} = \frac{b_0 b_1}{b_0^2 - c_1 x_n} \quad . \quad . \quad . \quad (18)$$

Inverse points.—Consider a spherical conductor (Fig. 4) maintained at zero potential and let there be a charge q of electricity at the point Q. Let O be the centre of the sphere and find a point Q′ in OQ such that OQ . OQ′ $= b_0^2$ where b_0 is the radius of the sphere. Take any point P on the sphere and join PO, PQ′ and PQ. Since OQ′/OP = OP/OQ and the triangles POQ and POQ′ have a common angle at O, they are equiangular, and thus

$$\frac{\text{OP}}{\text{PQ}'} = \frac{\text{OQ}}{\text{PQ}}$$

and hence
$$\frac{q}{\text{PQ}} - \frac{q(\text{OP}/\text{OQ})}{\text{PQ}'} = 0$$

Hence, if the spherical conductor were removed, the spherical surface would be the zero equipotential surface of the charges q and $-q$(OP/OQ) placed at Q and Q′ respectively. The electric field outside the spherical conductor is therefore exactly the same as if the conductor were removed and a point charge $-q$(OP/OQ) placed at Q′. From analogy Kelvin called Q′ the electrical image of Q, but it is necessary to remember that this image does not coincide with the optical image. When Q is at infinity, for example, the electrical image is at O, but the optical image would be at the middle point of the radius which lies on OQ. It is perhaps better, therefore, to call the point Q′ the inverse of Q.

Let us suppose that the sphere in Fig. 4 is electrified in some definite manner. Let us denote by $F(x/b_0)$ the

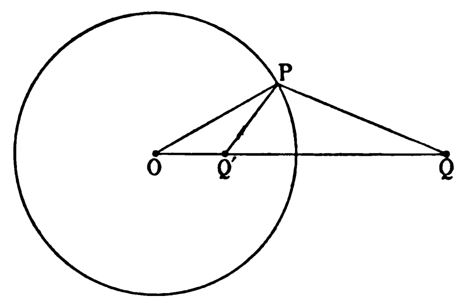

FIG. 4.
OQ . OQ′ = (OP)².

potential at the point Q, where OQ is x. Then if OQ . OQ′ $= b_0^2$, we have

$$F\left(\frac{x}{b_0}\right) = \sum \frac{\partial q}{\text{PQ}}$$

where ∂q is the element of the charge at P. We also have

$$\frac{\text{Q}'\text{P}}{\text{QP}} = \frac{\text{OP}}{\text{OQ}} = \frac{b_0}{x}$$

and hence

$$F\left(\frac{x}{b_0}\right) = \frac{b_0}{x} \sum \frac{\partial q}{\text{Q}'\text{P}} = \frac{b_0}{x} F\left(\frac{\text{OQ}'}{b_0}\right) = \frac{b_0}{x} F\left(\frac{b_0}{x}\right) \quad (19)$$

This relation, due to Poisson, is true for all values of x.

The Capacity of a Spherical Condenser.

Let B_0 (Fig. 5) be the centre of a spherical cavity in a conducting solid, and let B_1 be the centre of a spherical conductor in this cavity. Let $B_0B_1 = c_1$ and let the radii of the spheres be b_0 and b_1. Let the inner sphere have a charge q on its surface. It follows that there will be a charge $-q$ over the surface of the cavity. The potential at a point in the outer conductor at a great distance away from the cavity will be zero, for its distances from the charges $+q$ and $-q$ will be practically the same. Hence every point on the outer conductor must be at zero potential. We shall suppose that the inner conductor is at potential V. Let P

(Fig. 5) be any point on the line RB_0B_1Q inside the sphere whose centre is at B_1, and let $B_0P = x$. Let $F_1(x/b_0)$ be the potential at P produced by the charge $-q$, and let $F_2[(x-c_1)/b_1]$ be the potential at the same point produced by the charge $+q$, where c_1 denotes B_0B_1. Since the outer conductor is at zero potential, we get by considering the potential at any point Q in it on RB_1 produced,

$$F_1\left(\frac{B_0Q}{b_0}\right) + F_2\left(\frac{B_1Q}{b_1}\right) = 0$$

Hence, writing $B_0Q = \xi$, we get by (19)

$$\frac{b_0}{\xi}F_1\left(\frac{b_0}{\xi}\right) + \frac{b_1}{\xi - c_1}F_2\left(\frac{b_1}{\xi - c_1}\right) = 0 \quad . \quad (20)$$

where ξ is greater than b_0 or less than $-b_0$.

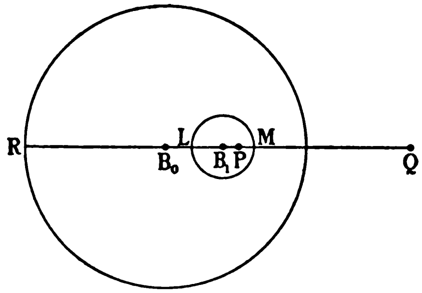

FIG. 5.
$B_0R = b_0$; $B_1M = b_1$; $B_0B_1 = c_1$
$K(b_0, b_1, c_1) = b_1 + b_2 + b_3 + \ldots$

At every point P inside the smaller sphere we have

$$F_1\left(\frac{x}{b_0}\right) + F_2\left(\frac{x - c_1}{b_1}\right) = V \quad . \quad . \quad . \quad (21)$$

where $B_0P = x$, and the values of x lie between $(c_1 - b_1)$ and $(c_1 + b_1)$.

Now consider pairs of points P and Q such that $B_0P \cdot B_0Q = b_0^2$ and so $x/b_0 = b_0/\xi$. Substituting for ξ in (20) we get

$$F_1\left(\frac{x}{b_0}\right) + \frac{b_0b_1}{b_0^2 - c_1x}F_2\left(\frac{b_1x}{b_0^2 - c_1x}\right) = 0$$

Subtracting this equation from (21), we get

$$F_2\left(\frac{x - c_1}{b_1}\right) - \frac{b_0b_1}{b_0^2 - c_1x}F_2\left(\frac{b_1x}{b_0^2 - c_1x}\right) = V \quad . \quad (22)$$

Now putting $x = x_1$, and writing

$$\frac{x_n - c_1}{b_1} = \frac{b_1x_{n-1}}{b_0^2 - c_1x_{n-1}} \quad . \quad . \quad . \quad (23)$$

an equation which enables x_n to be determined in terms of x_1; (22) becomes

$$F_2\left(\frac{x_1 - c_1}{b_1}\right) = V + \frac{b_0b_1}{b_0^2 - c_1x_1}F_2\left(\frac{x_2 - c_1}{b_1}\right)$$

Writing x_2 for x in (22) and substituting in this equation, and then writing x_3 for x, etc., we get

$$F_2\left(\frac{x_1 - c_1}{b_1}\right) = V\left\{1 + \frac{b_0b_1}{b_0^2 - c_1x_1} + \frac{b_0^2b_1^2}{(b_0^2 - c_1x_1)(b_0^2 - c_1x_2)} + \ldots\right\} \quad (24)$$

Since the values of $x_2, x_3, \ldots$ can be found in succession in terms of x_1 by (23), we see that (24) enables us to find the potential at any point on LM (Fig. 5) due to the distribution of the electricity q on its surface.

We have already seen by (18) that if $x_n = B_0B_n$, then

$$x_n = \frac{b_0^2}{c_1} - \frac{b_0b_1}{c_1} \cdot \frac{b_n}{b_{n+1}}$$

It readily follows from (13) that this value of x_n satisfies (23). Hence if we make $x_1 = c_1$, the values of x_n computed by (23) are the same as the values of x_n given by (18).

We have therefore

$$\frac{b_2}{b_1} = \frac{b_0b_1}{b_0^2 - c_1^2}; \quad \frac{b_3}{b_2} = \frac{b_0b_1}{b_0^2 - c_1x_2}; \quad \text{etc.}$$

Thus, substituting in (24), we get

$$F_2(0) = V\left(1 + \frac{b_2}{b_1} + \frac{b_2}{b_1} \cdot \frac{b_3}{b_2} + \frac{b_2}{b_1} \cdot \frac{b_3}{b_2} \cdot \frac{b_4}{b_3} + \ldots\right)$$
$$= \frac{V}{b_1}(b_1 + b_2 + b_3 + \ldots)$$

But the potential $F_2(0)$ at B_1 due to q is obviously q/b_1, since all the charge q is at the same distance b_1 from this point. Hence

$$q = V(b_1 + b_2 + b_3 + \ldots) \quad . \quad . \quad . \quad (25)$$

and since $\quad q = K(b_0, b_1, c_1)(V - 0)$

therefore

$$K(b_0, b_1, c_1) = b_1 + b_2 + b_3 + b_4 + \ldots \quad . \quad (26)$$

We see that the capacity of a spherical condenser equals the radius of the inner surface added to the sum of the radii of all the inverse spheres.

In many cases the formula (26) can be used directly to compute the value of $K(b_0, b_1, c_1)$. As a numerical example, take the case when $b_0 = 8$, $b_1 = 1$ and $c_1 = 3$.

Then $$\lambda = \frac{b_0^2 + b_1^2 - c_1^2}{b_0b_1} = 7$$

And by (13)

$$\frac{1}{b_2} = \frac{\lambda}{b_1} - \frac{1}{b_0} = 7 - \frac{1}{8} = \frac{55}{8}$$

$$\frac{1}{b_3} = \frac{385}{8} - 1 = \frac{377}{8}$$

$$\frac{1}{b_4} = 7 \times \frac{377}{8} - \frac{55}{8} = \frac{2\,584}{8}, \text{ etc., and thus}$$

$b_0 = 8$, $b_1 = 1$, $b_2 = 8/55$, $b_3 = 8/377$, $b_4 = 8/2\,584$, $b_5 = 8/17\,711$, $b_6 = 8/106\,266$, etc.

Thus $K(8, 1, 3)$

$$= 8\left(\frac{1}{8} + \frac{1}{55} + \frac{1}{377} + \frac{1}{2\,584} + \frac{1}{17\,711} + \frac{1}{106\,266} + \ldots\right)$$
$$= 1\cdot 1702993 \ldots$$

which is correct to the last figure.

When λ is small, however, this method is laborious. In this case it is better to proceed as follows. By (26) we have

$$K(b_1, b_2, c_2) = b_2 + b_3 + b_4 + \ldots$$

and thus

$$K(b_0, b_1, c_1) = b_1 + K(b_1, b_2, c_2) \quad . \quad . \quad . \quad . \quad . \quad . \quad (27)$$
$$= b_1 + b_2 + K(b_2, b_3, c_3) \quad . \quad . \quad . \quad . \quad (28)$$
$$= b_2 + \ldots + b_n + K(b_n, b_{n+1}, c_{n+1}) \quad . \quad (29)$$

where by (12) $\qquad c_{n+1} = b_{n+1}b_nc_1/b_0b_1$

For example, using (28) and noticing that

$$K(ma, mb, mc) = mK(a, b, c),$$

we get $K(8, 1, 3) = 1 + \dfrac{8}{55} + \dfrac{8}{55 \times 377}K(377, 55, 3)$

Now the condenser $K(377, 55, 3)$ is approximately concentric and so, noticing that

$$K(377, 55, 0) = 377 \times 55/(377 - 55)$$

we get $\quad K(8, 1, 3) = 1 + 8/55 + 8/322$
$\qquad\qquad\qquad\quad = 1\cdot 1702993$ approximately,

the approximation being true to the last figure. If we had taken $n = 4$ in (29) a much closer approximation would have been obtained.

We can write (27) in the form *

$$K(b_0, b_1, c_1) = b_1 + \frac{b_1^2}{b_0^2 - c_1^2}K\left(\frac{b_0^2 - c_1^2}{b_1}, b_0, c_1\right) \quad (29a)$$

When b_1 is greater than c_1, we also have

$$K(b_0, b_1, c_1) = \frac{b_0^2}{b_1^2 - c_1^2}K\left(b_1, \frac{b_1^2 - c_1^2}{b_0}, c_1\right) - b_0 \quad . \quad (29b)$$

For example, by (29a)

$$K(7, 1, 1) = 1 + \tfrac{1}{48}K(48, 7, 1)$$
$$= 1 + 7/43 \text{ approximately}$$
$$= 1\cdot 163 \text{ approximately}$$

But expanding $K(48, 7, 1)$ in a similar way, we get

$$K(48, 7, 1) = 7 + \tfrac{1}{49}K(329, 48, 1)$$
$$= 7 + 7 \times 48/281$$

and thus

$$K(7, 1, 1) = 1 + 7/48 + 7/281 \text{ very approx.}$$
$$= 1\cdot 170743 \ldots$$

It can be shown that $K(b_0, b_1, c_1)$ is less than

$$b_1 + b_2 + \ldots + b_{n-1} + b_n\left[\frac{1}{2} + \frac{1}{2}\sqrt{\left(\frac{\lambda + 2}{\lambda - 2}\right)}\right] \quad (30)$$

* *Proceedings of the Royal Society*, A, 1920, vol. 97, p. 161.

where $\lambda = (b_0^2 + b_1^2 - c_1^2)/b_0b_1$ and $K(b_0, b_1, c_1)$ is greater than

$$b_1 + b_2 + \ldots + b_{n-1} + \frac{b_nb_{n-1}}{b_{n-1} - b_n} \quad . \quad (31)$$

For example, putting $n = 3$ in (30), we see that $K(8, 1, 3)$ is less than

$$1 + \frac{8}{55} + \frac{8}{377}\left(\frac{1}{2} + \frac{1}{2}\sqrt{\frac{9}{5}}\right)$$

which equals $1\cdot 1702994 \ldots$ but by (31) it is greater than $1\cdot 1702993 \ldots$

The accuracy of (30) and (31) is therefore quite satisfactory.

Equations Connecting the Capacities of Spherical Condensers.

It can be shown that, provided c be greater than 2, we always have

$K(c, 1, 1)$

$$= 1 + \frac{c}{c^2 - 1}K(c^2 - 1, 1, c) + \frac{1}{c^2 - 2}K(c^2 - 2, 1, 1) \quad . \quad (32)$$
$$= 1 + \frac{1}{c^2 - 1}K(c^2 - 1, c, 1)$$

For example, we have

$$K(3, 1, 1) = 1 + \tfrac{3}{8}K(8, 1, 3) + \tfrac{1}{7}K(7, 1, 1)$$
$$= 1\cdot 60611 \ldots$$

Substituting for $K(8, 1, 3)$ and $K(7, 1, 1)$ the values we found previously, we also see that

$$1 + \tfrac{1}{8}K(8, 3, 1) = 1\cdot 60611$$

and thus $\qquad K(8, 3, 1) = 4\cdot 8489$

This can be readily proved by (31).

The Resultant Electric Force on the Inner Sphere.

If W be the electrostatic energy stored in the condenser, we have

$$W = \frac{q^2}{2K(b_0, b_1, c_1)} = \tfrac{1}{2}K(b_0, b_1, c_1)V^2 \quad . \quad (33)$$

where $+\,q$ and $-\,q$ are the charges on the two surfaces and V is the difference of potential between them. It can be shown from (26) that $K(b_0, b_1, c_1)$ always increases as c_1 increases. Consequently if q remains constant W diminishes as the inner sphere approaches the outer one. If, however, V remains constant we see that W increases as c_1 increases. When the inner sphere is insulated, q is constant, and if no external forces are applied to the system we see by the conservation of energy that the resultant electric force acting on it must diminish W. By (33), therefore, $K(b_0, b_1, c_1)$ must increase and so the inner sphere moves towards the outer one.

If F be the force which acts in the direction of c_1

increasing, we have, when the charges are maintained constant,

$$F\partial c_1 = -\partial W$$

and so by (33)

$$F = \frac{q^2}{2[K(b_0, b_1, c_1)]^2}K'(b_0, b_1, c_1) \quad . \quad . \quad (34)$$

where $$K'(b_0, b_1, c_1) = \frac{\partial}{\partial c}[K(b_0, b_1, c_1)]$$

Hence also, by (33),

$$F = \tfrac{1}{2}V^2K'(b_0, b_1, c_1) \quad . \quad . \quad . \quad . \quad (35)$$

These expressions give the magnitude of the force F for any position of the inner sphere, the line of action of the force being the line joining the centres of the spheres.

We have now to show how the numerical value of $K'(b_0, b_1, c_1)$ can be computed. Using (31) and writing $\partial b_n/\partial c_1 = b_n'$, we get

$$K'(b_0, b_1, c_1) = b_2' + b_3' + \ldots + b_{n+1}' + \frac{b_n'/b_n^2 - b_{n-1}'/b_{n-1}^2}{(1/b_n - 1/b_{n-1})^2} \quad . \quad (36)$$

approximately.

The accuracy of the formula is higher the greater the value of n. In practice, not many terms are required and the calculation is not laborious. We first, by means of (13), compute in succession the values of $b_2, b_3 \ldots$

By differentiating (13) we get

$$\frac{b_n'}{b_n^2} = \lambda\frac{b_{n-1}'}{b_{n-1}^2} + \frac{2c_1}{b_0b_1}\cdot\frac{1}{b_{n-1}} - \frac{b_{n-2}'}{b_{n-2}^2} \quad . \quad . \quad (37)$$

Noticing that $b_1'/b_1^2 = 0$ and $b_2'/b_2^2 = 2c_1/b_0b_1^2$, we readily compute in succession $b_2', b_3' \ldots$

Hence by (36) and (34) or (35) we find F.

As an example, suppose that $b_0 = 5$, $b_1 = 1$ and $c_1 = 1$. Then by (31) and (13)

$$\begin{aligned} K(5, 1, 1) &= b_1 + b_2 + \ldots + b_6b_5/(b_6 - b_5) \\ &= 1 + \frac{10}{48} + \frac{1}{23} + \frac{10}{1\,102} + \frac{1}{528} + \frac{5}{10\,009} \\ &= 1\cdot263279 \end{aligned}$$

and thus $q = 1\cdot263279\ V$

By (37) $b_2'/b_2^2 = 2/5$, $b_3'/b_3^2 = 3\cdot92$, $b_4'/b_4^2 = 28\cdot4$, $b_5'/b_5^2 = 182\cdot16$ and $b_6'/b_6^2 = 1\,093\cdot6$.

$$\begin{aligned} \text{Thus } K'(5, 1, 1) &= 0\cdot0173611 + 0\cdot0074102 \\ &\quad + 0\cdot002386 + 0\cdot0006534 \\ &\quad + 0\cdot0002275 \\ &= 0\cdot0279908 \end{aligned}$$

$$\begin{aligned} \text{Hence} \quad F &= 0\cdot0139954V^2 \\ &= 0\cdot00876973q^2 \end{aligned}$$

It must be noticed that the lengths $b_0, b_1, \ldots$ are measured in centimetres and that q and V are in electrostatic units. In this case F is in dynes. If V is in volts, all we have to do is to divide it by 300, so as to reduce it to electrostatic units. Similarly if q is given in coulombs we must multiply its value by 3×10^9. To reduce $K(a, b, c)$ to microfarads we divide by 900 000.

Simplified formulæ.—Putting $n = 3$ in (36), and using (35), we get

$$\frac{F}{V^2} = \frac{c_1b_0b_1^2}{(b_0^2 - c_1^2)^2} + \frac{[(2\lambda - 1)b_0 - b_1]c_1}{[(\lambda^2 - \lambda - 1)b_0 - (\lambda - 1)b_1]^2} \quad (38)$$

Applying this formula to the condenser (5, 1, 1) we get

$$F = 0\cdot013994V^2$$

the error being less than 1 in 10 000.

If V is in volts, we must divide it by 300 before substituting, so as to get F in dynes. The following formula * is sometimes given for $K(b_0, b_1, c_1)$. It is applicable when $c_1/(b_0 - b_1)$ is small.

$$K(b_0, b_1, c_1) = \frac{b_0b_1}{b_0 - b_1}\left\{1 + \frac{b_0b_1}{b_0^2 + b_0b_1 + b_1^2}\cdot\frac{c_1^2}{(b_0 - b_1)^2}\right\} \quad (38a)$$

We deduce by (35) that

$$\frac{F}{V^2} = \frac{b_0^2b_1^2c_1}{(b_0^3 - b_1^3)(b_0 - b_1)^2}$$

These formulæ make $K(5, 1, 1) = 1\cdot2626 \ldots$ and $F/V^2 = 0\cdot01260 \ldots$ The error in the capacity formula is about 6 in 10 000, but in the force formula it is nearly 10 per cent.

When the spheres are at a microscopic distance x apart, we have †

$$F = \frac{b_0b_1V^2}{4(b_0 - b_1)x} \quad . \quad . \quad . \quad . \quad (39)$$

The Maximum and Minimum Potential Gradients at the Surface of the Inner Sphere.

The maximum ($R_{max.}$) and the minimum values of the potential gradients at the surface of the inner sphere occur at the points L and N respectively (Fig. 6) where the line joining the centres of the spheres cuts the inner sphere. The most direct way of getting a series for them is to use Kelvin's method of images.‡ By this method we show that if a series of point charges $q_1, q_2, \ldots q_1', q_2', \ldots$ be placed at the points $B_1, B_2, \ldots B_1', B_2', \ldots$ respectively (Fig. 6), then if the points and charges be properly chosen and the conducting spheres be removed, the electric field produced by these charges will have the original surfaces of the spheres for equipotential surfaces. By choosing the charges properly, we can make the equipotential surface through L at potential V and the one through M at zero potential. These surfaces may become conducting without upsetting the equilibrium of the field. Hence the field produced by the given point charges will be the same as the actual field.

* J. H. Jeans: "Electricity and Magnetism." Also L. Cohen: "Alternating-Current Problems."
† *Proceedings of the Royal Society*, A, 1917–18, vol. 94, p. 215.
‡ A. Russell: "Alternating Currents," vol. 1, p. 236.

The points are connected by the following relations :—

$$B_0B_1 \,.\, B_0B_1' = b_0^2\,;\quad B_1B_1' \,.\, B_1B_2 = b_1^2$$
$$B_0B_2 \,.\, B_0B_2' = b_0^2\,;\quad B_1B_2' \,.\, B_1B_3 = b_1^2$$
$$\cdots\cdots\cdots\cdots$$
$$B_0B_n \,.\, B_0B_n' = b_0^2\,;\quad B_1B_n' \,.\, B_1B_{n+1} = b_1^2 \quad . \quad (40)$$

Thus if $B_0B_n = x_n$, we get by (40)

$$x_n\left(\frac{b_1^2}{x_{n+1} - c_1} + c_1\right) = b_0^2$$

and therefore $\dfrac{x_{n+1} - c_1}{x_n} = \dfrac{b_1^2}{b_0^2 - c_1x_n}$

We see that this equation is the same as (23), and since $x_1 = c_1$, we have

$$x_n = c_1 + c_2 + \ldots + c_n$$

The points B_2, B_3, . . . are therefore the centres of

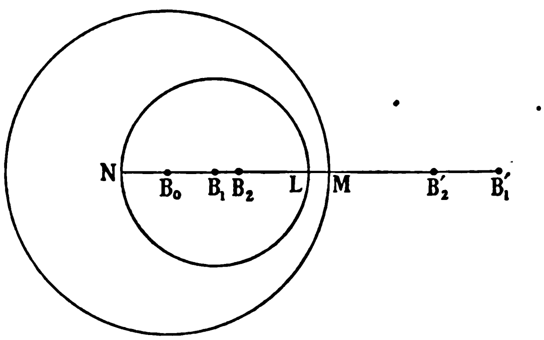

FIG. 6.

The equivalent point charges $q_1, q_2 \ldots q_1', q_2' \ldots$ are placed at $B_1, B_2, \ldots B_1', B_2', \ldots$ where

$$B_0B_1 \,.\, B_0B_1' = b_0^2\,;\quad B_1B_1' \,.\, B_1B_2 = b_1^2$$
$$\frac{q_1}{B_1M} = -\frac{q_1'}{B_1'M}\,;\quad \frac{q_2}{B_2L} = -\frac{q_1'}{B_1'L}$$

the series of inverse spheres previously considered. We also have

$$\frac{b_0b_1}{b_0^2 - c_1x_n} = \frac{x_{n+1} - c_1}{x_n} \cdot \frac{b_0}{b_1} = \frac{b_{n+1}}{b_n} \quad . \quad (41)$$

by (18), where b_n is the radius of the nth inverse sphere.

If we make the charge q_1 at B_1 equal to b_1, the potential of the inner sphere will be unity. To make the potential of the outer one equal to zero, we must place a charge q_1' at B_1', where

$$\frac{q_1}{B_1M} = \frac{-q_1'}{B_1'M}$$

Similarly, to reduce the inner sphere again to unity potential we place a charge q_2 at B_2 and make

$$\frac{q_2}{B_2L} = \frac{-q_1'}{B_1'L}$$

Thus $$\frac{q_2}{q_1} = \frac{B_2L}{B_1'L} \cdot \frac{B_1'M}{B_1M}$$

In general,

$$\frac{q_{n+1}}{q_n} = \frac{B_{n+1}L}{B_n'L} \cdot \frac{B_n'M}{B_nM}$$
$$= \frac{b_1 + c_1 - x_1}{b_1^2/(x_{n+1} - c_1) - b_1} \cdot \frac{(b_0^2/x_n) - b_0}{b_0 - x_n}$$
$$= \frac{x_{n+1} - c_1}{x_n} \cdot \frac{b_0}{b_1}$$
$$= \frac{b_{n+1}}{b_n}, \text{ by (41).}$$

Since $q_1 = b_1$, we see that $q_n = b_n$.

Hence the charges q_1, q_2, . . . are placed at B_1, B_2, . . . the centres of the inverse spheres, and their magnitudes equal b_1, b_2, . . . the radii of these spheres.

We can now write down the value of the maximum potential gradient $R_{max.}$ which occurs at L. We have

$$R_{max.} = \frac{q_1}{B_1L^2} + \frac{q_2}{B_2L^2} + \frac{q_3}{B_3L^2} + \ldots$$
$$- \frac{q_1'}{B_1'L^2} - \frac{q_2'}{B_2'L^2} - \frac{q_3'}{B_3'L^2} - \ldots$$

We also have

$$\frac{q_2}{B_2L} = -\frac{q_1'}{B_1'L},\quad \frac{q_3}{B_3L} = -\frac{q_2'}{B_2'L}, \ldots$$

Thus

$$R_{max.} = \frac{q_1}{b_1^2} + \frac{q_2}{B_2L}\left(\frac{1}{B_2L} + \frac{1}{B_1'L}\right) + \frac{q_3}{B_3L}\left(\frac{1}{B_3L} + \frac{1}{B_2'L}\right) + \ldots$$
$$= \frac{q_1}{b_1^2} + \frac{q_2(b_1 + d_2)}{b_1(b_1 - d_2)^2} + \frac{q_3(b_1 + d_3)}{b_1(b_1 - d_3)^2} + \ldots \quad . \quad (42)$$

where $d_n = x_n - c_1$, so that by (23)

$$\frac{b_1^2}{d_n} = \frac{b_0^2}{d_{n-1} + c_1} - c_1 \quad . \quad . \quad . \quad . \quad (43)$$

If we make $q_1 = Vb_1$, $q_2 = Vb_2$, . . . the potential difference across the spherical condenser will be V. In this case we have

$$R_{max.} = \frac{V}{b_1}\left\{1 + \frac{b_2(b_1 + d_2)}{(b_1 - d_2)^2} + \frac{b_3(b_1 + d_3)}{(b_1 - d_3)^2} + \ldots \right.$$
$$\left. + \frac{b_n(b_1 + d_n)}{(b_1 - d_n)^2} + \ldots\right\} \quad . \quad (44)$$

Similarly for the minimum potential gradient at N, we have

$$R_{min.} = \frac{V}{b_1}\left\{1 + \frac{b_2(b_1 - d_2)}{(b_1 + d_2)^2} + \frac{b_3(b_1 - d_3)}{(b_1 + d_3)^2} + \ldots\right\} \quad (45)$$

The computation of the values of $R_{max.}$ and $R_{min.}$ can be simplified by noticing that the value of d_n increases very slowly with n when n is large. If d be the value of d_n, when d is infinite it will equal B_1A, A being the point where the orthogonal sphere cuts the line B_0B_1 produced. If r be the radius of this sphere,

$$d(d + 2r) = b_1^2$$

and thus

$$d = (b_1^2 + r^2)^{\frac{1}{2}} - r \quad . \quad . \quad . \quad . \quad (46)$$

If X_n denote the remainder of the series given in (44) after n terms, we have

$$X_n = \frac{(b_{n+1} + b_{n+2} + \ldots)(b_1 + d)}{(b_1 - d)^2}$$
$$= \frac{(K - b_1 - \ldots - b_n)(b_1 + d)}{(b_1 - d)^2} \quad . \quad (47)$$

approximately. This approximation makes $R_{max.}$ slightly too great. But if we substitute d_{n+1} for d in (47) the value found will be slightly too small. We thus find limits between which the true value must lie.

Numerical example.—Let us consider the condenser (5, 2, 2). Noticing that $b_0 = 5$, $b_1 = 2$, $c_1 = 2$ we get $\lambda = 5/2$, and thus by (13)

$$b_2 = 20/21,\ b_3 = 8/17,\ b_4 = 80/341,\ b_5 = 32/273$$

and by (43), since $d_1 = 0$, we get

$$d_2 = 8/21,\ d_3 = 8/17,\ d_4 = 168/341,\ d_5 = 136/273$$

and, by (16), $r = 15/4$ and therefore, by (46), $d = \frac{1}{2}$. It will be noticed that there is little difference between d and d_5. It is unnecessary, therefore, to go to high values of n.

Taking $n = 5$, we find by (31) that

$$K = 3 \cdot 891981$$

[If we had used (38*a*) we should have found that $K = 3 \cdot 7132$.]

Hence by (44) and (47) we see that $R_{max.}/V$ is less than

$$\frac{1}{2} + \frac{10}{21} \cdot \frac{(2 + 8/21)}{(2 - 8/21)^2} + \ldots + X_5$$

where $X_5 = 0 \cdot 13023$, and thus $R_{max.}$ is less than $1 \cdot 43998V$. Similarly it is greater than $1 \cdot 43957V$. The true value found by (58) given below is $1 \cdot 43973$. The geometrical method, therefore, is sufficiently accurate for practical work. Similarly we find that $R_{max.}$ lies in value between $0 \cdot 75162V$ and $0 \cdot 75154V$. Its true value is $0 \cdot 75159V$.

Hyperbolic Functions.

Some of the formulæ given previously can be written very conveniently in terms of hyperbolic functions.* We denote the new variables by α, β and ω, and define them as follows:—

$$\cosh \alpha = \frac{b_0^2 + c_1^2 - b_1^2}{2b_0c_1}$$
$$\cosh \beta = \frac{b_0^2 - b_1^2 - c_1^2}{2b_1c_1}$$

and
$$\cosh \omega = \frac{b_0^2 + b_1^2 - c_1^2}{2b_0b_1} = \frac{\lambda}{2}$$

It follows from these equations that $\beta = \alpha + \omega$, $\sinh \alpha = r/b_0$, $\sinh \beta = r/b_1$ and $\sinh \omega = c_1r/b_0b_1$, where r is the radius of the sphere cutting at right angles the spheres and the system of inverse spheres. It then follows from (13) that $b_n = r/\sinh(\alpha + n\omega)$, and thus by (26)

$$K(b_0, b_1, c_1) = \frac{r}{\sinh \beta} + \frac{r}{\sinh(\beta + \omega)} + \frac{r}{\sinh(\beta + 2\omega)} + \ldots \quad . \quad (48)$$

This can also be written in the form,

$$K(b_0, b_1, c_1) = b_1 + \frac{b_0b_1^2}{d^2} + \frac{b_0^2b_1^3}{d^4 - b_1^2c_1^2} + \frac{b_0^3b_1^4}{d^2(d^4 - 2b_1^2c_1^2) - b_0^4c_1^2} + \ldots \quad . \quad (49)$$

where $d^2 = b_0^2 - c_1^2$. As a rule it is less laborious to calculate $b_2, b_3 \ldots$ successively by (13). When, however, the spheres are close together, the following modification of (49) obtained by a method previously described * is useful.

$$K(b_0, b_1, c_1) = b_1 + \frac{b_0b_1^2}{d^2} + \frac{b_0^2b_1^3}{d^4 - b_1^2c_1^2} + \frac{b_0b_1}{c_1}(m + 1)\left\{\frac{1}{nm^3} + \frac{1}{n^3m^7(m^2 + m + 1)} + \frac{1}{n^5m^{11}(m^4 + m^3 + m^2 + m + 1)} + \ldots\right\} \quad (50)$$

where $n = \dfrac{r}{b_1} + \dfrac{\sqrt{(r^2 + b_1^2)}}{b_1}$, $m = \dfrac{b_0n}{c_1 + b_1n}$

$$c_1r = 2\{s(b_0 - s)(s - b_1)(s - c_1)\}^{\frac{1}{2}},$$

and
$$2s = b_0 + b_1 + c_1 \quad . \quad . \quad . \quad . \quad (51)$$

For example, let us suppose that $b_0 = 10$, $b_1 = 1$, and $c_1 = 7$. By (51), $7r = 24$, $n = 7$, and $m = 5$. Thus by (50)

$$K(10, 1, 7) = 1 + \frac{10}{51} + \frac{100}{2\,552} + \frac{12}{1\,225} + \frac{12}{35^4 \times 25 \times 31} + \ldots$$
$$= 1 \cdot 2450593 \ldots$$

It will be seen that the series is rapidly convergent. The capacity in this case can also be readily computed by (29*a*). Thus

$$K(10, 1, 7) = 1 + \tfrac{1}{51}K(51, 10, 7)$$
$$= 1 + \frac{10}{51} + \frac{100}{51 \times 2552}K(2552, 51, 7)$$
$$= 1 \cdot 2450593.$$

When $b_0 - b_1 - c_1$ is very small, so that the spheres are nearly touching, we get

$$K(b_0, b_1, c_1) = \frac{r}{\omega}\left\{-\psi\left(\frac{\beta}{\omega}\right) + \log_e \frac{2}{\omega} + \frac{\omega^2}{72} + \frac{7\omega^4}{43\,200} + \ldots + \frac{\alpha\beta}{12} - \frac{7\alpha^2\beta^2}{1\,440} + \ldots\right\} \quad . \quad (52)$$

* Cf. MAXWELL, vol. 1, § 173; and *Journal I.E.E.*, 1926, vol. 64, p. 240.

* *Proceedings of the Royal Society*, A, 1917–18, vol. 94, p. 108.

where $\psi(x)$ is a function the values of which can be found either by the formulæ or from the table given in Russell's "Alternating Currents," vol. 1, pp. 240 and 241. The values of α, β and ω can be found either from their definitions or by noticing that $\beta = \log_\epsilon n$, $\omega = \log_\epsilon m$ and $\alpha = \beta - \omega$. When $b_1 = c_1$, (52) becomes

$$K(b_0, b_1, b_1) = \frac{r}{\omega}\left\{\gamma + \log_\epsilon \frac{2}{\omega} + \frac{\omega^2}{72} + \frac{7\omega^4}{43\,200} + \dots\right\} - b_0 \quad (52a)$$

where γ is Euler's constant $(0{\cdot}577216\dots)$.

When the distance between the spheres is microscopic we can use the formula *

$$K(b_0, b_1, c_1) = \frac{b_0 b_1}{b_0 - b_1}\left\{\tfrac{1}{2}\log_\epsilon \frac{2b_0 b_1}{(b_0 - b_1)(b_0 - b_1 - c_1)} - \psi\left(\frac{b_0}{b_0 - b_1}\right)\right\} \quad (53)$$

By differentiating (48) we get for the mutual force F,

$$F = \frac{V^2}{2}\left\{\sum_1^\infty n \frac{\cosh(\beta + n\omega)}{\sinh^2(\beta + n\omega)} - \frac{\cosh\alpha\cosh\beta}{\sinh\omega}\sum_0^\infty \frac{1}{\sinh(\beta + n\omega)} + \frac{\sinh\beta\cosh\alpha}{\sinh\omega}\sum_0^\infty \frac{\cosh(\beta + n\omega)}{\sinh^2(\beta + n\omega)}\right\} \quad . \quad (54)$$

and this can be put into forms more suitable for computation in special cases.

Noticing that $b_n = \dfrac{r}{\sinh(\alpha + n\omega)}$

and that $d_n = \dfrac{b_1 \sinh(n-1)\omega}{\sinh(\alpha + n\omega)}$

(44) and (45) become

$$R_{max.} = \frac{V}{b_1}\left(\frac{\cosh^2 \frac{1}{2}\beta}{\sinh \frac{1}{2}\beta}\right)\left[\frac{\sinh\frac{1}{2}\beta}{\cosh^2\frac{1}{2}\beta} + \frac{\sinh(\frac{1}{2}\beta + \omega)}{\cosh^2(\frac{1}{2}\beta + \omega)} + \frac{\sinh(\frac{1}{2}\beta + 2\omega)}{\cosh^2(\frac{1}{2}\beta + 2\omega)} + \dots\right] \quad . \quad (55)$$

and

$$R_{min.} = \frac{V}{b_1}\left(\frac{\sinh^2 \frac{1}{2}\beta}{\cosh \frac{1}{2}\beta}\right)\left[\frac{\cosh\frac{1}{2}\beta}{\sinh^2\frac{1}{2}\beta} + \frac{\cosh(\frac{1}{2}\beta + \omega)}{\sinh^2(\frac{1}{2}\beta + \omega)} + \frac{\cosh(\frac{1}{2}\beta + 2\omega)}{\sinh^2(\frac{1}{2}\beta + 2\omega)} + \dots\right] \quad . \quad (56)$$

* *Proceedings of the Royal Society*, A, 1917–18, vol. 94, p. 212.

The following series deducible from (55) and (56), although they look clumsy, are rapidly convergent and are suitable for computing purposes even when the spheres are very near one another.

$$R_{max.} = \frac{V}{b_1}\left\{1 + \frac{b_0 b_1[b_0^2 - c_1(c_1 - b_1)]}{[b_0^2 - c_1(c_1 + b_1)]^2} + \epsilon^{-\omega}\frac{(1 + \epsilon^{-\beta})^2}{1 - \epsilon^{-\beta}}\left[\frac{\epsilon^{-\omega}}{1 - \epsilon^{-\omega}} - 3\frac{\epsilon^{-3\omega}}{1 - \epsilon^{-3\omega}}\epsilon^{-(\beta+2\omega)} + 5\frac{\epsilon^{-5\omega}}{1 - \epsilon^{-5\omega}}\epsilon^{-2(\beta+2\omega)} - \dots\right]\right\} \quad . \quad . \quad . \quad (57)$$

and

$$R_{min.} = \frac{V}{b_1}\left\{1 + \frac{b_0 b_1[b_1^2 - c_1(c_1 + b_1)]}{[b_0^2 - c_1(c_1 - b_1)]^2} + \epsilon^{-\omega}\frac{(1 - \epsilon^{-\beta})^2}{1 + \epsilon^{-\beta}}\left[\frac{\epsilon^{-\omega}}{1 - \epsilon^{-\omega}} + 3\frac{\epsilon^{-3\omega}}{1 - \epsilon^{-3\omega}}\epsilon^{-(\beta+2\omega)} + 5\frac{\epsilon^{-5\omega}}{1 - \epsilon^{-5\omega}}\epsilon^{-2(\beta+2\omega)} + \dots\right]\right\} \quad . \quad . \quad . \quad (58)$$

where $\epsilon^{-\beta} = \cosh\beta - \sinh\beta = \left(1 + \dfrac{r^2}{b_1^2}\right)^{\frac{1}{2}} - \dfrac{r}{b_1}$

and $\epsilon^{-\omega} = \left(1 + \dfrac{c_1^2 r^2}{b_0^2 b_1^2}\right)^{\frac{1}{2}} - \dfrac{c_1 r}{b_0 b_1}$

As an example, consider the condenser (5, 2, 2). In this case $\epsilon^{-\omega} = \frac{1}{2}$, $\epsilon^{-\beta} = \frac{1}{4}$, and so, substituting in (57), we get

$$\begin{aligned} R_{max.} &= \frac{V}{2}[1 + 0{\cdot}8650520 + \tfrac{25}{24}(1 - 0{\cdot}0267857 \\ &\qquad + 0{\cdot}0006301 - 0{\cdot}0000135 \\ &\qquad + 0{\cdot}0000003 - \dots)] \\ &= 1{\cdot}4397297V \end{aligned}$$

If we write x for $b_0 - b_1 - c_1$ and neglect cubes and higher powers of $c_1/(b_0 - b_1)$, we find, after laborious algebraical work, that

$$R_{max.} = \left\{1 + \frac{(2b_0 + b_1)x}{3b_0 b_1} + \frac{[4(b_0 + b_1)^2 - b_0 b_1]x^2}{45 b_0^2 b_1^2}\right\}\frac{V}{x} \quad (59)$$

As an example, let $b_0 = 5$, $b_1 = 2$, $c_1 = 2$, so that $x = 1$, and $c_1/(b_1 - b_0) = \frac{1}{3}$.

In this case $R_{max.} = 1{\cdot}4413V$.

Comparing with the true value found above, we see that although $c_1/(b_1 - b_0)$ is as great as $\frac{1}{3}$, the error introduced by using (59) is only about 1 in 704. For smaller values of x the accuracy is much higher.

A METHOD OF OBSERVING FLAWS IN METAL SURFACES AND OF COMPARING THE CONDUCTIVITIES OF METAL PLATES.*

By Professor E. W. Marchant, D.Sc., Member, and J. L. Miller, B.Eng., Student.

(Paper first received 2nd December, and in final form 14th December, 1925.)

Summary.

This paper describes an apparatus which has been developed for observing, by a direct deflection method, small changes in the effective resistance and inductance of a coil. It consists of a bridge network, with two inductive arms, which is normally balanced. The bridge is supplied with alternating currents, the indicating instrument being a d.c. galvanometer connected through a synchronously driven commutator. One of the arms of the bridge contains the "exploring" coil, which is placed on the metal surface to be examined. It is shown that if the commutator is so adjusted as to indicate the current in phase with the applied voltage, its deflection is proportional to the change in effective resistance of the exploring coil. With the commutator adjusted to observe currents 90° out of phase with the applied voltage, the deflection depends on the change in effective inductance of the coil, when this change is brought about by the presence of a metal plate. For non-magnetic materials it is best to use the commutator in the "out of phase" position. The change in effective inductance depends on the specific conductivity of the plate, and the apparatus may be used for quickly comparing the specific conductivities of metal plates. If such plates have cracks normal to the surface, their presence is indicated by a reduction in the galvanometer deflection as the coil passes over a crack. For magnetic materials the commutator should be set in the "in phase" position. Cracks in magnetic materials can be observed in the same way as those in non-magnetic materials.

Table of Contents.

(1) Principle of Action of the Apparatus.

When a coil of wire, through which an alternating current is flowing, is brought near a piece of metal, currents are induced in the metal which have the effect of producing an apparent increase in the impedance of the primary coil, the change in the impedance being a function of the resistance offered by the metal to the induced secondary currents.† The resistance offered to the induced secondary currents depends on the conductivity and thickness of the metal plate, and if the change in effective resistance or inductance of the coil is measured, the change in resistance or inductance will enable the conductivity of the metal plate to be estimated for a given size and shape of coil.

The apparatus is arranged as follows: The coil, which will, throughout the paper, be called the "exploring coil," is so connected as to form one arm of an ordinary Wheatstone bridge network, of which a coil, having the same resistance and inductance as the exploring coil, forms the third arm. The "proportional" arms are non-inductive resistances, and are made equal to each other. The two inductive arms are also made as nearly similar to each other as possible. The bridge is supplied with constant frequency alternating current at constant voltage, and is balanced approximately.

When the exploring coil is placed on a metal plate, its effective impedance is altered, and thus the balance of the bridge is disturbed; a current depending on the total impedance change therefore flows through the galvanometer circuit.

In Fig. 1 (*a*) is shown the diagram of connections. BD is the exploring coil, whose resistance and inductance are respectively R_4 and L_4, AD being an exactly similar coil. CB and CA are the two non-inductive resistances which form the proportional arms.

A small alternator or rotary converter is connected across CD and supplies the bridge with the necessary alternating current. A galvanometer is connected across AB, the connection being made through a two-part commutator driven synchronously by an extension of the shaft of the alternator.

If the brush gear is rocked round the commutator, there is one position where the rectified current is in phase with the impressed voltage, and another position 90 electrical degrees removed from the former, where the rectified current is 90° out of phase with the impressed voltage, and it will be shown later mathematically that in the former position the deflection of the galvanometer is proportional to the change in effective resistance of the coil, and is in the latter position proportional to the change in effective inductance of the coil. As already explained, if a metal plate is brought near to the coil R_4 L_4 there is a deflection of the galvanometer, which is proportional to the effective resistance or inductance change, according to the position in which the brush rocker may be. If the brush rocker is set in such a position that the deflection of the galvanometer is due to change in effective resistance only, and the resistance of one of the arms is altered by a

* The Papers Committee invite written communications (with a view to publication in the *Journal* if approved by the Committee) on papers published in the *Journal* without being read at a meeting. Communications should reach the Secretary of the Institution not later than one month after publication of the paper to which they relate.

known amount and the galvanometer deflection observed, then the effective resistance-change for a known galvanometer deflection is determined. In the same way, by inserting a known, small inductance in one of the arms, the change in effective inductance of the coil corresponding to a given galvanometer deflection can be determined with the brushes in the out-of-phase position. By means of this calibration the change in effective resistance or inductance of the exploring coil under any conditions can be measured.

The apparatus under consideration is not only suitable for measuring the change in effective resistance or inductance of a coil due to the presence of a metal plate, but can readily be used to detect flaws and cracks in the plate, since the slightest crack in the metal is sufficient to put a very high resistance in the path of the induced secondary currents in the material of which the plate is made, hence causing a change in the balance of the bridge.

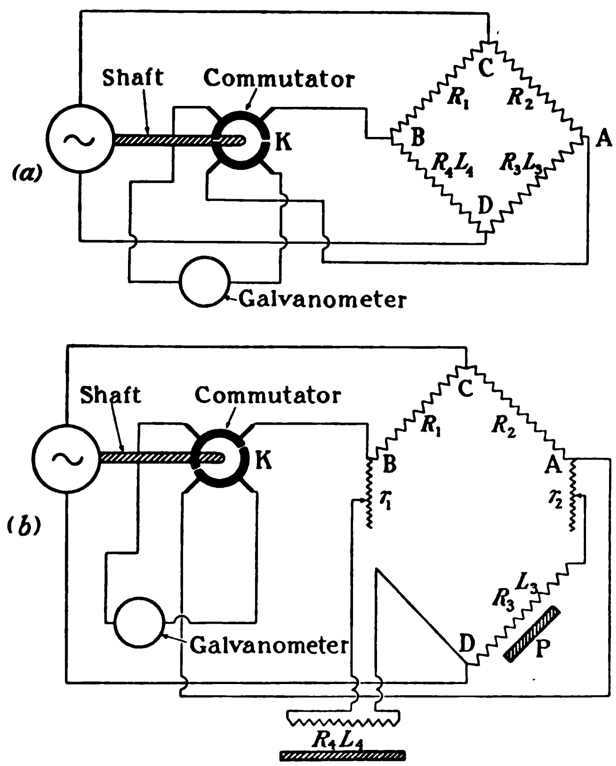

FIG. 1.—Diagram of connections.

(2) DESIGN AND METHOD OF USE OF APPARATUS.

(*a*) *Early form of apparatus.*—In Fig. 1 (*b*) is shown the actual connection of the early form of the apparatus. K is the two-part commutator driven synchronously from the shaft of a 4-pole rotary converter. The rotary converter is separately excited, and when so arranged both its speed and voltage can be readily controlled. R_1 and R_2 are the two non-inductive resistances each of about 10 ohms resistance, while L_3, R_3, and L_4, R_4, are the two inductive resistances, also of about 10 ohms resistance.

In series with L_3, R_3, and L_4, R_4, are the two sets of adjustable resistances r_1 and r_2 which were used to balance the bridge. For fine adjustment, a metal plate P could be brought near the coil L_3, R_3, thus altering its effective impedance and providing a very simple method of controlling the zero of the galvanometer. The exploring coil R_4, L_4, was connected to the bridge by a length of flexible cable. Fig. 2 shows the arrangement actually used in the early tests with the commutator.

The "radial arm" variable resistances used for balancing purposes are shown as r_1 and r_2, and P is the adjustable metal plate. The letters in Fig. 2 correspond to those in Fig. 1. The three bridge arms,

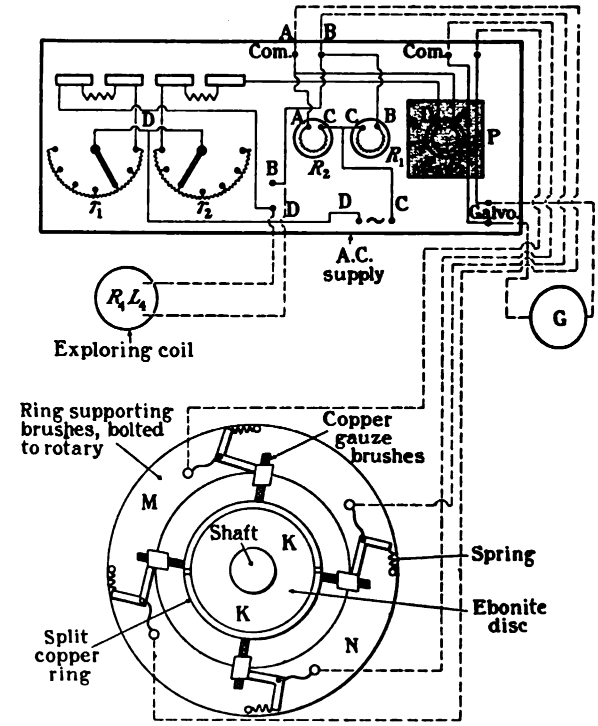

FIG. 2.

with the exception of L_4, R_4, were housed in a wooden box with terminals on the top, and connections were made to the rotary and commutator as shown. Originally the resistances AC and CB were made of manganin wire wound on a wooden bobbin and fixed in a wooden case. Each separate coil in the adjustable arms r_1 and r_2 had a resistance of approximately 0·01 ohm, and these were used both for balancing and for calibration purposes. Copper gauze brushes were used and these were fixed to an ebonite ring MN (see Fig. 2) which was screwed to an iron ring by means of bolts in slots, so allowing the brush gear to be rocked. The iron ring was fixed rigidly to the converter. The brush pressure was adjusted by means of small springs.

The apparatus as described above was fairly satisfactory, and readings could be obtained if great care was taken in adjusting the brush gear.

There were, however, many drawbacks, the chief of which were :—

(1) Gradual creep of the zero of the galvanometer, due to heating of the coils.
(2) Variation in the contact resistance of the variable resistances r_1 and r_2.
(3) Owing to lack of rigidity of the brushes, it was difficult to keep them in their correct relative position.

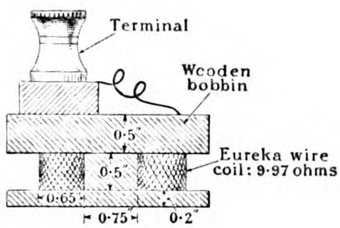

FIG. 2A.

(4) It was difficult to equalize the spring pressures of the brushes, and the pressures required were great enough to cause heating at the commutator surface and the development of thermo-E.M.F.'s.

(*b*) *Final form of apparatus.*—The above difficulties were overcome as follows :—

(1) Rewinding all the coils with No. 20 S.W.G. Eureka wire, each coil having a resistance of 9·97 ohms. The exploring coil is shown in section in Fig. 2A.

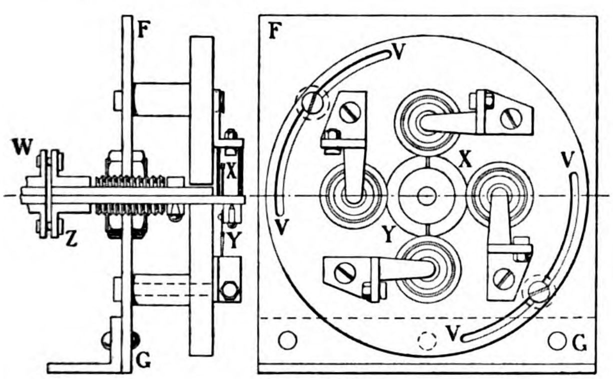

FIG. 3.

(2) Cutting out the regulating resistances and so doing away with the rubbing contacts. A small portion of r_1, however, was retained in order to obtain a balance, the connection to r_1 being made direct and not through a rubbing contact.
(3 and 4) were overcome by changing the design of the commutator.

The arrangement adopted is shown in Fig. 3. XY is the two-part commutator, mounted on an ebonite disc. The diameter of the commutator is considerably less than in the case of the one previously used, thus reducing the peripheral speed at the brush surface. The commutator, as before, is mounted on an extension of the shaft of the rotary converter, and is driven through a flexible coupling WZ. The brushes consisted of thin copper flexible discs.

It will be seen that the roller brushes * make contact with both faces of the commutator disc, and this, coupled with the fact that the roller brushes themselves had a great deal of "spring," ensured a very good surface contact, without the danger of any slipping between the revolving brush and the commutator disc. The roller brushes themselves were very light, and as their bearings were very thin steel spindles, no trouble was experienced with friction or heating at the roller brush bearings. These brushes ran for many hours faultlessly, it only being necessary occasionally to oil the bearings and contact surfaces and to make the contact between the brushes and the commutator disc greater as the brushes lost their "springiness."

It was only after a very considerable time that the brushes had to be replaced by new ones. No trouble

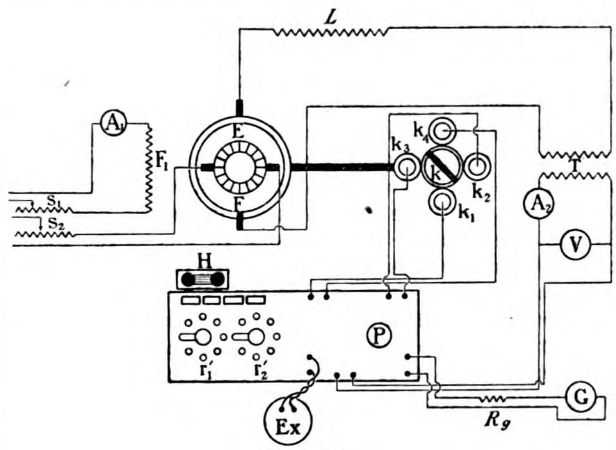

FIG. 4.

was caused due to thermo-E.M.F.'s. The mountings for the roller brushes were fixed to a large ebonite circular plate, which was attached to the main support GF by means of screws running in slots VV, so allowing the brushes to be rocked relative to the commutator. In this way it was possible to control the phase of the commutated current.

To enable the apparatus to be calibrated, a resistance of known magnitude and composed of Eureka wire was put in series with the coil DA. It was connected to the circuit through two mercury cups which were short-circuited by a thick copper strip when the resistance was removed (see H, Fig. 4).

The final diagram of connections is shown in Fig. 4. It will be seen that the supply from the converter to the bridge is made through a transformer, thus insulating the converter from the network.

A choking coil L is placed in series with the transformer in order to vary the value of the current.

The galvanometer previously used was a sensitive pointer unipivot type, but this was replaced by a reflecting galvanometer for most of the tests. In series with this galvanometer was placed a resistance of

* These brushes were kindly supplied by Mr. S. Evershed, and were similar to those used in the early form of ohmmeter.

400 ohms, and variations in the contact resistance of the roller brushes had consequently less effect on the galvanometer deflection than when the only resistance in the galvanometer circuit was the resistance of the galvanometer itself.

(c) *Method of using the apparatus.*—For most of the tests the speed of the 4-pole rotary converter was 1 500 r.p.m., so that the frequency was 50 cycles per second. Above this speed, vibration was considerable and difficulty was experienced with the brush contacts on the commutator. Some results were obtained, however, with a frequency as high as 66⅔ cycles per second. The effective change in resistance or inductance of the coil is dependent on the frequency of the supply—the lower the frequency, the smaller the effective change. When running at low speeds, therefore, the deflection of the galvanometer is smaller. In some later experiments it was found, however, that a speed to give about 35 cycles per second was quite sufficient to enable a large galvanometer deflection to be obtained, while at this speed the wear and tear on the brush gear is much less. It would appear, therefore, that a speed of 1 000 r.p.m. with a 4-pole machine would be the most suitable for ordinary testing.

In carrying out the tests the deflection of the galvanometer was brought near zero by means of the metal adjusting plate, and the exploring coil was then placed on the plate and the galvanometer deflection observed. In the later stages of the work it was never found necessary to alter the zero after it had once been set.

When working the apparatus there are usually only two positions in which the brushes on the commutator will be placed, i.e. the position corresponding to a measurement of effective resistance change, and the position corresponding to a measurement of effective inductance change. There are three methods available for determining these two brush positions. In the description of the apparatus it was stated that, in order to obtain a calibration, there was, in series with the coil DA, a resistance of known magnitude, the resistance being connected to two mercury cups, so that it could be put in circuit or taken out by short-circuiting the cups. Now if i_g * and i_g' represent the two components of the galvanometer current, i_g being the in-phase component, then it is shown in the Appendix that

$$i_g = K\delta R$$
$$i_g' = K'\delta L\omega$$

where δR and $\delta L\omega$ are the changes in effective resistance and inductance respectively and K and K are constants.

If the brushes are in such a position that i_g' is being commutated, there will be no current in the galvanometer circuit when the known resistance is put in or taken out of circuit. If the brushes are in the position where i_g is being commutated, the insertion of the known resistance will cause the galvanometer current to reach a maximum.

Actually, the position which gives no deflection for resistance-change was found as described above, and then the brush gear was rocked round 90 electrical degrees. It was found that in this position the insertion or removal of the known resistance gave the maximum deflection of the galvanometer.

* See Appendix.

As a further check, oscillograms were taken of the rectified wave of current when one pair of brushes was connected to the a.c. supply and the other side to the oscillograph, the brush gear being in the position corresponding to maximum resistance-change. It was found that in this position the commutator gave "complete" rectification.

The three methods of obtaining the positions of maximum deflection for resistance-change, therefore, give consistent results. From the oscillograms it would appear that any slight errors in obtaining the position in which it is desired to work would not have very great bearing on the accuracy of the results. This is borne out by the fact that the curve connecting the deflection of the galvanometer and the brush setting is very flat near the position of maximum effective resistance-change.* The actual values of the components of the galvanometer current in phase (i_g) and 90° out of phase (i_g') with the applied potential difference are given by

$$i_g = \frac{E\delta R}{4R_1R_g}$$

and

$$i_g' = \frac{EL_3\omega}{4R_1R_g}\left(\frac{\delta L\omega}{L_3\omega} - \frac{\delta R}{R_1}\right)$$

where the resistances of three of the arms of the bridge are each assumed to be equal to R_1 (the resistance of the fourth arm being $R_1 + \delta R$), the galvanometer resistance $= R_g$, and the applied P.D. $= E$.

The reactance of one inductive arm of the bridge is $L_3\omega$ and of the other inductive arm $L_3\omega + \delta L\omega$.

δR and $\delta L\omega$ are the changes in resistance and reactance of the exploring coil (the fourth arm) when a metal plate is brought near to it. For this apparatus it may be shown that $\delta L\omega/(L_3\omega)$ is about 100 times as great as $\delta R/R_1$, and, therefore, that i_g' is very nearly equal to $E\delta L\omega/(4R_1R_g)$.

(3) Some Experimental Results.

The apparatus was used to determine:—

(a) The change in effective resistance of the exploring coil due to metal plates of different thicknesses.
(b) The change in effective resistance of the exploring coil due to metal plates of different thicknesses at different distances from the exploring coil.
(c) The effect of change in frequency of the supply on the effective change in resistance of the coil when brought near to metal plates of different thickness.
(d) The change in effective inductance of the exploring coil due to metal plates of different thicknesses.

(a) *The change in effective resistance of the exploring coil due to metal plates of different thicknesses.*—This series of tests was carried out on copper, brass and zinc plates, varying in thickness from 0·0625 in. to 1 in., the frequency of supply to the bridge being

* The theory of the bridge network is given in an Appendix.

50 cycles per second, and the supply voltage being 4·3 volts. The distance of the base of the coil from the plates was 0·1 in. The results obtained are shown in Table 1.

1·0	11·7	7·8	9·1

In Fig. 5, which has been plotted from Table 1, is shown the relationship between the deflection of the galvanometer (which is proportional to the change in

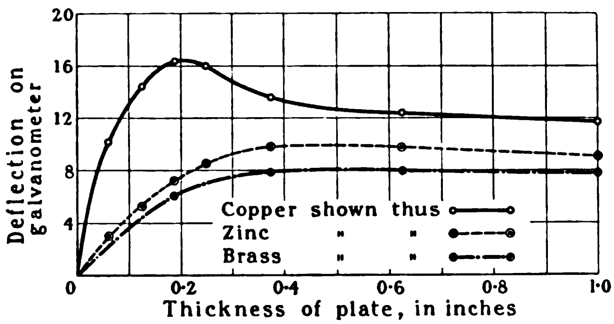

FIG. 5.

effective resistance of the exploring coil) and the thickness of the plate.

With the type of flux distribution set up by the coil shown in Fig. 2A, the equations of the curves in Fig. 5 are of the form

mercial copper and electrolytic copper plates, each plate being $\frac{1}{8}$ in. thick.

(*b*) *The change in effective resistance of the exploring coil due to metal plates of different thicknesses at different distances from the exploring coil.*—In Table 3 are shown

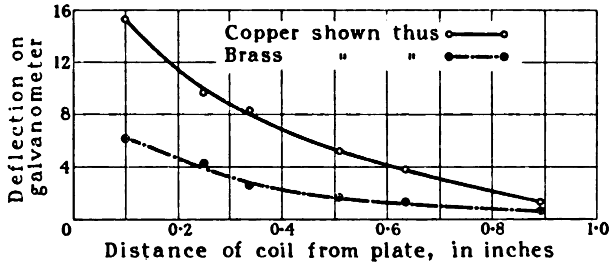

FIG. 6.

the experimentally determined values of the deflection of the galvanometer with the exploring coil at different distances from the plate. The tests were carried out at 50 cycles per second and with an applied voltage of 4·3.

The results are plotted in Fig. 6.

TABLE 2.

(*c*) *The effect of change in frequency of the supply on the effective change in resistance of the coil when brought near to metal plates of different thicknesses.*—The experiments were carried out at three different frequencies, viz. 66⅔, 50, and 30 cycles per second. The distance of the coil from the plates was 0·218 in. The results are shown in Table 4, from which Fig. 7 has been plotted.

It will be seen that the deflections are approximately proportional to the square of the frequency.

$$\delta R = kL_3 w\left\{\frac{2\cosh\lambda Kh + \lambda\sinh\lambda Kh - 2\cos\nu Kh + \nu\sin\nu Kh}{\lambda^2(1+\frac{1}{4}\lambda^2)\cosh\lambda Kh + \lambda^3\sinh\lambda Kh + \nu^2(1-\frac{1}{4}\nu^2)\cos\nu Kh - \nu^3\sin\nu Kh}\right\}$$

where δR = change in effective resistance of the coil,
h = thickness of plate,

and where λ, ν, K and k are constants depending on the specific resistance of the plate, the frequency of the supply, the distance of the coil from the plate, and the nature of the flux distribution due to the coil. The curves rise very rapidly at first, reach a maximum, and then approach an asymptote, the change in effective resistance of the coil becoming independent of the thickness of the metal. The difference in deflection, however, with very thick plates of widely different specific resistances is relatively small. With thin plates the difference between the deflections observed with materials of different specific resistances is much greater. In Table 2 are shown results obtained with zinc, com-

It can be shown mathematically that the shapes of these curves are given by

$$\delta L\omega = -L_3 \omega k \left\{ \frac{k \cosh \lambda K h + \nu \sinh \lambda K h - k \cos \nu K h - \lambda \sin \nu K h}{\lambda^2 (1 + \frac{1}{4}\lambda^2) \cosh \lambda K h + \lambda^3 \sinh \lambda K h + \nu^2 (1 - \frac{1}{4}\nu^2) \cos \nu K h - \nu^3 \sin \nu K h} \right\}$$

where $\delta L\omega$ is the change in inductance, h is the thickness of plate, and λ, ν, K and k are constants depending on the specific resistance, frequency, distance of the coil from the plate and the nature of the flux distribution due to the coil.

These curves do not reach a maximum in the same way as the resistance curves, but rise continuously to an asymptotic value for very thick plates. The ratio between the deflections for different materials with very thick plates is much greater than when observing changes in effective resistance and is approximately proportional to the square root of the specific conductivity.

The measurement of inductance-change, therefore, is suitable for comparing the conductivity of non-magnetic metals, and, provided the plate is more than ½ in. thick, the deflection is almost independent of the thickness of the plate.

With the brushes in the out-of-phase position, the

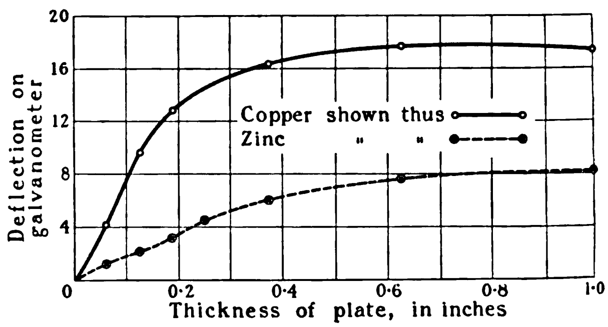

FIG. 8.

apparatus provides a quick and easy method of comparing the conductivities of metal plates. It may, for example, be used for testing whether copper sheet or brass sheet is of uniform quality, and, provided the thickness of the plates is known, it will enable the specific conductivities to be compared directly, but if plates of different thicknesses are to be compared, provided the thickness is less than ½ in., it will be necessary to use a correction factor if accurate results are to be obtained. If a plate of material has a crack or other defect in the surface, this is at once indicated if the coil is moved over the surface of the plate, by a reduction in the deflection of the indicating instrument. Copper plates have been cracked and put together again so as to be practically continuous, but the presence of the cracks is always shown, the deflection of the instrument falling almost to zero when the area containing the crack is passed over. If the apparatus is to be used for testing magnetic materials, it will be necessary to use it in the "in phase" position, otherwise the change of inductance due to the presence of the magnetic material will be observed. If, however, the coil is brought near to an iron plate, eddy currents which change its effective resistance are induced in it, and the presence of a crack in the surface is at once shown in the deflection of the galvanometer.

Another possible application of the apparatus is in testing the electrical conductivity of welded rails. If the electrical circuit between the rails is sound, this would be indicated by a steady deflection of the galvanometer if a suitably shaped coil is passed over the joint, whereas if any crack is present it is indicated by a change in the deflection of the instrument.

APPENDIX.

Theory of the Bridge Network.

CB and CA are the two non-inductive coils of resistance R_1 and R_2, forming the "proportional arms." BD and AD are the two "ratio arms," whose resist-

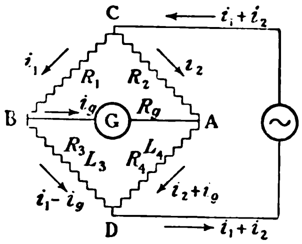

Fig. 9.

ances and inductances are R_3, L_3, and R_4, L_4, respectively. In Fig. 9 are shown the instantaneous values of the currents.

If current $i_1 = i_1 + ji_1'$ and current $i_2 = i_2 + ji_2'$

then P.D. from C to B $= R_1(i_1 + ji_1')$

and P.D. from C to A $= R_2(i_2 + ji_2')$

$$\therefore\ i_g = \frac{R_1(i_1 + ji') - R_2(i_2 + ji_2')}{R_g}$$

(*Continued at top of next column.*)

where R_g = total resistance in galvanometer circuit, or

$$i_g = \frac{R_1 i_1 - R_2 i_2}{R_g} + j\left\{\frac{(R_1 i_1' - R_2 i_2')}{R_g}\right\}$$

If $i_g = i_g + ji_g'$, then

$$i_g = \frac{R_1 i_1 - R_2 i_2}{R_g} \quad \text{and} \quad i_g' = \frac{R_1 i_1' - R_2 i_2'}{R_g}$$

As $R_1 = R_2$

$$i_g = \frac{R_1}{R_g}(i_1 - i_2) \quad . \quad . \quad . \quad . \quad . \quad . \quad (1)$$

and

$$i_g' = \frac{R_1}{R_g}(i_1' - i_2') \quad . \quad . \quad . \quad . \quad . \quad . \quad (2)$$

P.D. between B and D

$$= \{(i_1 - i_g) + j(i_1' - i_g')\}\{R_3 + jL_3\omega\}$$

P.D. between A and D

$$= \{(i_2 + i_g) + j(i_2' = i_g')\}\{R_4 + jL_4\omega\}$$

Now P.D. in CBD = P.D. in CAD

$$\therefore\ R_1(i_1 + ji_1') + \{(i_1 - i_g) + j(i_1' - i_g')\}\{R_3 + jL_3\omega\}$$
$$= R_2(i_2 + ji_2') + \{(i_2 + i_g) + j(i_2' + i_g')\}\{R_4 + jL_4\omega\}$$
$$= E + jE'$$

where $E + jE'$ is the applied P.D.

Equating real and unreal parts, taking $E' = 0$, then

$$(R_1 + R_3)i_1' + L_3\omega i_1 - R_3 i_g' - L_3\omega i_g = 0 \quad . \quad (3)$$
$$(R_1 + R_3)i_1 - L_3\omega i_1' - R_3 i_g + L_3\omega i_g' = E \quad . \quad (4)$$
$$L_4\omega i_2 + (R_2 + R_4)i_2' + L_4\omega i_g + R_4 i_g' = 0 \quad . \quad (5)$$
$$(R_2 + R_4)i_2 - L_4\omega i_2' + R_4 i_g - L_4\omega i_g' = E \quad . \quad (6)$$

Eliminating i_1, i_2, i_1', i_2' from equations (1), (2), (3), (4), (5) and (6), then

$$i_g\left[1 - \frac{R_1\{R_3^2 + R_1R_3 + L_3\omega^2\}}{R_g\{(R_1 + R_3)^2 + L_3\omega^2\}} - \frac{R_1\{R_4^2 + R_2R_4 + L_4\omega^2\}}{R_g\{(R_2 + R_4)^2 + L_4\omega^2\}}\right]$$
$$= \frac{ER_1}{R_g}\left[\frac{R_1 + R_3}{\{(R_1 + R_3)^2 + L_3\omega^2\}} - \frac{R_2 + R_4}{\{(R_2 + R_4)^2 + L_4\omega^2\}}\right] - i_g'\left[\frac{R_1^2 L_3\omega}{\{(R_1 + R_3)^2 + L_3\omega^2\}R_g} + \frac{R_1R_2L_4\omega}{R_g\{(R_2 + R_4)^2 + L_4\omega^2\}}\right]$$

and

$$i_g'\left[1 - \frac{R_1\{R_3^2 + R_1R_3 + L_3\omega^2\}}{R_g\{(R_1 + R_3)^2 + L_3\omega^2\}} - \frac{R_1\{R_4^2 + R_2R_4 + L_4\omega^2\}}{R_g\{(R_2 + R_4)^2 + L_4\omega^2\}}\right]$$
$$= \frac{ER_1}{R_g}\left[\frac{L_4\omega}{\{(R_2 + R_4)^2 + L_4\omega^2\}} - \frac{L_3\omega}{\{(R_1 + R_3)^2 + L_3\omega^2\}}\right] + i_g\left[\frac{R_1^2 L_3\omega}{R_g\{(R_1 + R_3)^2 + L_3\omega^2\}} + \frac{R_1R_2L_4\omega}{R_g\{(R_2 + R_4)^2 + L_4\omega^2\}}\right]$$

Now $R_1 = R_2$.

Put $R_4 = R_3 + \delta R$ and $L_4\omega = L_3\omega + \delta L\omega$,

and arrange :—

$$i_g\left[1 - \frac{R_1\{R_3^2 + R_1R_3 + L_3\omega^2\}}{R_g\{(R_1 + R_3)^2 + L_3\omega^2\}}\left\{1 + \frac{1 + [\delta R(R_1 + 2R_3)/(R_3^2 + R_1R_3 + L_3\omega^2)] + [2L_3\omega\delta L\omega/(R_3^2 + R_1R_3 + L_3\omega^2)]}{1 + [\{2\delta R(R_1 + R_3)\}/\{(R_1 + R_3)^2 + L_3\omega^2\}] + [(2L_3\omega\delta L\omega)/\{(R_1 + R_3)^2 + L_3\omega^2\}]}\right\}\right]$$
$$= \frac{ER_1(R_1 + R_3)}{R_g\{(R_1 + R_3)^2 + L_3\omega^2\}}\left[1 - \frac{1 + \{\delta R/(R_1 + R_3)\}}{1 + [2\delta R(R_1 + R_3)/\{(R_1 + R_3)^2 + L_3\omega^2\}] + [2L_3\omega\delta L\omega/\{(R_1 + R_3)^2 + L_3\omega^2\}]}\right]$$
$$- \frac{i_g' R_1^2 L_3\omega}{R_g\{(R_1 + R_3)^2 + L_3\omega^2\}}\left[1 + \frac{1 + \{\delta L\omega/L_3\omega\}}{[1 + 2\delta R(R_1 + R_3)/\{(R_1 + R_3)^2 + L_3\omega^2\}] + [2L_3\omega\delta L\omega/\{(R_1 + R_3)^2 + L_3\omega^2\}]}\right]$$

or

$$i_g(R_gM - 2R_1N) = ER_1(R_1 + R_3)\left[\frac{2\delta R(R_1 + R_3)}{M} + \frac{2L_3\omega\delta L\omega}{M} - \frac{\delta R}{(R_1 + R_3)}\right] - 2i_g' R_1^2 L_3\omega$$

if δR and $\delta L\omega$ are very small compared with R_1 and $L_3\omega$ respectively, where

$$M = (R_1 + R_3)^2 + L_3\omega^2 \text{ and } N = R_3^2 + R_1R_3 + L_3\omega^2$$

We have, similarly, $i'_g(R_gM - 2R_1N) = 2i_gR_1^2L_3\omega - ER_1L_3\omega\left[\frac{2\delta R(R_1 + R_3)}{M} + \frac{2L_3\omega\delta L\omega}{M} - \frac{\delta L\omega}{L_3\omega}\right]$

From these equations i_g can be obtained :—

$$i_g = \frac{ER_1}{R_gM}\left[(R_1 + R_3)\left\{\frac{2\delta R(R_1 + R_3)}{\{(R_1 + R_3)^2 + L_3\omega^2\}} + \frac{2L_3\omega\delta L\omega}{\{(R_1 + R_3)^2 + L_3\omega^2\}} - \frac{\delta R}{R_1 + R_3}\right\}\right] = \frac{ER_1\delta R}{R_g(R_1 + R_3)^2}$$

which shows that if the values of R_1, R_2, R_3 and R_4 are large compared with $L_3\omega$, the current in the galvanometer circuit, when the brushes are in the "in phase" position, depends only on the effective change in resistance of the coil.

In the case when $R_1 = R_3$, $i_g = \dfrac{E\delta R}{4R_1R_g}$.

Taking the actual values used in the experiments, i.e. $E = 4\cdot3$, $R_1 = 10$ ohms, $R_g = 440$ ohms,* then $i_{g\,max.} = 0\cdot244\ \delta R \times 10^{-3}$ amp.

When the calibrating resistance, which has a resistance of $0\cdot0022$ ohm and is in series with R_1, is inserted, the calculated maximum value of the galvanometer current is $0\cdot537 \times 10^{-6}$ amp.

The observed galvanometer current was $0\cdot396 \times 10^{-6}$ amp. In order to obtain agreement between the calculated R.M.S. value and the observed value of the galvanometer current, a form factor of $1\cdot36$ must be used. This form factor is obtained because, owing to the short-circuiting of the two halves of the commutator by the brushes, each half wave of the rectified current is not sinusoidal.

As a further check on the theory, the two 10-ohm ratio arm coils were replaced by two coils, each having a resistance of 1 ohm.

Again taking the actual value in the experiment, i.e. $E = 3\cdot8$ volts, $R_1 = 10$ ohms, $R_3 = 1$ ohm and $R_g = 150$ ohms,* and substituting in

$$i_g = \frac{ER_1\delta R}{R_g(R_1 + R_3)^2 \times 1\cdot36}$$

then $i_g = 3\cdot39 \times 10^{-6}$ amp.

The observed current was $3\cdot3 \times 10^{-6}$ amp.

In the same way

$$i'_g = \frac{EL_3\omega}{4R_1R_g}\left\{\frac{\delta L\omega}{L_3\omega} - \frac{\delta R}{R_1}\right\}$$

if $R_1 = R_3$ and $R_1 > L_3\omega$.

With the brushes in the "out of phase" position there is no galvanometer current when the calibrating resistance is inserted, which shows that the galvanometer current is independent of resistance change with the brushes in the out-of-phase position.

$$\therefore\ \delta R/R_1 < \delta L\omega/(L_3\omega)\ \dagger$$

$$\therefore\ i'_g = \frac{E\delta L\omega}{4R_1R_g} \text{ very nearly.}$$

When the coils R_1 and R_2 are equal in resistance but are different from R_3 and R_4, the value of i'_g is given by

$$i'_g = \frac{ER_1\delta L\omega}{R_g(R_1 + R_3)^2}.$$

* This value of R takes account of the brush contact resistance. This was measured and found to vary from 10 ohms when the brushes were new and well lubricated, to about 40 ohms when the springiness and trim of the brushes had worn off.

As an approximation, 25 ohms was added to the known galvanometer circuit resistance of 415 ohms.

* A smaller resistance was used in the galvanometer circuit with this coil. The 150 ohms takes account of brush contact resistance.

† This can be shown by a mathematical investigation of the eddy currents induced in the metal plates. In this case it was found that $\delta R/(\delta L\omega)$ was approximately 1/100.

THE GENERATION OF VERY INTENSE MAGNETIC FIELDS.*

By T. F. WALL, D.Sc., D. Eng., Member.

(*Paper first received* 27*th October*, 1925, *and in final form* 26*th May*, 1926.)

SUMMARY.

The paper describes a method for generating magnetic fields of the order of magnitude of 1 million gauss, and for impressing such fields on a specimen of magnetic material at regular intervals, with a view to ascertaining whether any disturbance of the electronic orbits could be obtained of sufficient magnitude to produce a marked effect on the magnetization curve of the specimen.

An account is given of the means used for measuring the magnitude and frequency of the heavy transient currents to which the intense magnetic fields are due.

The influence of the dimensions of the solenoid through which the transient currents flow is considered as determining the intensity of the magnetic field produced.

A comparison is given of the calculated and measured values of the transient currents for three different solenoids. It is found that, whilst the calculated values agree well with the measured values for solenoids with a relatively small number of turns of thick wire, there is an appreciable discrepancy in the case of a solenoid with a large number of turns of thin wire. An attempt is made to explain this discrepancy as due to the condenser effect of the contact E.M.F. between the copper wire and the oil-soaked cotton insulation which is in contact with the wire.

INTRODUCTION.

In the reply † to the discussion on a recent paper, Mr. S. Evershed made some interesting suggestions as to the possibility of a disturbance of the electronic orbits within the atoms of a magnetic substance being effected by impressing on them a very intense magnetic field.

The following investigation ‡ was undertaken primarily for the purpose of generating very intense magnetic fields and impressing these fields on a magnetic substance with a view to disturbing the electronic orbits within the atoms.

Now calculation shows § that even if the impressed magnetic field is of the order of 1 million gauss, the corresponding change in the magnetic moment of a revolving electron will only be of the order of 0·1 per cent.

It appeared to the author, however, that there might be a reasonable possibility of obtaining an appreciable disturbance of the electronic orbits if the impressed magnetic fields were to be repeatedly applied. Taking, as an analogous case, the breakdown of the structure of materials by the repeated application of stresses of a magnitude such that a single application would not produce any noticeable effect on the strength, it seems reasonable to suppose that, in an analogous manner, a repeated application of an impressed magnetic field on the electronic orbits would produce a cumulative effect so that eventually a marked change in the magnetic properties of the material would be observed—in particular, a marked change in the magnetization curve of the material.

Although this case of the breakdown of the mechanical structure by repeated application of relatively weak stresses is only mentioned here as an analogy, the author is of the opinion that there is nevertheless a very real relationship between the two cases, the phenomenon of coherence and other mechanical properties of a material being probably, in their ultimate aspect, electromagnetic phenomena.

The problem therefore resolved itself into the following parts :—

(1) The generation of very intense magnetic fields and the impression of these fields on a sample of magnetic material.

(2) The repeated application of these intense magnetic fields by means of a suitable automatically-operated device.

(3) A comparison of the magnetization curve of the sample after the repeated application of the intense magnetic fields, with the magnetization curve of the sample before being subjected to these intense fields.

In the present paper, attention is confined mainly to the problem of generating the very intense magnetic fields and the measurement of the condenser discharge currents to which these fields are due.

Section 1. DESCRIPTION OF THE METHOD AND APPARATUS USED FOR THE GENERATION OF VERY INTENSE MAGNETIC FIELDS.

The basic idea of the method for producing very intense magnetic fields is this : Since the heat generated by a current of i amperes flowing for a time of t seconds in a conductor of resistance R ohms is

$$i^2Rt \text{ joules,}$$

it follows that if the time t be sufficiently small it is possible to pass an indefinitely large current through the conductor without fusing it.

Now if a solenoid is uniformly wound with w turns per cm length, the intensity of the magnetic field generated at the central part within the core is

$$H = k\frac{4\pi}{10}iw \text{ gauss,}$$

where i is the current in amperes and k is a correction coefficient depending on the dimensions of the solenoid.

* The Papers Committee invite written communications (with a view to publication in the *Journal* if approved by the Committee) on papers published in the *Journal* without being read at a meeting. Communications should reach the Secretary of the Institution not later than one month after publication of the paper to which they relate.

† *Journal I.E.E.*, 1920, vol. 58, p. 832.

‡ See also *Nature*, 1924, vol. 113, p. 568.

§ S. EVERSHED, *loc. cit.*; also "Dictionary of Applied Physics," vol. 2, p. 514.

If the solenoid is of very great length as compared with its diameter, the value of k may be taken to be unity.*

If, therefore, the magnitude of the current i is made sufficiently large, the intensity of the magnetic field may be increased indefinitely. Suppose, for example, that a long solenoid is wound with 40 turns per cm length and it is required to obtain a magnetic field of intensity 10^6 gauss at the central part within the core of the solenoid. The current necessary to produce this field will be

$$i = \frac{10^7}{4\pi w} = 19\,900 \text{ amperes.}$$

If the solenoid is wound with, say, No. 16 S.W.G. wire, the normal current-carrying capacity of which is about 13 amperes, it is clear that the current of about 20 000 amperes can only be permitted to flow for a very small fraction of a second if the solenoid winding is not to be burned out.

In order, therefore, that the two essential requirements should be fulfilled, viz.

(i) that very large currents should be generated in the solenoid winding; and

(ii) that these currents should only be allowed to flow for a very small fraction of a second,

the author decided to use the oscillatory discharge of electrostatic condensers of high capacity and charged to a high potential difference.†

The condensers used were of the paper-insulated, oil-immersed power type as supplied by Messrs. British Insulated and Helsby Cables, Ltd. These condensers were supplied in units of a nominal value of 50 μF each, and each unit was capable of withstanding a charging pressure of 2 000 volts (d.c.).

For the tests described in the following, 28 of these units were available, the total capacity of the units when connected in parallel being 1 366 μF.

The condensers were charged by means of a small d.c. generator as built for wireless telegraph purposes. This generator develops an E.M.F. of about 1 200 volts and is capable of supplying a current of about 0·02 ampere. In series with this generator were connected a number of small accumulators as used for wireless telegraph work, so that the total available d.c. pressure for charging the condensers was about 2 000 volts.

The d.c. supply so provided was connected in series with a high resistance of the value of about 0·25 megohm, so that when the discharged condensers were connected to the supply there would not be any heavy rush of current from the generator and accumulators.

The condensers required about 3 to 4 minutes to become fully charged under these conditions.

After having become fully charged, the condensers were then connected directly to the solenoid winding within the core of which the intense magnetic fields were to be generated, care being taken to keep the resistance and inductance of the leads from the condensers to the solenoid as small as practicable.

The solenoid was immersed in a bath of transformer oil which served the double purpose of maintaining a high value for the insulation resistance between neighbouring turns of the winding, and for effectively cooling the solenoid winding after the passage of the very heavy discharge currents from the condensers. As these currents reached momentary values of many thousands of amperes, it was essential to ensure that the heat generated in the solenoid winding should be conducted away as quickly and effectively as possible.

The measurement of the magnitudes of the very heavy currents generated when the condensers are discharged through the solenoid winding has been a problem of some difficulty. The method employed is the use of the Duddell high-frequency oscillograph and "falling plate" camera.

In order to ensure that the photographic plate shall pass across the exposure slit at precisely the moment at which the condenser discharge is taking place, an electromagnetic release device for the plate is employed. The electromagnet circuit is closed by means of a contact fixed to the arm of the switch which closes the discharge circuit of the condensers. By suitably adjusting the position of the contact it is possible so to arrange matters that the condenser discharge takes place just as the plate is passing across the exposure slit.

The setting of the contact maker for the plate-release electromagnet proved to be extremely sensitive, and a very slight change in the friction of the plate in the guides was sufficient to upset it completely so that the condenser discharge was completed either before or after the plate had passed across the exposure slit. It was eventually found to be necessary to provide means for eliminating the disturbing effect of slight errors or alterations in the setting of the contact maker. For this purpose a special plate frame was made which would carry three plates, thus forming, in effect, one continuous plate about 18 in. long. In this way it has been found possible to ensure that the condenser discharge takes place while at least some portion of this composite plate is crossing the exposure slit.

The frequency of the oscillatory current produced by the condenser discharge is measured by connecting one strip of the oscillograph to a source of sinusoidal alternating current of known frequency, e.g. the town supply mains, whilst the other strip of the oscillograph is in circuit with the discharge current of the condenser.

Fig. 1 shows diagrammatically the general arrangement of the connections. Reference to this diagram shows that when the switch lever E is over on the left-hand side and the switch U is closed, the condensers are all connected in parallel to the high-voltage supply system C. The P.D. at the condenser terminals is measured by the Kelvin electrostatic voltmeter O. When the switch lever E moves over to the right-hand side, contact is first made in the two mercury cups J, the result of this being to connect the two condenser sets B in series. The actual closing of the condenser discharge circuit is effected by contact in the large mercury cup H.

* The actual value of the correction coefficient is

$$k = \frac{2b}{4d} \log_e \left[\frac{(a+d) + \sqrt{[(a+d)^2 + b^2]}}{(a-d) + \sqrt{[(a-d)^2 + b^2]}} \right]$$

where a is the mean radius in cm of the solenoid winding,
$2d$ is the radial depth in cm of the solenoid winding,
$2b$ is the length in cm of the solenoid winding.

See A. GRAY: "Absolute Measurements in Electricity and Magnetism," 2nd Edition, page 216.

† P. KAPITZA has described (*Proceedings of the Royal Society*, A, 1924, vol. 105, p. 691) a method of producing intense magnetic fields by means of the discharge of accumulators.

The resistance Q is provided as a safety discharge resistance so that, if desired, the condensers may be short-circuited when necessary and thus rendered safe for handling.

The condenser discharge current through the solenoid passes through the standard resistance R. The value of this resistance was 0·002 ohm for many of the tests, whilst for the remainder of the tests the value was 0·001 ohm.

from the self-induction of the resistance itself. That is to say, the P.D. across the terminals of the resistance will not be merely that due to the IR drop, but there may be a relatively high voltage induced by the self-induction and therefore proportional to the rate of change dI/dt, and this voltage of self-induction may be relatively large, notwithstanding the fact that the resistance is a conductor in the form of a straight rod.

In order to obviate any trouble due to self-induction

Y = A.C. supply (50 cycles) for calibrating oscillograph.

In view of the very large currents to be dealt with, the measurement of the magnitudes of these currents by means of the oscillograph required special precautions to eliminate mutual induction effects between the solenoid leads and the leads to the oscillograph. The current was measured by connecting one strip of the oscillograph as a shunt to the standard resistance R. The form of this resistance is therefore of considerable importance. For instance, if this resistance is of small ohmic value and if the length is large, trouble may arise

effects, the length of the resistance R was kept small, viz. 5 in. Further, instead of bringing the oscillograph leads from the standard resistance R at right angles, one of the leads was arranged to pass along the resistance and close to it, being then twisted round the other tapping lead as shown in Fig. 1. In this way, self-induction effects in the resistance R were eliminated and the P.D. supplied to the oscillograph strip circuit was strictly proportional to the current in the circuit of the solenoid A.

A special precaution was also taken in regard to the P.D. oscillograph connections for measuring the P.D. wave across the coil. For this purpose non-inductive double strips V (Fig. 1) were connected directly to the solenoid terminals, the length of each double strip being about 2 in. Tappings were taken from the top of these double strips, one of these tappings being shown in Fig. 1. In this way any mutual induction effects in the P.D. leads due to the heavy currents in the circuit could be eliminated. It was found, however, that mutual induction effects in the P.D. circuit of the oscillograph circuit were insignificantly small even without this special precaution.

The slide frame for the photographic plates is shown at N and the electromagnet for the plate release at M. The circuit of this electromagnet is closed as the switch lever E moves over to the right-hand side.

The a.c. wave of 50 frequency for measuring the frequency of the oscillatory discharge currents in the solenoid A, and also for calibrating the oscillograph, is obtained from the supply mains shown at Y.

The calibration of the oscillograph is performed by connecting the two strips in series with each other through a known resistance and supplying the circuit

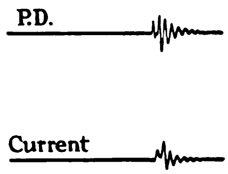

FIG. 2.

from the a.c. source Y, the P.D. being accurately measured.

For each condition of condenser discharge, two sets of oscillograms were usually taken, viz.

(i) One set giving the waves of the P.D. and the current in the solenoid.

(ii) One set giving the wave of the condenser discharge current and a sinusoidal wave of known frequency.

The second of these two sets of oscillograms provides the scale for measuring the frequency of the condenser discharge current.

As previously mentioned, a disturbing factor in the resistance of the discharge circuit is the mercury cup contact H through which the actual closing of the discharge circuit is effected. What appears to happen is the following: Before the switch blade of the large cup contact H (Fig. 1) actually touches the mercury surface, a spark passes, the mercury is partly vaporized and its surface set in violent motion. The contact resistance of the mercury is thus a somewhat uncertain quantity. Further, the mercury surface may oscillate so violently that the contact may be broken at some time during the discharge. This appears to be the case in the oscillograms such as those given in Figs. 4 (*a*) and 5 (*b*), in which there is an actual cessation of the current for a short time, after which the discharge is resumed. Moreover, even though the discharge does not start with a spark from the switch blade to the surface of the mercury, the surface may be set oscillating by the mechanical effect of the blade striking through the surface.

In order to minimize these effects at the surface of the mercury, the contact cup H (Fig. 1) through which the discharge circuit is completed is made very large, viz. about 6 inches in diameter and about 8 in. deep. The mercury is about 1 in. deep and the cup is filled to the top with oil. In this way the spark was largely suppressed and the oscillations at the surface of the mercury were largely wiped out.

For the purpose of examining a little further the effect of the mercury contact on the flow of current in the circuit, an oscillogram was taken for the condenser discharge current when the condensers were charged up to a very low voltage, so that any disturbance due to sparking at the contact should be insignificant. For this test the condensers were arranged in two sets in parallel, the capacity of the two sets being $243 \cdot 3\ \mu$F and $243 \cdot 2\ \mu$F respectively. These two sets were charged to a P.D. of 10 volts in parallel and connected in series for the discharge.

In Fig. 2 are shown oscillograms of the P.D. and current waves respectively, for these conditions of condenser discharge. An inspection of these oscillograms shows that in this instance there is a marked disturbance at the commencement of the discharge, after which the oscillations become normal.

As previously stated, the system of connections to the mercury cups shown in Fig. 1 is such that, whilst the condensers are all connected in parallel for charging (that is, the rocking-lever switch arm E is in contact with the left-hand set of mercury cups), before the discharge takes place the condensers are connected in two sets in series. By connecting the condensers in series in this way for discharging it is possible to obtain (within limits) much higher values for the discharge currents than if all the condensers remained in parallel at discharging.

For example, take the following values for the constants of the circuit, viz. inductance $L = 50/10^6$ henry, and resistance $R = 0 \cdot 15$ ohm. Suppose the total capacity of the condensers available is 1 360 μF and that these condensers will stand charging at 2 000 volts. If the condensers are all charged up to 2 000 volts in parallel and if they are kept in parallel at discharge, calculation shows that the magnitude of the first peak of the oscillatory discharge current will be 5 800 amperes and the frequency of the oscillatory current will be 563 cycles per second.

If, however, the condensers after being all charged in parallel to 2 000 volts are then arranged in two equal sets connected in series, the magnitude of the first peak of the oscillatory discharge current will be 7 780 amperes and the frequency 1 200 cycles per second.

It is seen, therefore, that the discharge current in the solenoid reaches a maximum value which is 34 per cent greater when the condensers are discharged in two equal sets in series than when the discharge takes place with all the condensers connected in parallel.

By connecting the condensers in, say, 4 equal sets in series when discharging, the maximum value of the discharge current may be still further increased.

Section 2. COMPARISON OF THE MEASURED VALUES OF THE CONDENSER DISCHARGE CURRENTS AND FREQUENCIES WITH THE VALUES CALCULATED FROM THE CONSTANTS OF THE CIRCUIT.

In order to provide a check on the method described in Section 1 for measuring the magnitudes of the transient currents obtained when the condensers are discharged through the solenoid, and also to ascertain whether any new phenomena were becoming evident due to the high values of the currents obtained, three special solenoids were wound and their dimensions accurately determined.

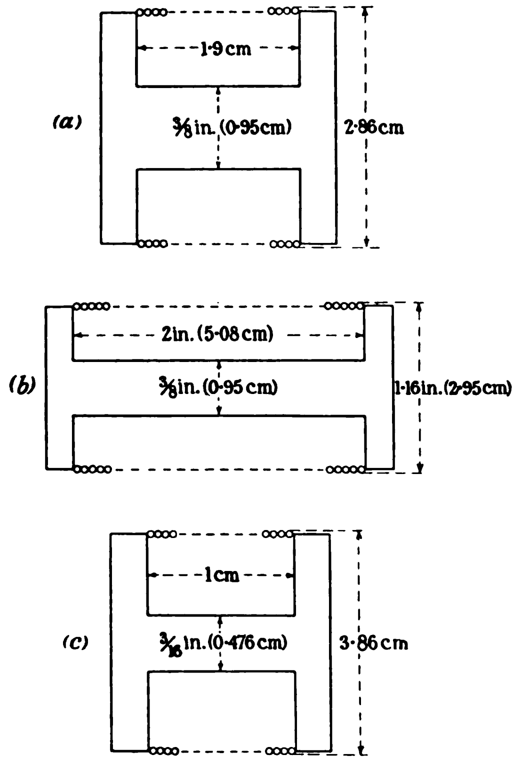

FIG. 3.

	Solenoid		
	A (a)	B (b)	C (c)
No. of turns per layer	9·6	26·5	10
No. of layers	5	5	18
Total no. of turns	48	132·5	180
Size of wire (S.W.G.)	No. 16	No. 16	No. 22

The results obtained in these tests, especially those referring to the solenoid described in the following as solenoid C, do in fact indicate that a peculiar phenomenon is coming to light. This is dealt with in the discussion of the results obtained with solenoid C.

Each of these solenoids was wound on an ebonite bobbin in order to eliminate any extraneous disturbing effects which might have occurred if the bobbin had been of metal.

The three solenoids are shown in section in Fig. 3, the winding data being also given for the respective solenoids.

* Inductance of solenoid B calculated from Butterworth's formula (see "Dictionary of Applied Physics," vol. 2, p. 391; also see A. GRAY: "Absolute Measurements," 2nd edition, p. 520).
† Inductance of solenoid C calculated from Lyle's formula (see "Dictionary of Applied Physics," vol. 2, p. 389).

The electrical data for the condenser discharge circuit for each solenoid are given in Table 1.

It is to be noted that (as was pointed out in Section 1) the resistance of the mercury contact H (Fig. 1) introduced an increase in the calculated value of the effective resistance of the discharge circuit.

The actual effective resistance of the condenser discharge circuit was found from the logarithmic decrement of the current oscillograms, and the values so obtained for the three solenoids are given in Tables 2, 4 and 6 respectively.

As stated in Section 1, two sets of oscillograms were taken for each value of the potential to which the condensers were charged. One set of oscillograms gives the wave of P.D. which actually develops across the solenoid,* and the simultaneous wave of current in the solenoid. The second set gives the frequency of the

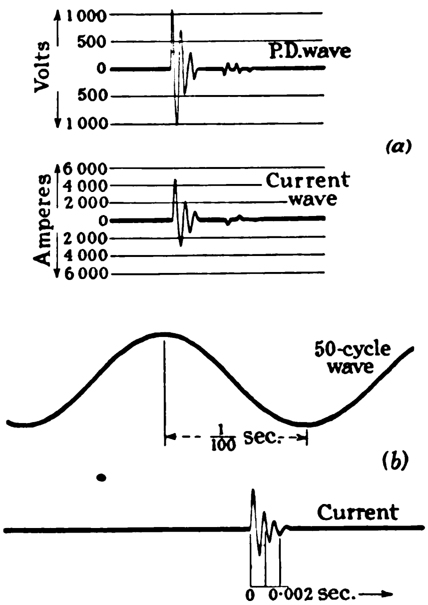

FIG. 4.

discharge current of the condensers. By means of these oscillograms it is possible to check the whole scheme of measurement of the current values by the oscillograph. For, knowing the value of the P.D. at the condenser terminals at the moment of discharge, the inductance of the discharge circuit including the solenoid and leads, the logarithmic decrement and also the frequency of the current wave, it is possible to calculate the effective resistance of the circuit. From a knowledge of the effective resistance, the magnitude of the first peak of the current wave can be calculated and then compared with the actual value as given by the oscillograms. Further, knowing the constants of the circuit, it becomes possible to calculate the frequency of the discharge current and to compare this calculated value with the frequency as actually measured from the oscillogram.

If any marked and consistent discrepancy occurs between the calculated and measured values of the current and frequency, and if this discrepancy cannot be explained in any other way, it is reasonable to suppose that some new phenomenon is having a marked effect on the result. As stated above, there is a marked discrepancy between the calculated and measured values for solenoid C but not for the other two solenoids. An attempt to find an adequate explanation for the discrepancy in the case of solenoid C is developed in Section 4.

Example.—In Fig. 4 the oscillograms refer to the case in which the condensers were charged to a P.D. of 2 126 volts and then discharged through the solenoid A. From both oscillograms the first peak of the current wave is found to be 4 520 amperes. The second peak of the current wave has a magnitude of 2 750 amperes.

The instantaneous value of the current at any time t subsequent to the commencement of the discharge is

$$i = \frac{V}{L\omega}e^{-\frac{1}{2}(R/L)t}\sin \omega t$$

where $$\omega = 2\pi f = \sqrt{\left[\frac{1}{LC} - \frac{R^2}{4L^2}\right]}$$

or $$f = \frac{1}{2\pi}\sqrt{\left[\frac{1}{LC} - \frac{R^2}{4L^2}\right]}$$

The magnitude I_1 of the first peak of the current wave is obtained by putting $t = 1/(4f)$, so that the magnitude of the first peak of the current wave is

$$I_1 = \frac{V}{L\omega}e^{-R/(8Lf)}$$

Similarly, the magnitude I_2 of the second peak is obtained by putting $t = 3/(4f)$, so that

$$I_2 = \frac{V}{L\omega}e^{-3R/(8Lf)}$$

and consequently $$\frac{I_2}{I_1} = e^{-R/(4Lf)}$$

Now it is found by measurement of the oscillogram (b) in Fig. 4 that the value of the frequency is

$$f = 1\,340 \text{ cycles per second,}$$

also, from the oscillograms in Fig. 4

$$\frac{I_2}{I_1} = 0\cdot 61,$$

from which it follows that

$$R = 0\cdot 114 \text{ ohm,}$$

since $$L = \frac{43\cdot 4}{10^6}\text{ henry}$$

Taking, then, the effective resistance of the discharge circuit to be $0\cdot 114$ ohm, the value of the first peak of the current wave and also the frequency may be calculated. Thus in this case,

$V = 2\,126$ volts; $L = 43\cdot 4 \times 10^{-6}$ henry; $C = 339\,\mu$F;

$$\left(\frac{1}{2}\frac{R}{L}\right)^2 = (1\,310)^2 = 1\cdot 73 \times 10^6$$

$$\omega = \sqrt{\left[\frac{1}{LC} - \left(\frac{1}{2}\frac{R}{L}\right)^2\right]} = 8\,150$$

that is, $f = 1\,300$ cycles per second.

* See also the discussion of the results obtained with solenoid A below, as to the effect of the connecting leads on the P.D. wave of the condenser discharge.

Substituting in the expression for the first current peak

$$I_1 = \frac{V}{L\omega} e^{-R/(8Lf)}$$

gives $\qquad I_1 = 4\,682$ amperes.

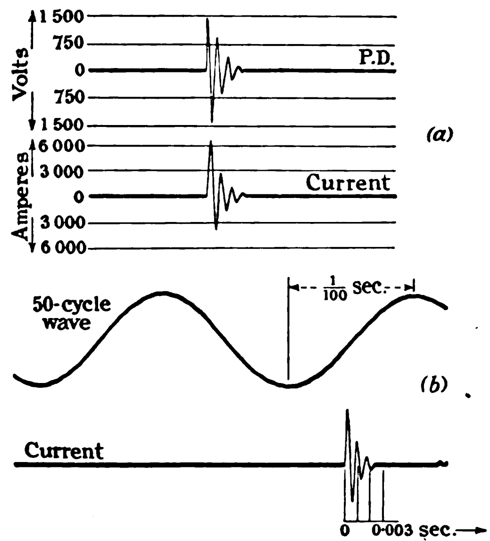

FIG. 5.

The calculated value of the first peak of the current wave is thus about 1·03 times the value measured from the oscillograms (*a*) and (*b*) in Fig. 4, whilst the calculated value of the frequency is about 0·97 of the value measured on the oscillogram (*b*), Fig. 4.

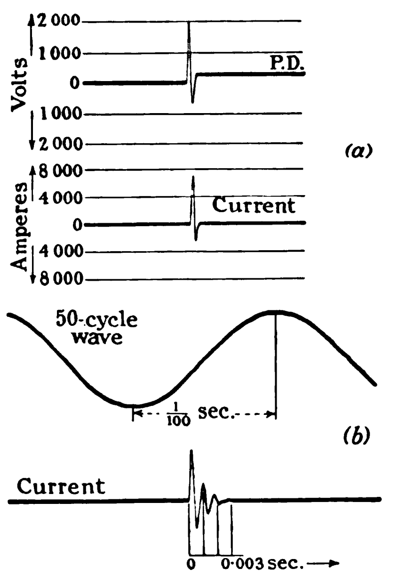

FIG. 6.

TESTS ON SOLENOID A.

For the tests on this solenoid the condensers were arranged in two equal sets. These two sets were connected in parallel for charging, and just before the discharge through the solenoid took place the two sets of charged condensers were connected in series (see Fig. 1).

The total capacity of the series arrangement of condensers was 339 μF.

Since each of the condenser units was capable of standing a P.D. of 2 000 volts, the terminal pressure of the series arrangement of the condensers could be taken as high as 4 000 volts.

A series of oscillograms were taken for this solenoid for a range of condenser discharge voltages from about 450 volts up to about 4 000 volts.

The series of oscillograms taken for this range of condenser discharge P.D.'s are reproduced in Figs. 4, 5 and 6.

In Table 2 are shown the data of the discharges as measured from the oscillograms, and several noteworthy facts are revealed by an examination of these data. These are :—

(i) The oscillograms giving the *pressure* wave of discharge show the curious result that the second peak of the wave is almost equal in magnitude to the first peak, the ratio of the magnitude of the second peak to that of the first peak being of the order of 0·90 throughout Table 2. This appears to be due to the fact that a relatively long length of cable is included between the tapping points for the P.D. strip of the oscillograph.

(ii) The magnitude of the resistance as deduced from the logarithmic decrement of the current wave is about 3 times the value of the resistance of the coil and leads. That is to say, the resistance of the mercury contact cup H (Fig. 1) appears to be much the larger portion of the total resistance of the circuit.

(iii) In the oscillogram, Fig. 4 (*a*), it is seen that the discharge of the condenser is interrupted and both the pressure across the solenoid and the current in the solenoid fall to zero for an appreciable time. The discharge is then continued for a short period and a second interruption then occurs after which the discharge becomes completed.

This effect appears to be due to the surging of the mercury in the large cup H (Fig. 1), whereby the contact with the switch becomes broken and then re-established. This same effect can be seen in the oscillograms of Fig. 5.

(iv) In the oscillogram (*a*) of Fig. 6 is seen the effect due to the bursting of the solenoid which occurred with the heavy current obtained from this discharge. It will be noted that the second current peak is relatively very small and falls rapidly to zero, after which the current ceases. The oscillogram of the P.D. wave, however, shows that after the solenoid has burst there is a pressure across the ends of the ruptured solenoid, i.e. the condensers have not become completely discharged.

It is of interest to note that only about 0·0005 sec. has elapsed between the closing of the discharge circuit and the rupturing of the solenoid. This gives an idea of the enormous mechanical forces developed by the discharge current which reached a peak value of about 7 000 amperes.

In order to measure the frequency for this condition of condenser discharge, a second solenoid was wound and another discharge obtained under the same conditions of condenser voltage. The oscillogram of this discharge is shown in (*b*), Fig. 6. This solenoid also burst when the discharge took place. It will be seen, however, in (*b*), Fig. 6 that the complete wave of current was obtained before the rupture occurred.

stants of the circuit and as measured from the oscillogram records. The agreement between the calculated and measured values is sufficiently close to make it impossible to detect any new phenomena due to the heavy values of the current discharge.

There is one other point worthy of notice in connection with the various P.D. oscillograms given in Figs. 4 (*a*) and 5 (*a*). Since the oscillograph P.D. strip was not connected directly across the solenoid terminals, there being a length of cable included in the circuit across which the P.D. strip was connected, the corresponding oscillograms consequently included the P.D. developed across this length of cable. Now for this solenoid the total length of wire in the winding was not very greatly in excess of the length of this included cable. The P.D. oscillograms do not therefore give an accurate measure of the P.D. across the solenoid terminals, the oscillogram being actually composed of the superposition of the current wave and a wave proportional to the P.D. wave.

NOTE.—Calculated values of current and frequency given in this table are deduced from the circuit constants $C = 339\ \mu F$; $L = 43\cdot4 \times 10^{-6}$ henry; $1/(LC) = 68\cdot0 \times 10^{6}$. R taken from Table 2.

In Table 3 is given a comparison of the values of the current and frequency as calculated from the con-

TESTS ON SOLENOID B.

The measurements made with this solenoid were carried out with the condensers all connected in parallel at discharge, the total condenser capacity being $1366\cdot6\ \mu F$.

Oscillograms were taken for the discharge through the solenoid for a range of condenser discharge voltages from about 250 volts to 1 800 volts.

In Table 4 the measurements of the condenser discharge are shown as obtained from the respective oscillograms. In these discharges the peculiarity in the P.D. wave noticed in the case of solenoid A, viz. the closeness of the magnitudes of the first and second peak values, has become much less marked (see Table 4). This fact gives further support to the view that in the case of solenoid A the effect is due to a superposition of current and P.D. waves in the relatively long cable included between the tapping points of the oscillograph P.D. strip.

In Table 5 a comparison is shown of the values of the current and frequency as calculated from the constants of the circuit and as measured from the oscillograms. Here, again, the agreement between the calculated values and those measured from the oscillograms is sufficiently close to make any incipient new phenomena due to the heavy value of current discharges not pronounced enough to be decisively recognizable.

Note.—Calculated values of current and frequency given in this table are deduced from the circuit constants $C = 1\,366 \cdot 6\mu\text{F}$; $L = 100 \times 10^{-6}$ henry; $1/(LC) = 7 \cdot 32 \times 10^{6}$. R taken from Table 4.

Tests on Solenoid C.

This solenoid was wound to give much greater intensities of magnetic fields than either of the other two solenoids. The core of the bobbin was of much smaller diameter and the number of turns per cm length of winding was about 8 times greater than the value for either of the other solenoids. It was thus possible to obtain a given intensity of magnetic field without the necessity for such large values of the discharge currents as were obtained in the previous cases. An advantageous feature of this is that the mercury in the large contact cup was subject to much less disturbance at the moment of making contact; this is shown in the oscillograms by the fact that no marked interruptions of the current due to the condenser discharges are apparent.

For this solenoid the condensers were all charged in parallel and arranged in two equal sets in series for the discharge, the total capacity of the series connection being 339 μF. Discharges were obtained for a range of condenser voltages from 259 volts to 4 220 volts.

In Table 6 the data of these discharges are shown as deduced from the respective oscillograms. It will be noticed that an intensity of magnetic field of nearly $0 \cdot 5 \times 10^{6}$ gauss was obtained at the highest voltage of condenser discharge. At this discharge the solenoid burst.

Table 7 shows a comparison of the values of the current and frequency as deduced from the constants of the discharge circuit, and the actually measured values as given in Table 6.

The noteworthy feature about the data in Table 7 is the large discrepancy between the calculated values and the observed values. In view of the relatively good agreement of the calculated and measured values in the cases of solenoids A and B respectively, it appears that some new effect is manifesting itself in the performance of this solenoid. This new effect seems to be

equivalent to a reduction in the effective inductance of the solenoid.

In attempting to locate the cause of this it should be borne in mind that the conditions for this solenoid are different from those for solenoids A and B respectively, in that the magnetic fields generated in the core of solenoid C attain a much greater intensity than those generated in either solenoid A or B. The effect of this is that the mechanical pressure developed between neighbouring turns of the solenoid winding is very much greater. Further, the total length of wire in the winding of solenoid C is much greater than in either of the other two solenoids.

The conditions therefore may be summarized as follows: In solenoid C there are a large number of turns of wire insulated with cotton and soaked in oil. These turns all become pressed together with a very great mechanical force when the condenser discharge currents pass through the winding, and moreover, since the discharge currents are oscillatory, the mechanical force which presses the oil-soaked cotton against the wire will also be a periodic force.

* Resistance $R = 0{\cdot}69$ ohm, deduced from ratio $I_2/I_1 = 0{\cdot}355$ (see Table 6).

NOTE.—Calculated values of current and frequency given in this table are deduced from the circuit constants $C = 340\ \mu F$; $L = 393 \times 10^{-6}$ henry; $1/(LC) = 7{\cdot}48 \times 10^6$. R taken from Table 6.

In Section 4 an attempt is made to outline an explanation of the apparent effective reduction of the inductance of this solenoid on the basis of the contact E.M.F. developed between the wire and the oil-soaked cotton insulation which is pressed into intimate contact with the wire.

Section 3. THE INFLUENCE OF A CHANGE IN THE DIMENSIONS OF THE SOLENOID WINDING ON THE INTENSITY OF THE MAGNETIC FIELD GENERATED WITHIN THE CORE OF THE SOLENOID.

It is of interest to inquire what effect any variation in the design of the solenoid may be expected to have on the maximum intensity of magnetic field which may be obtained.

In this connection it is to be observed that, as the leads to the coil from the condensers must have a certain inductance and resistance and, in particular, since the mercury contact resistance is relatively considerable, it is not at first sight obvious what are the best proportions to give the solenoid.

For the particular purpose in view, for which the present investigation has been undertaken, it is to be remembered that the size of the magnetic sample which is to be submitted to the intense field must not be too small, otherwise it becomes very difficult to test its

magnetic properties with sufficient accuracy. This consideration places a limit on the internal diameter of the solenoid tubular core within which the test sample is placed. Further, in order that the field shall be reasonably uniform in the space within the core which is occupied by the sample, the length of the solenoid must not be too small.

The solenoid winding cannot therefore be expected to have a smaller internal diameter or a shorter length than the values given in Fig. 3 for solenoid C. That is to say, the winding will be not less than 1 cm long and not less than $\frac{3}{16}$ in. internal diameter. These values have consequently been taken as fixed, and the inductance of the leads is assumed to be fixed at 15×10^{-6} henry.

The mercury cup contact resistance is assumed to be negligibly small.

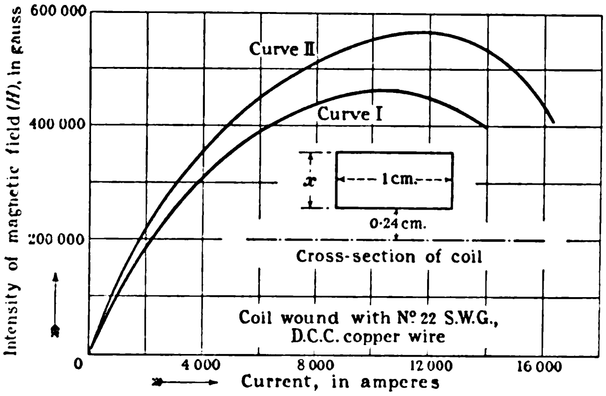

FIG. 7.

Curve I.—Condenser capacity = 1 360 μF; condensers charged to 2 000 volts.
Curve II.—Condenser capacity = 340 μF; condensers charged to 4 000 volts.

From calculations of the inductance and resistance of the solenoid for a series of values of x, the radial depth of the winding, the author has worked out the relationship between the first peak of the discharge current in the solenoid and the corresponding values of the magnetic intensity at the central part within the core of the solenoid. The solenoid is wound with No. 22 S.W.G. d.c.c. copper wire.

The results are plotted in Fig. 7 as curves I and II. Two cases have been considered, viz.

(1) Curve I refers to the case in which the condenser capacity is 1 360 μF, the condensers being charged to 2 000 volts.

(2) Curve II refers to the case in which the condenser capacity is 340 μF, the condensers being charged to 4 000 volts. This corresponds to charging the whole bank of 1 360 μF in parallel at 2 000 volts and discharging them as two equal banks in series.

As an example of the significance of these results, the data given in Table 8 will serve.

Reference to Fig. 7 shows some interesting facts. First of all, other things remaining the same, there is a value for the winding depth x which gives the maximum value for the intensity of the magnetic field within the solenoid core. Next, it is seen that the device of

TABLE 8.

Solenoid Wound with No. 22 S.W.G. Copper Wire [*see Curve II* (*Fig.* 7)].

Radial winding depth	Number of turns per cm length, w	Magnitude of first peak of condenser discharge current wave, I_1	Magnetic intensity corresponding to first peak of current wave $H = k\frac{4\pi}{10}I_1w$
cm		amps.	gauss
0·25	25	16 240	413 000
1·0	100	6 000	446 000
3·0	300	1 080	130 000

charging the condensers in parallel and connecting them in two groups in series for discharging gives a distinctly larger value for the maximum value of the magnetic field within the core. By carrying this procedure still farther and, for example, by charging the condensers all in parallel and then dividing them into 4 groups in series before discharging, still higher values for the maximum intensity of the magnetic field generated within the solenoid core may be expected.

Section 4. AN ATTEMPT TO EXPLAIN THE DISCREPANCY BETWEEN THE CALCULATED AND MEASURED VALUES OF THE CONDENSER DISCHARGE CURRENTS IN SOLENOID C, ON THE BASIS OF THE CONTACT E.M.F. DEVELOPED BETWEEN THE WIRE AND THE OIL-SOAKED COTTON INSULATION.

The author advances the theory that the so-called "frictional" electricity or "contact E.M.F." which is developed when any two unlike substances are brought into intimate contact * is sufficient to account for the apparent decrease of the inductance of solenoid C, as shown by the discrepancy between the measured values of current and frequency given in Table 7 and the calculated values of the same quantities also given in Table 7. A reduction in the effective inductance would, in fact, mean an increase in the frequency and (within limits) an increase in the current also.

Referring to Fig. 8, suppose that a strip of metal AB is pressed into intimate contact with a layer of oil-soaked cotton wool, and also suppose that, by virtue of the contact E.M.F., the metal becomes thereby negatively electrified and the cotton positively electrified.

In Fig. 9 this is illustrated by showing the potential of the cotton by a horizontal straight line below the datum line, this datum line being intended to represent the potential of the centre of the metal strip.

Now suppose that a potential difference is established between the two ends of the metal strip, e.g. by connecting them to a source of direct-current supply. Since the oil-soaked cotton is an insulator, it cannot, of course, allow a conduction current to pass. The contact E.M.F., however, between the metal and the cotton will tend to remain constant and it follows,

* See ELIHU THOMSON: *General Electric Review*, 1922, vol. 25, p. 418; also *Elektrotechnische Zeitschrift*, 1924, vol. 45, p. 878.

therefore, that a current will flow across the contact surface of metal and oil-soaked cotton.

This current will be so directed as to maintain a uniform value of the contact E.M.F. between the metal and the oil-soaked cotton at every point of the surface of contact. Thus, if the end A of the metal is raised to a positive potential and the end B lowered to a

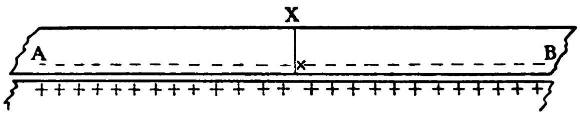

FIG. 8.

negative potential with respect to the datum XX, there will be a flow of electricity *from the metal into the cotton* at points along the contact surface between the end A and the centre X, and there will be a flow of electricity *from the cotton into the metal* at points along the contact surface between the end B and the centre X.

If now the source of d.c. potential is removed from

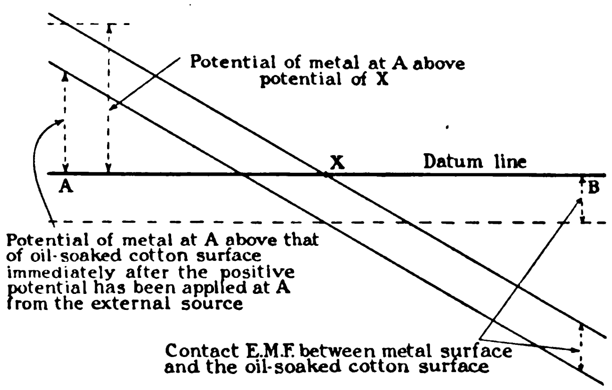

FIG. 9.

the ends A, B, the metal will immediately become an equipotential surface and, in order that the characteristic contact E.M.F. between the cotton and metal surfaces shall be maintained, there will be a flow of electricity *from the cotton into the metal* at points along the surface between the end A and the centre X, and a flow of electricity *from the metal into the cotton* at points along the surface between the end B and the centre X. It thus appears that the cotton insulation stores up energy and releases it in a precisely similar way to that in which a condenser stores and releases electrical energy.

This condenser effect due to the contact E.M.F. must not, however, be confused with the ordinary self-capacity of a coil. In the case of ordinary self-capacity effects the condenser is a normal one comprising two conductors separated by a non-conductor. In the case of the contact E.M.F. condenser effects, however, the condenser has only one metal plate, and the cotton surface itself forms the other plate. The distance between the plates thus becomes one of atomic dimensions.*

Since the contact E.M.F. is relatively high, viz. of the order of 1 volt, and since the distance between the equivalent plates of this contact E.M.F. condenser is of atomic dimensions, it follows that the capacity may become relatively enormous.

The total value for any given solenoid, of this capacity due to the contact E.M.F. effect, will depend upon the total surface of the side of the coil and the mechanical pressure with which the wire surface is forced on to the oil-soaked cotton. Since, in the case of solenoid C, both the surface contact area and the mechanical pressure of contact are very much greater than in either of the solenoids B and A, this contact E.M.F. condenser effect will be correspondingly greater for solenoid C than for either of the other two solenoids.

Preliminary attempts have been made to check this theory of a contact E.M.F. condenser, the method adopted being to build up a special solenoid and make one end flange adjustable so that very large mechanical pressures can be exerted to press the windings into close contact. By supplying alternating current at 50 frequency, endeavours were made to produce a leading current when great mechanical pressure was applied to the end flange of the coil. Up to the present this experiment has not been successfully accomplished, but it is hoped that it may be possible to renew the attempt at an early date.

Section 5. SOLENOID WOUND ON A STEEL BOBBIN.

An interesting oscillogram is shown in Fig. 10, which refers to a solenoid wound on a steel bobbin. The condensers were connected all in parallel, charged up to 2 126 volts and then connected in two sets in series for discharging. The coil burst when the discharge took place and the oscillogram of Fig. 10 shows the sequence of events after the discharge circuit was closed.

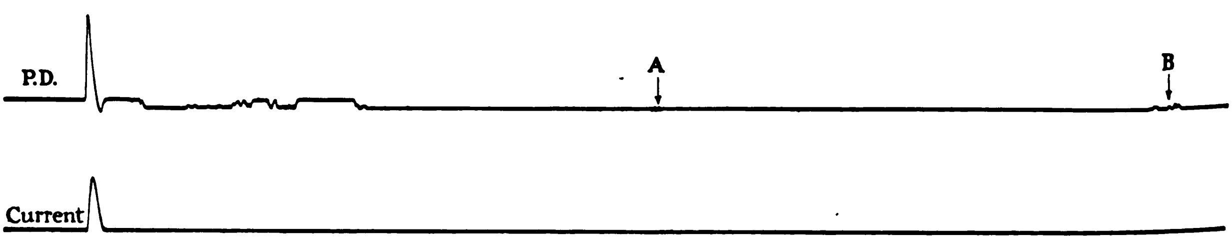

FIG. 10.

The current wave comprises a single peak and then falls to zero. The peak value of the current wave as measured from the oscillogram is found to be 2 230 amperes.

* See ELIHU THOMSON, *loc. cit.*

The P.D. wave shown in the oscillogram exhibits some remarkable features. For example, the P.D. becomes zero at the same time that the current falls to zero, and the P.D. remains zero for about 0·002 sec. The P.D. oscillogram then shows high-frequency ripples of small amplitude, afterwards becoming definitely negative and remaining negative for about 0·005 sec. The P.D. then becomes oscillatory and reaches the zero value, remaining zero for about 0·001 sec. After further fluctuations the P.D. again becomes definitely negative and remains negative but develops occasional ripples of high frequency and small amplitude (see A, B, Fig. 10).

The curious activity of the P.D. after the current has ceased to flow appears to be definitely due to the iron of the bobbin. This is evident from the fact that when a solenoid of similar winding data but wound on an ebonite bobbin burst [see Fig. 6 (*a*), solenoid B], no such high-frequency ripples were developed in the P.D.

It would further appear that the atomic disturbance of the material of the bobbin took some considerable time to settle down to a state of quiescence, that is, in so far as its external effects are concerned.

It is hoped to obtain, at a later date, further experimental data relative to these curious phenomena in the P.D. wave.

Concluding Remarks.

As previously stated, the prime purpose for which this method of generating very intense magnetic fields was devised was to ascertain the effect of repeated application of such fields on a magnetic substance. For this purpose, the magnetic specimen is prepared in the form of a short tube of approximately the following dimensions: Length $\frac{3}{16}$ in., internal diameter $\frac{1}{8}$ in., external diameter $\frac{3}{16}$ in.

The specimen is inserted in the hollow core of a solenoid which is wound on a steel bobbin. The bobbin has a longitudinal slit to minimize the generation of eddy currents in the metal of the bobbin.

Before subjecting the specimen to the intense magnetic fields the magnetization (i.e. the *B-H*) curve is determined. The specimen is then inserted in the tubular core of the solenoid and the oscillating switch E, Fig. 1, is set in operation so that a condenser discharge passes through the solenoid about once every 5 minutes. After a few hundred discharges have in this way taken place, the specimen is removed and its magnetization curve is again determined.

It has been found that the magnetization curve for a specimen of stalloy is distinctly improved after having been subjected to the intense magnetic fields in this way.

This process is being carried out for a long period of time to ascertain what limit, if any, there is to the observed change in the magnetization curve due to the repeated application of the very intense magnetic fields.

Tests will also be made on specimens of bismuth and other representative materials.

RECURRENT CIRCUITS; A METHOD OF SOLUTION.*

By A. G. WARREN, M.Sc., Member.

[FROM THE RADIOLOGICAL SECTION OF THE RESEARCH DEPARTMENT, WOOLWICH.]

(*Paper first received 26th November, 1925, and in final form 23rd February, 1926.*)

SUMMARY.

The paper consists of the statement and illustration of a method of solving recurrent circuits (of which the filter is the simplest example) when operating in the "steady-state" condition, by reducing each element to a "rejector" resonant at the operating frequency.

The method is stated and is illustrated by the "low-pass" and "high-pass" filters. The general case of a filter is solved. Characteristics of the simpler types of filters are stated briefly.

The initial sending-end impedance of the line and the condition for non-reflection are written down from inspection. It is shown that, for one-way working, it is not necessary, or desirable (as is often stated), that the transmitter, receiver, and initial sending-end impedances should all be equal.

Line distortion due to reflection is considered briefly.

A worked example is given in the Appendix.

Although the method is applied here to filters only, it is readily extended to both continuous and loaded lines.

In the following method of treatment of lines consisting of recurrent circuits, no results are obtained which are not already well known, but it is believed that the method of obtaining them is novel and capable of more extended application. It would appear, too, that the method is more direct than that usually employed, and the physical properties of the circuits are kept clearly in view.

The following simple principles are used :—

(1) Any impedance may be replaced by two parallel impedances connected between the same points, the two together taking the same current in the same phase as the original impedance. There is no objection, from an analytical point of view, to one of these impedances including a negative resistance (there is now, in fact, little objection from a practical point of view).

Utilizing this principle it is possible to render every recurrent unit of a circuit of zero circuital impedance.

(2) A circuit which has a zero circuital impedance is of infinite impedance between any two points which are separated by paths neither of whose impedances is zero. (This principle is self-evident when the circuit is isolated and not coupled to any other. For the present it is sufficient to consider that case. It will, however, be shown later that, under the conditions obtaining in recurrent circuits, an equivalent self-inductance can be imagined included in each unit of the circuit to replace the mutual inductance. In this sense the term "effective impedance" is used.)

* The Papers Committee invite written communications (with a view to publication in the *Journal* if approved by the Committee) on papers published in the *Journal* without being read at a meeting. Communications should reach the Secretary of the Institution not later than one month after publication of the paper to which they relate.

(3) An infinite impedance may be connected between any two points in a circuit without producing any change in the circuit.

The application of these principles is, briefly, as follows. Fig. 1 represents any recurrent circuit, where Z_1 and Z_2 are impedances of the most general type; they may include the effective impedance introduced by any magnetic or capacity coupling between successive sections.

Let us imagine Z_2 to be replaced by two parallel

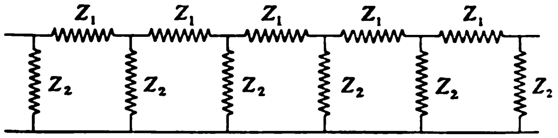

FIG. 1.

impedances, Z_2' and Z_2'', which must necessarily conform to the relation

$$\frac{1}{Z_2'} + \frac{1}{Z_2''} = \frac{1}{Z_2} \quad . \quad . \quad . \quad . \quad . \quad (1)$$

If, to define Z_2' and Z_2'' completely, it be stipulated that

$$Z_2' + Z_2'' + Z_1 = 0 \quad . \quad . \quad . \quad . \quad (2)$$

then the network has been resolved into a number of similar units, each resonant to the particular operating frequency considered (Fig. 2).

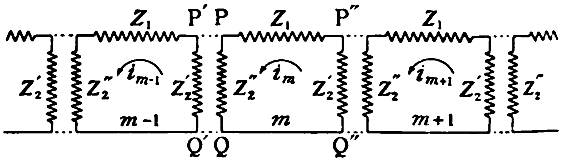

FIG. 2.

Considering the unit m, its circuital impedance is zero, and its impedance between the points P and Q (or P″ and Q″) infinite. Its connection to the unit $m-1$ at the points PP′, QQ′ in no way changes the impedance of either unit, but a further necessary condition follows, since the potentials across PQ and P′Q′ are equal, viz.

$$i_m Z_2'' = -i_{m-1} Z_2' \quad . \quad . \quad . \quad . \quad (3)$$

It therefore follows that the currents in successive units bear to one another the constant ratio

$$e^k \equiv -\frac{Z_2'}{Z_2''} \quad . \quad . \quad . \quad . \quad . \quad (4)$$

whence it follows that one solution of the circuit is afforded by the equation

$$i_n = Ae^{nk} \quad . \quad . \quad . \quad . \quad . \quad . \quad (5)$$

Noting that equations (1) and (2) constitute a quadratic relation symmetrical in Z_2' and Z_2'', it follows that

$$i_n = Be^{-nk} \quad . \quad . \quad . \quad . \quad . \quad . \quad (6)$$

is also a solution and that, in general, the current i_n will be made up of two components and may be expressed as

$$i_n = Ae^{nk} + Be^{-nk} \quad . \quad . \quad . \quad . \quad . \quad (7)$$

The current consists of two trains, one travelling from the source, the other towards it, each equally and uniformly decrescent in its direction of travel. The constants A and B are fixed by the terminal conditions.

Very long line.—In the case of an infinite line supplied from one end

$$i_\infty = 0 \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (8)$$

whence either A or B must be zero. In a long line i_n approaches zero at distances remote from the ends,

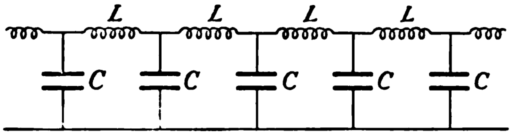

FIG. 3.

whether the line is supplied from one end only, or from both. A doubly-fed long line may be considered practically to be two infinite lines joined at their far ends.

The index k, determined by equations (1), (2) and (3), may be real, imaginary or complex, according to the natures of Z_2' and Z_2''. The equations are equally satisfied by the value $-k$. We may, therefore, define which solution we shall call k, and which $-k$. If we stipulate that the real part of k shall be negative, then it is clear that, for an infinite line, B in equation (7) must be zero and equation (5) is the one applicable.

Before proceeding to the general case the method may be illustrated conveniently by two comparatively simple cases.

Infinitely long " low-pass " filter.

Case 1. *Resistance zero.*—This circuit is represented by Fig. 3. For it equations (1) and (2) become

$$C' + C'' = C \quad . \quad . \quad . \quad . \quad . \quad . \quad (9)$$

and

$$\frac{1}{\omega C'} + \frac{1}{\omega C''} - \omega L = 0 \quad . \quad . \quad . \quad (10)$$

whence

$$\omega = 1\Big/\sqrt{\left(L\frac{C'C''}{C'+C''}\right)} \quad . \quad . \quad . \quad (11)$$

Since $C'C''/(C'+C'')$ cannot exceed $\frac{1}{4}C$ if C' and C'' are *real* fractions of C, we see that, if we define

$$\Omega \equiv 1/\sqrt{(LC)} \quad . \quad . \quad . \quad . \quad . \quad (12)$$

real values of C' and C'' can be determined so long as $\omega > 2\Omega$, but if $\omega < 2\Omega$ the values of C' and C'' must be imaginary or complex.

From equations (9), (10) and (12) we obtain

$$\left.\begin{aligned} C' &= \frac{C}{2}\left[1 + \sqrt{\left\{1 - \frac{4\Omega^2}{\omega^2}\right\}}\right] \\ C'' &= \frac{C}{2}\left[1 - \sqrt{\left\{1 - \frac{4\Omega^2}{\omega^2}\right\}}\right] \end{aligned}\right\} \quad . \quad . \quad (13)$$

If $\omega > 2\Omega$ both these values are real and positive and we have

$$e^k = -\frac{1 - \sqrt{\left\{1 - \frac{4\Omega^2}{\omega^2}\right\}}}{1 + \sqrt{\left\{1 - \frac{4\Omega^2}{\omega^2}\right\}}} \quad . \quad . \quad (14)$$

Since this expression must be negative there is a change to antiphase between sections. The numerical value of the attenuation is usually expressed

$$k = \text{arc cosh}\left(\frac{\omega^2}{2\Omega^2} - 1\right) \quad . \quad . \quad . \quad (15)$$

which follows from equation (14).

If $\omega < 2\Omega$ the determined values C' and C'' of equation (13) are complex and may be expressed as

$$\left.\begin{aligned} C' &= \frac{C}{2}\left[1 + j\sqrt{\left\{\frac{4\Omega^2}{\omega^2} - 1\right\}}\right] \\ C'' &= \frac{C}{2}\left[1 - j\sqrt{\left\{\frac{4\Omega^2}{\omega^2} - 1\right\}}\right] \end{aligned}\right\} \quad . \quad . \quad (16)$$

The physical meaning of these is clear. The condenser C is divided into two equal parts, one of which is shunted by a positive resistance, the other by an equal negative resistance.

$$e^k = -\frac{1 - j\sqrt{\left\{\frac{4\Omega^2}{\omega^2} - 1\right\}}}{1 + j\sqrt{\left\{\frac{4\Omega^2}{\omega^2} - 1\right\}}} \quad . \quad . \quad (17)$$

The numerical value of this is unity so that there is no attenuation. But there is a phase change.

Writing

$$e^k \equiv e^{\gamma + j\delta} \equiv \frac{ja - 1}{ja + 1} \equiv \frac{a^2 - 1 - 2ja}{a^2 + 1} \quad . \quad (18)$$

where $a^2 = (4\Omega^2/\omega^2) - 1$ [from (17)] we have

$$\cos\delta = \frac{a^2 - 1}{a^2 + 1} = 1 - \frac{\omega^2}{2\Omega^2} \quad . \quad . \quad . \quad (19)$$

where δ is the phase change.

The numerical values of the attenuation for various frequencies are shown in Fig. 4.

Case 2. *Inductances having resistance.*—For this case equations (1) and (2) become $C' + C'' = C$ (9)

$$-\frac{j}{\omega C'} - \frac{j}{\omega C''} + j\omega L + R = 0 \quad . \quad . \quad (20)$$

whence

$$\left.\begin{aligned} C' &= \frac{C}{2}\left[1+\sqrt{1-\frac{4\Omega^2}{\omega^2}\left\{\left(1+\frac{jR}{\omega L}\right)\Big/\left(1+\frac{R^2}{\omega^2L^2}\right)\right\}}\right] \\ C'' &= \frac{C}{2}\left[1-\sqrt{1-\frac{4\Omega^2}{\omega^2}\left\{\left(1+\frac{jR}{\omega L}\right)\Big/\left(1+\frac{R^2}{\omega^2L^2}\right)\right\}}\right] \end{aligned}\right\} \quad (21)$$

Writing

$$\sqrt{\left[1-\frac{4\Omega^2}{\omega^2}\left\{\left(1+\frac{jR}{\omega L}\right)\Big/\left(1+\frac{R^2}{\omega^2L^2}\right)\right\}\right]} \equiv \sqrt{(A+jB)} \equiv P+jQ \quad . \quad (22)$$

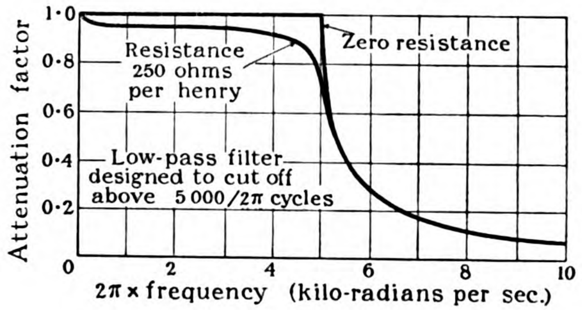

FIG. 4.

we have

$$\left.\begin{aligned} P^2 &= \frac{+\sqrt{(A^2+B^2)}+A}{2} \\ Q^2 &= \frac{+\sqrt{(A^2+B^2)}-A}{2} \end{aligned}\right\} \quad . \quad . \quad (23)$$

and

$$e^k = -\frac{1-(P+jQ)}{1+(P+jQ)} \quad . \quad . \quad . \quad (24)$$

and

$$[e^k]_{num.} = \frac{\sqrt{\{(1-P)^2+Q^2\}}}{\sqrt{\{(1+P)^2+Q^2\}}} \quad . \quad . \quad (25)$$

An examination of these expressions shows that P cannot be zero unless R is zero, and there is always attenuation. The value of that attenuation is plotted

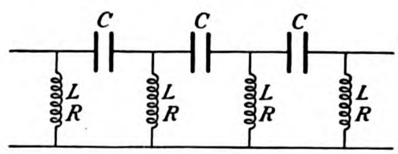

FIG. 5.

in Fig. 4 for the case in which the resistance is 250 ohms per henry, the cut-off frequency being designed to be 5 000/(2π).

Infinitely long "high-pass" filter.—For this case (shown in Fig. 5) equations (1) and (2) become

$$\frac{1}{Z_2'}+\frac{1}{Z_2''}=\frac{1}{j\omega L+R} \quad . \quad . \quad . \quad . \quad (26)$$

$$Z_2'+Z_2''-\frac{j}{\omega C}=0 \quad . \quad . \quad . \quad . \quad (27)$$

whence

$$\left.\begin{aligned} Z_2' &= \frac{j}{\omega C}\left[1-\sqrt{\left\{1-\frac{4\omega^2}{\Omega^2}\left(1-\frac{jR}{\omega L}\right)\right\}}\right] \\ Z_2'' &= \frac{j}{\omega C}\left[1+\sqrt{\left\{1-\frac{4\omega^2}{\Omega^2}\left(1-\frac{jR}{\omega L}\right)\right\}}\right] \end{aligned}\right\} \quad (28)$$

If the inductances have no resistance it is clear that for frequencies greater than ½Ω there is no attenuation, but for frequencies below ½Ω

$$e^k = -\frac{1-\sqrt{\left\{1-\frac{4\omega^2}{\Omega^2}\right\}}}{1+\sqrt{\left\{1-\frac{4\omega^2}{\Omega^2}\right\}}} \quad . \quad . \quad . \quad (29)$$

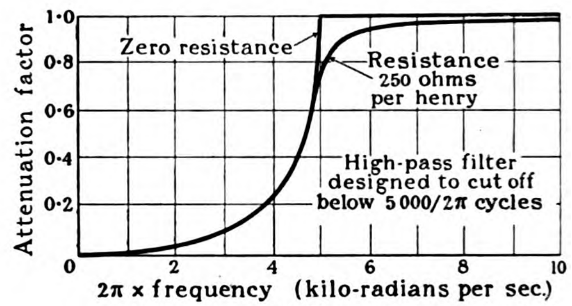

FIG. 6.

When the inductances have resistance we may write

$$\sqrt{\left[1-\frac{4\omega^2}{\Omega^2}\left(1-\frac{jR}{\omega L}\right)\right]} \equiv (A+jB) \equiv P+jQ \quad (30)$$

Equations (23), (24) and (25) then afford the solution. Values are plotted in Fig. 6.

General case.—The most commonly occurring general case is that of the T section line with a finite number of sections in which each unit may be supposed to possess a mutual inductance to immediately adjacent units (Fig. 7).

For this circuit we have

$$\frac{1}{Z_2'}+\frac{1}{Z_2''}=\frac{1}{Z_2} \quad (1)$$

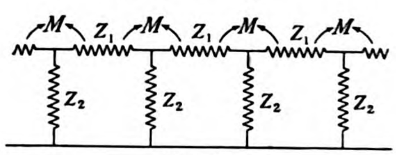

FIG. 7.

Corresponding to equation (2) we have

$$i_m(Z_1+Z_2'+Z_2'')+j\omega M i_{m-1}+j\omega M i_{m+1}=0 \quad (31)$$

We have also

$$\left.\begin{aligned} Z_2'' i_m &= -Z_2' i_{m-1} \\ Z_2' i_m &= -Z_2'' i_{m+1} \end{aligned}\right\} \quad . \quad . \quad . \quad . \quad (32)$$

Substituting (32) in (31) we obtain

$$Z_1+Z_2'+Z_2''-j\omega M\left(\frac{Z_2'}{Z_2''}+\frac{Z_2''}{Z_2'}\right)=0 \quad . \quad (33)$$

The effective impedance introduced by magnetic coupling is shown by equations (32) and (33). We may imagine, as is indicated in Fig. 8, that the impedance of each section is increased by amounts $j\omega Me^k$ and $j\omega Me^{-k}$.

Equations (1) and (33) are sufficient to determine the solution in the form of equation (7), the constants being fixed by the terminal conditions.

It may, however, be worth while to indicate the method of determining the general attenuation per section. For convenience let us write

$$\left.\begin{aligned} Z_1 &\equiv b \\ Z_2 &\equiv a \\ j\omega M &= c \\ Z_2' &\equiv x \\ Z_2'' &\equiv y \end{aligned}\right\} \quad . \quad . \quad . \quad . \quad . \quad (34)$$

The general attenuation is then $-x/y$.

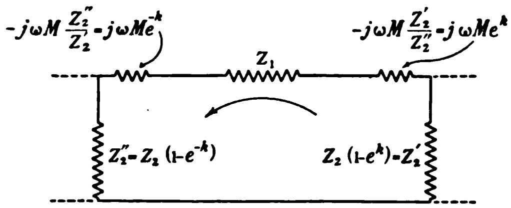

FIG. 8.

On substitution, equations (1) and (33) become

$$\left.\begin{aligned} \frac{1}{x} + \frac{1}{y} &= \frac{1}{a} \\ b + x + y - c\left(\frac{x}{y} + \frac{y}{x}\right) &= 0 \end{aligned}\right\} \quad . \quad . \quad (35)$$

whence $$x + y = \frac{b + 2c}{c - a} \cdot a \quad . \quad . \quad . \quad . \quad (36)$$

Substituting (36) in the second equation of (35) and solving for x/y we obtain

$$\frac{x}{y} = \frac{Z_2'}{Z_2''} = \frac{2a + b}{2(c - a)} \pm \sqrt{\left[\left\{\frac{2a + b}{2(c - a)}\right\}^2 - 1\right]} \quad (37)$$

which may be re-written as

$$e^k = -\frac{Z_1 + 2Z_2}{2(j\omega M - Z_2)} \mp \sqrt{\left[\left\{\frac{Z_1 + 2Z_2}{2(j\omega M - Z_2)}\right\}^2 - 1\right]} \quad (38)$$

or $$k = \text{arc cosh}\,\frac{Z_1 + 2Z_2}{2(j\omega M - Z_2)} \quad . \quad . \quad . \quad (39)$$

For any values of Z_1, Z_2 and M the attenuation may be calculated by the method indicated in equations (22) to (25).

Characteristics of various filters.—For the present, long or non-reflective lines only will be considered.

Equation (38) may be written in the form

$$e^k = x \mp \sqrt{(x^2 - 1)} \quad . \quad . \quad . \quad (40)$$

where x is in general a complex quantity (because of resistance). If x is complex, e^k must be complex and, between sections, there must be both change of amplitude and change of phase. Usually, however, the resistance will be small: the circuits become particularly interesting when the resistance is negligible. In this case x is real. If $x > 1$, e^k is wholly real and there is no change of phase (except possibly to antiphase, which may be considered to be a change of amplitude) between sections; the change is wholly one of amplitude. If $x < 1$ we may write

$$e^k = x \mp j\sqrt{(1 - x^2)} \quad . \quad . \quad . \quad (41)$$

showing that the general attenuation per section consists entirely in a phase change of magnitude arc cos x between sections, there being no change of amplitude.

Assuming that both Z_1 and Z_2 are single impedances, neither possessing both positive and negative reactance, then x must increase or decrease continuously, as the frequency changes. Change of amplitude can, therefore, only occur on *one* side of a definite cut-off frequency. Change of phase can only occur on the *other* side of the same frequency.

This point has already been illustrated in the case of the "low-pass" and "high-pass" filters having no resistance. Figs. 4 and 6 show this point of cut-off

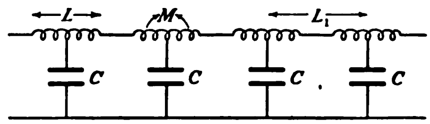

FIG. 9.

and also the manner in which practical conditions deviate from the ideal when the circuits have resistance.

If we consider the recurrent circuit of Fig. 9 it is clear that in a general way its characteristics will be similar to those of the "low-pass" filter of Fig. 3. There will be no reduction of amplitude until a definite cut-off frequency is attained. The circuit, however, becomes of particular interest when we may consider the loading coils to have no leakage. If the inductance of each is L we have the inductance per section

$$L_1 = \tfrac{1}{2}L \quad . \quad . \quad . \quad . \quad . \quad (42)$$

and $$M = \tfrac{1}{4}L \quad . \quad . \quad . \quad . \quad . \quad (43)$$

Substituting these values in (38) we find that it reduces to the form of (41), where

$$x = \frac{4 - \omega^2 LC}{4 + \omega^2 LC} \quad . \quad . \quad . \quad . \quad (44)$$

This expression is numerically always less than unity and hence there is no amplitude attenuation at any frequency. All frequencies are transmitted equally well. Such a circuit does not act as a filter at all. An examination of (44) shows, however, that so long as $\omega^2 LC$ is fairly small the phase change per section is proportional to the frequency, or the time-lag is constant.

In short lines, which are reflective, amplitude change between sections must occur, even though the numerical value of e^k is unity. For, in this case, the current in each section is made up of two numerically constant components the relative phase of which changes by an amount 2 arc cos x between one section and the next. The current in a section may therefore have any value between $[A]_{num.} + [B]_{num.}$ and $[A]_{num.} - [B]_{num.}$.

If instead of considering successive sections we fix our attention upon one particular section, and imagine the frequency to increase progressively, it is clear that the magnitude of the current will pass through a series of variations of a similar nature. Certain frequencies will therefore be transmitted with undue prominence. It is, however, possible to render the line sensibly non-reflective over the most important part of the range of transmissible frequencies; this type of distortion then practically disappears.

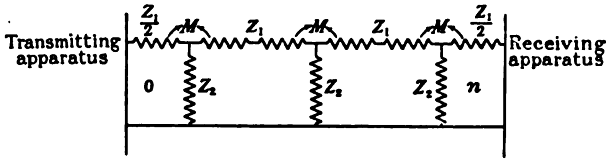

FIG. 10.

Initial sending-end (or surge) impedance. Non-reflective lines.—The initial sending-end impedance Z_0 is defined as that impedance by which the line, imagined long or non-reflective, can be replaced without changing the current in the zero section. The completed general line is shown in Fig. 10; Fig. 11 shows the line resolved (see also Fig. 8). It is clear that if the line is long or non-reflective the initial sending-end impedance is that included between the points X and Y, and we have

$$Z_0 = \tfrac{1}{2}Z_1 + j\omega M e^k + Z_2(1 - e^k) \quad . \quad . \quad (45)$$

or, substituting from (38),

$$Z_0 = \sqrt{\{(\tfrac{1}{2}Z_1 + Z_2)^2 - (j\omega M - Z_2)^2\}} \quad . \quad (46)$$

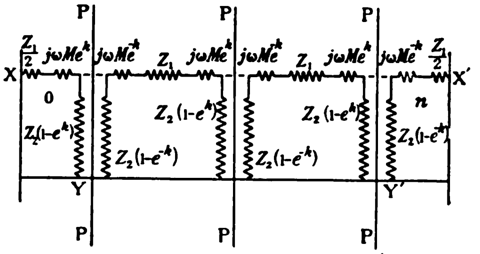

FIG. 11.

Since the line would be non-reflective if everything to the right of any line such as PP (Fig. 11) were removed, it will be equally non-reflective if an impedance

$$Z_R = Z_0 \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (47)$$

be connected between the points X', Y'. This is, therefore, the necessary condition for non-reflection at the receiving end.

If this condition could be fulfilled over the whole range of transmissible frequencies no undue prominence would be given by the *line* to any particular frequency (neglecting the small progressive change due to line resistance). The matter cannot, however, be so simply dismissed. An examination of (46) shows that for a line without resistance, Z_0 is of the nature of a pure resistance, over the range of frequencies transmitted. For a line having resistance its value approximates to a pure resistance. In any case, however, its magnitude is a function of the frequency, becoming zero (or nearly zero) at the point of cut-off.

All that it is possible to do, therefore, is to select a value for Z_R which shall be equal to Z_0 in the middle of the most important band of frequencies. Then over a considerable range the line will be sensibly non-reflective.

For instance, for the low-pass filter of no resistance (Fig. 3)

$$Z_0 = \sqrt{[(L/C) - (\omega^2 L^2/4)]} \quad . \quad . \quad . \quad (48)$$

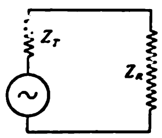

FIG. 12.

At the point of cut-off ω is $2/\sqrt{(LC)}$ and Z_0 is zero. Its value is $\sqrt{(L/C)}$ for low frequencies.

Undue prominence may also be given to particular frequencies by incorrect choice of the impedance of the transmitting apparatus. If the line is rendered practically free from distortion the current in the receiving section will bear an approximately constant ratio to the current in the transmitting section. It is necessary that this current in the transmitting section should be more or less independent of frequency. If

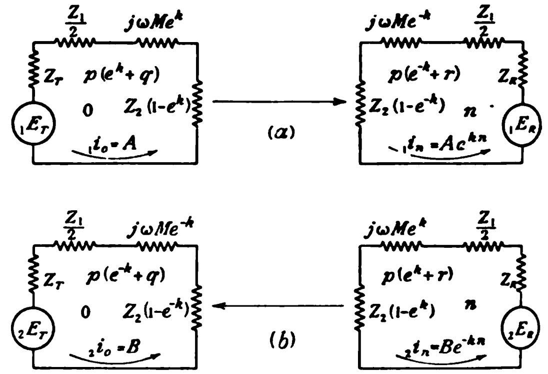

FIG. 13.

we assume that Z_R has been made equal to Z_0, the zero section may be represented by Fig. 12. It is then seen that the necessary condition is that $Z_T + Z_R$ should approximate as closely as possible to a pure resistance.

For maximum current transmitted $Z_T + Z_R$ should be as small as possible.

The general solution for a reflective line.—We have already considered the possibility of making the receiving section of the line non-reflective by adjustment of the receiver impedance. We may, however, imagine the same result effected by a source of potential inserted in the final section to supply the current through the impedance which actually exists.

For a potential ${}_1E_T$ in the zero section, transmitting to the nth section, suppose that a potential ${}_1E_R$, in the nth section, makes the line non-reflective (Fig. 13*a*). Assume that these potentials are removed and that a

potential ${}_2E_R$ is inserted in the nth section, transmitting to the zero section. To make the line non-reflective a potential ${}_2E_T$ is inserted in the zero section (Fig. 13*b*).

If we write

$$\left.\begin{aligned} p &\equiv j\omega M - Z_2 \\ q &\equiv \frac{Z_T + \frac{1}{2}Z_1 + Z_2}{j\omega M - Z_2} \\ r &\equiv \frac{Z_R + \frac{1}{2}Z_1 + Z_2}{j\omega M - Z_2} \end{aligned}\right\} \quad . \quad . \quad . \quad (49)$$

then we have

$$\left.\begin{aligned} {}_1E_T &= Ap(e^k + q) \\ {}_1E_R &= Ap(e^{-k} + r)e^{kn} \\ {}_2E_T &= Bp(e^{-k} + q) \\ {}_2E_R &= Bp(e^k + r)e^{-kn} \end{aligned}\right\} \quad . \quad . \quad . \quad (50)$$

Actual reflective conditions are obtained by superposing these two transmissions, making

$$\left.\begin{aligned} {}_1E_T + {}_2E_T &= E_T \\ {}_1E_R + {}_2E_R &= E_R \end{aligned}\right\} \quad . \quad . \quad . \quad . \quad (51)$$

Suppose that $E_R = 0$, then we have

$$\left.\begin{aligned} Ae^{kn}(e^{-k} + r) + Be^{-kn}(e^k + r) &= 0 \\ A(e^k + q) + B(e^{-k} + q) &= E/p \end{aligned}\right\} \quad . \quad (52)$$

Let us write

$$X \equiv \frac{e^k + q}{e^{-k} + q}, \quad Y \equiv \frac{e^k + r}{e^{-k} + r} \quad . \quad . \quad (53)$$

giving us

$$\left.\begin{aligned} AX + B &= \frac{E}{p(e^{-k} + q)} \\ Ae^{kn} + Be^{-kn}Y &= 0 \end{aligned}\right\} \quad . \quad . \quad . \quad (54)$$

or

$$\left.\begin{aligned} B &= \frac{E}{p(e^{-k} + q)(1 - e^{-2kn}XY)} \\ A &= \frac{-Ye^{-2kn}E}{p(e^{-k} + q)(1 - e^{-2kn}XY)} \end{aligned}\right\} \quad . \quad . \quad (55)$$

The following transformations are of value. From equation (33) and Fig. 8 we have

$$(j\omega M - Z_2)(e^k + e^{-k}) + Z_1 + 2Z_2 = 0 \quad . \quad (56)$$

or

$$\frac{\frac{1}{2}Z_1 + Z_2}{j\omega M - Z_2} = -\frac{e^k + e^{-k}}{2} \quad . \quad . \quad . \quad (57)$$

giving us

$$\left.\begin{aligned} q &= \frac{Z_T}{p} - \frac{e^k + e^{-k}}{2} \\ r &= \frac{Z_R}{p} - \frac{e^k + e^{-k}}{2} \end{aligned}\right\} \quad . \quad . \quad . \quad (58)$$

whence

$$\left.\begin{aligned} X &= \frac{2Z_T + p(e^k - e^{-k})}{2Z_T - p(e^k - e^{-k})} \\ Y &= \frac{2Z_R + p(e^k - e^{-k})}{2Z_R - p(e^k - e^{-k})} \end{aligned}\right\} \quad . \quad . \quad . \quad (59)$$

When the attenuation becomes great the values of A and B reduce to

$$\left.\begin{aligned} A &= \frac{2E}{2Z_T + p(e^k - e^{-k})} \\ B &= -\frac{e^{2kn}}{Y} \cdot \frac{2E}{2Z_T + p(e^k - e^{-k})} \end{aligned}\right\} \quad . \quad (60)$$

Selective transmission of particular frequencies.—Reference has already been made to the fact that in a reflective line particular frequencies may transmit with undue prominence. This can be clearly seen from the quantities just deduced. Let us consider a filter having no resistance, the impedances Z_T and Z_R being negligible. In this case the distortion is exaggerated, but the assumption enables us to examine the nature of the phenomenon easily.

For this case

$$X = -1, \; Y = -1, \; q = -\tfrac{1}{2}(e^k + e^{-k}) = r \quad . \quad (61)$$

$$e^{-k} + q = \tfrac{1}{2}(e^{-k} - e^k) \quad . \quad . \quad . \quad (62)$$

$$\left.\begin{aligned} A &= \frac{2e^{-2kn}}{p(e^{-k} - e^k)(1 - e^{-2kn})}E \\ B &= \frac{2}{p(e^{-k} - e^k)(1 - e^{-2kn})}E \end{aligned}\right\} \quad . \quad . \quad (63)$$

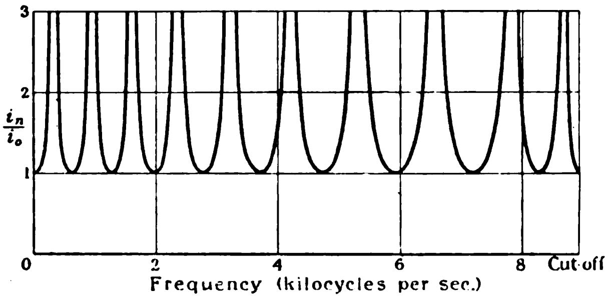

FIG. 14.

The transmitted current

$$i_0 = \frac{2E}{p(e^{-k} - e^k)} \cdot \frac{1 + e^{-2kn}}{1 - e^{-2kn}} \quad . \quad . \quad (64)$$

The received current

$$i_n = \frac{2E}{p(e^{-k} - e^k)} \cdot \frac{2e^{-kn}}{1 - e^{-2kn}} \quad . \quad . \quad (65)$$

$$\therefore \frac{i_n}{i_0} = \frac{2e^{-kn}}{1 + e^{-2kn}} = \frac{2}{e^{kn} + e^{-kn}} \quad . \quad . \quad (66)$$

This may be written

$$\left.\begin{aligned} \frac{i_n}{i_0} &= \sec n\alpha \\ \text{where} \quad e^k &\equiv \cos\alpha + j\sin\alpha \end{aligned}\right\} \quad . \quad . \quad . \quad (67)$$

(we are only considering the case where the numerical value of e^k is unity).

From one end of the frequency scale to the point of cut-off, α changes from 0 to π. Hence $n\alpha$ changes by an angle π as many times as there are sections in the line. Fig. 14 shows a rough graph of this ratio for a low-pass filter of 10 sections, having no resistance and cutting off at about $\omega = 8\,900$.

APPENDIX.

Solution of a General Case.

The quantities chosen in the following example are intended to be illustrative rather than practical. The circuit is that of Fig. 10. The chokes are assumed to have considerable leakage, so that an approximate cut-off is obtained within the practical range of frequencies. The line is supposed to consist of 10 sections. The constants of the circuit are :—

$$L = 0\cdot5\text{H},\ M = 0\cdot1\text{H},$$

whence $L_1 = 0\cdot3\text{H}$, $C = 0\cdot5 \times 10^{-6}\text{ F}$, $R_1 = 100$ ohms, $Z_T = Z_R = 1\,000$ ohms, $n = 10$.

Beyond the point of cut-off ($\omega = 8\,944$) the approximate expressions (60) may be used. As far as the transmitted current is concerned B is negligible after cut-off, but it naturally contributes a substantial fraction of the received current.

The received current is determined as follows :—

$$i_n = Ae^{kn} + Be^{-kn} \quad . \quad . \quad . \quad . \quad (68)$$

Substituting from (54) we obtain

$$i_n = Ae^{kn}\left(\frac{Y-1}{Y}\right) \quad . \quad . \quad . \quad . \quad (69)$$

If only the amplitude of the current is required we may write

$$[i_n]_{num.} = [A]\,[e^{kn}]\left[\frac{Y-1}{Y}\right] \quad . \quad . \quad (70)$$

The method and order of working are clear from Tables 1 to 5. The effect of reflection is clearly seen, although it is limited.

THE ATTENUATION OF WIRELESS WAVES DUE TO THE RESISTANCE OF THE EARTH.*

By R. L. SMITH-ROSE, D.Sc., Ph.D., and R. H. BARFIELD, M.Sc., Associate Members.

[Communicated by peımission of the Radio Research Board.]

(*Paper first received* 10*th December*, 1925, *and in final form* 15*th February*, 1926.)

SUMMARY.

The paper calls attention to the present condition of knowledge on the subject of the attenuation of wireless waves travelling over the earth's surface, due to energy absorption by the earth itself. The theories put forward on this problem by Sommerfeld and Zenneck are briefly outlined, and it is shown that the latter has taken account only of a special case of the more general theory of Sommerfeld. The results deduced from this theory have been worked out for some typical practical cases of both short- and long-wave transmission, but, owing to the complete lack of experimental evidence, no practical test of the theory has yet been made. In view of the importance of a knowledge of ground absorption in connection with the complete study of the propagation of wireless waves of all lengths over the earth's surface, it is highly desirable that a systematic experimental investigation should be carried out in the near future.

(1) SCOPE OF THE PAPER.

During recent years the problem of the propagation of wireless waves over the earth's surface has been attacked by several experimenters by the systematic measurement of the intensity and direction of the fields arriving at a receiver from a distant transmitting station. The results of this research show generally that two series of waves arrive at the receiving station from the transmitter. The first of these is the "direct" wave which is propagated along the surface of the earth following its curvature by diffraction. The second series comprises those "indirect" waves which have travelled by way of the upper regions of the atmosphere, having reached the receiver by one or more suitable deflections. In a complete study of the problem it is evidently very desirable to ascertain what are the relative contributions of the direct and indirect waves to the resultant field strength under all practical conditions of wireless transmission over the earth's surface; and, further, to account on satisfactory theoretical grounds for all the experimental results obtained.

The complete problem may be conveniently divided into two parts: first, that of determining the field strength at distances from the transmitter so great that the curvature of the earth has to be taken into account; and second, that of determining this quantity at points relatively close to the receiver, i.e. over distances for which the earth may be considered flat. The first part of the problem has proved to be of greater interest in the past and has accordingly had a great deal of attention paid to it. This has probably been due to the fact that within the range of wave-lengths to which commercial communication has been restricted in the past, no difficulty was experienced in obtaining satisfactory transmission over distances which come within the second category. Within this region it is evident that the direct wave will appreciably contribute to the resultant field strength, and it is thus important to have an exact knowledge of the extent to which this wave is attenuated due to the finite conductivity of the earth. This question is becoming more important with the use of shorter wave-lengths, and cases are already on record in which the direct wave has become too weak for detection or measurement at distances much less than those at which the indirect wave has become the sole contributor to the field at the earth's surface. For example, in some observations published by A. H. Taylor,* it has been shown that for wave-lengths of 40 metres and less, and with a given power, the maximum range of transmission directly along the earth's surface was less than 100 miles, and that no signals could be received at greater ranges until a distance exceeding 400 miles was reached. At these greater distances the signals were evidently due to the reception of waves from the upper atmosphere. The intervening range in which neither the direct nor the downcoming waves can be received is commonly referred to as the "jump over" or "skipped distance."

This attenuation problem has been studied theoretically by Sommerfeld † and Zenneck ‡, but as far as the authors are aware the formulæ which they obtained have never been experimentally tested. In Sommerfeld's work, results were obtained which can be employed for the calculation of attenuation over a very large range of wave-lengths, including the shorter waves which are now coming into practical use and on which the matter has assumed greatly increased importance. Owing to the lack of experimental data upon the subject, an investigation has been planned and will be carried out as soon as opportunity permits. Pending the results of this, it has been considered useful to give a brief outline of Sommerfeld's work, together with a series

of attenuation curves calculated for such cases as are of interest.

(2) Outline of Sommerfeld's Theory.

Given a Hertzian oscillator situated on the earth's surface, Sommerfeld obtains an expression for the intensity of the field at any other point on the earth, taking into account the conductivity and dielectric constant of the ground. Throughout his work he neglects the effect of the curvature of the earth and assumes the atmosphere to be homogeneous. (It may be pointed out here that Duddell and Taylor's experimental results for transmission oversea, as mentioned on page 769, show that the effect of the curvature of the earth up to a distance of 60 miles is practically negligible.) The formulæ obtained by Sommerfeld, which are most suitable for numerical calculation, are simplified by assuming $2\sigma/f$ to be much greater than unity, where σ is the conductivity of the earth in electrostatic units, and f is the frequency corresponding to the waves. Taking the accepted value of σ as 10^8 * for land in this country, then $2\sigma/f$ will exceed 10 for all wave-lengths above 15 metres, and so this assumption is applicable to almost the entire range of practical cases.

The notation employed for this résumé is as follows :— Principal axes are assumed with the transmitter at the origin and Ox the direction of transmission.

K = dielectric constant of the earth,
σ = conductivity of the earth,
f = frequency,
$j = \sqrt{(-1)}$
$K' = K - (j2\sigma/f)$
$\mu = \sqrt{K'}$ = " refractive index " of the earth,
P = vector potential = distance rate of change of the radiated magnetic field = $\partial H/\partial x$.

$$\rho = \frac{\pi}{\mu^2} \cdot \frac{x}{\lambda} = \text{" numerical distance."}$$

Beginning with the classical equations of Clerk Maxwell and applying boundary conditions, Sommerfeld obtains a series for P which is finally reduced to forms suitable for calculation. The approximate solutions differ according to whether the numerical distance ρ is large or small.

(a) If ρ is large, say, not less than 10, then the following equation applies :—

$$P = -\left\{\frac{1}{2\rho} + \frac{1\,.\,3}{2\,.\,2\rho^2} + \frac{1\,.\,3\,.\,5}{2\,.\,2\,.\,2\rho^3} + \ldots\right\}\frac{e^{j2\pi x/\lambda}}{x} \qquad (1)$$

When ρ is very large this reduces to

$$P = \frac{A\lambda^2}{x^2} \quad . \quad . \quad . \quad . \quad . \quad . \qquad (2)$$

i.e. for a given current in the oscillator the radiated field intensity is proportional to the square of the wave-length and inversely proportional to the square of the distance.

(b) If ρ is small, the approximate formula is as follows :—

$$P = (u - jv)\frac{e^{j2\pi x/\lambda}}{x} \quad . \quad . \quad . \quad . \qquad (3)$$

where $$u = 1 - \frac{2}{1}\rho + \frac{2\,.\,2}{1\,.\,3}\rho^2 - \frac{2\,.\,2\,.\,2}{1\,.\,3\,.\,5}\rho^3 + \ldots$$

and $$v = \sqrt{(\pi\rho)}e^{-\rho}$$

From formulæ (1) to (3) it is possible to calculate the intensity of the radiation field at any distance over which it can be assumed that the curvature of the earth produces no appreciable effect.

(3) Discussion of Calculations from Sommerfeld's Equations.

In Figs. 1 to 4 the values of the radiated field have been calculated for distances up to 150 km and for wave-lengths from 30 to 1 000 m. Graphs are given

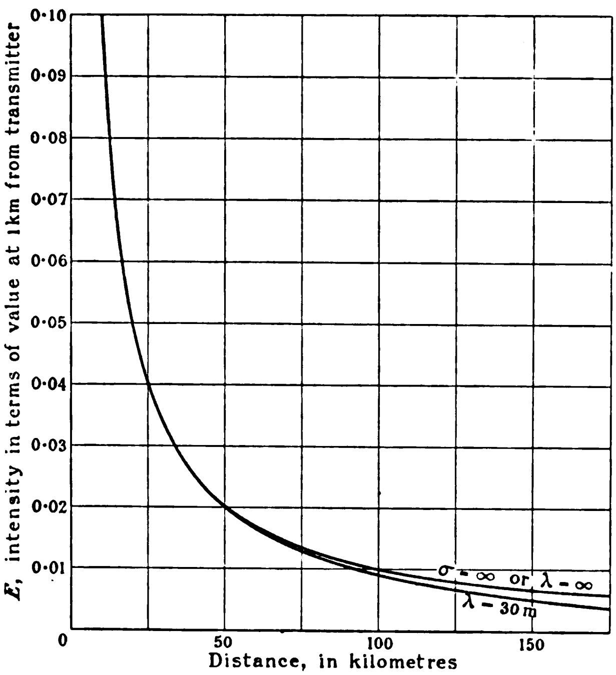

Fig. 1.—Attenuation over sea ($\sigma = 10^{10}$ E.S.U.).

for transmission over sea water (assuming $\sigma = 10^{10}$ E.S.U.*) and over land for which $\sigma = 10^8$ E.S.U.† In Figs. 1 and 2 the actual field intensity at various distances is shown in terms of the value at 1 km from the transmitter. In Figs. 3 and 4 the results are shown as the ratio of the intensity of the field which pertains for transmission over sea or land to the intensity which would be obtained if the earth were a perfect conductor.

In each of Figs. 1 to 4 a curve is given as applying to the condition $\lambda = \infty$ or $\sigma = \infty$. It is of course realized that in considering the radiated field intensity the minimum distance of the point under consideration from the transmitter is of the order of a wave-length. The above hypothetical curves are, however, inserted as showing the upper limits of the field intensity which could be obtained either by using very long wireless waves or by transmission over a perfectly conducting earth.

* This corresponds to approximately 10^{-13} in electromagnetic units, or to 10 000 ohms per cm cube.

* Equals approximately 10^{-11} in E.M.U., or 100 ohms per cm cube.
† Equals approximately 10^{-13} in E.M.U., or 10 000 ohms per cm cube.

(*a*) *Transmission over sea.*—Figs. 1 and 3 demonstrate very clearly that for wave-lengths above 100 m the attenuation over sea is practically identical with that

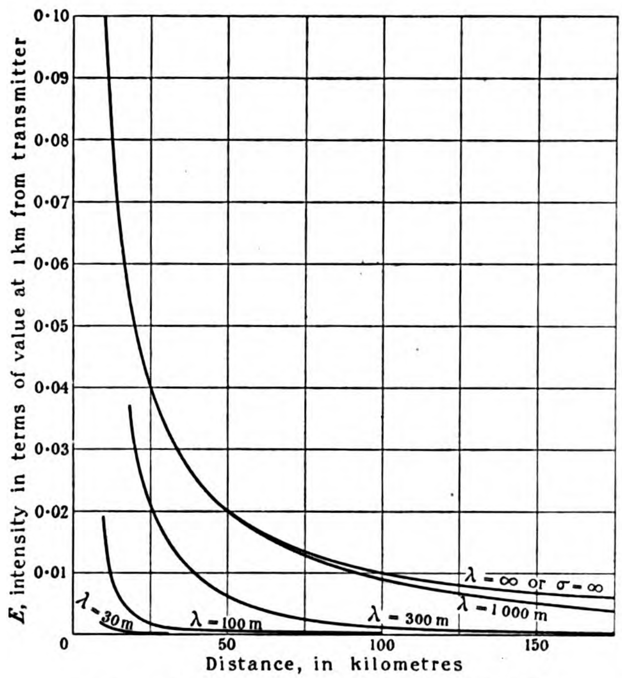

FIG. 2.—Attenuation over land ($\sigma = 10^8$ E.S.U.).

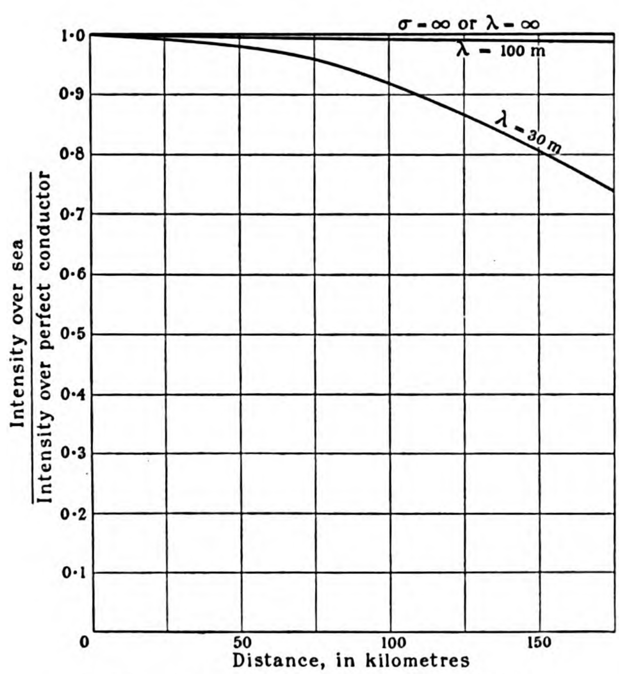

FIG. 3.—Attenuation over sea ($\sigma = 10^{10}$ E.S.U.).

which would hold for the ideal case of a perfect conductor, the field intensity decreasing inversely as the distance. With a wave-length of 30 m, however, a noticeable departure from the ideal case is observed, and at a distance of 150 km the field has fallen to about 0·8 of its ideal value.

(*b*) *Transmission over land.*—When the transmission is entirely over land the effect of the energy absorption due to the higher resistance is very marked on wave-lengths below 1 000 m, as shown in Figs. 2 and 4. The 1 000-m wave is attenuated over land to approximately the same extent as the 30-m wave over sea. On a wave-length of 300 m, however, the intensity at a distance of 150 km over land is only 0·08 of the ideal value or of its value for transmission over sea to the same distance. On the shorter wave-lengths the attenuation becomes still more marked. For example, on a wave-length of 30 m the intensity at only 10 km over land is reduced to 0·01 of its ideal or approximate

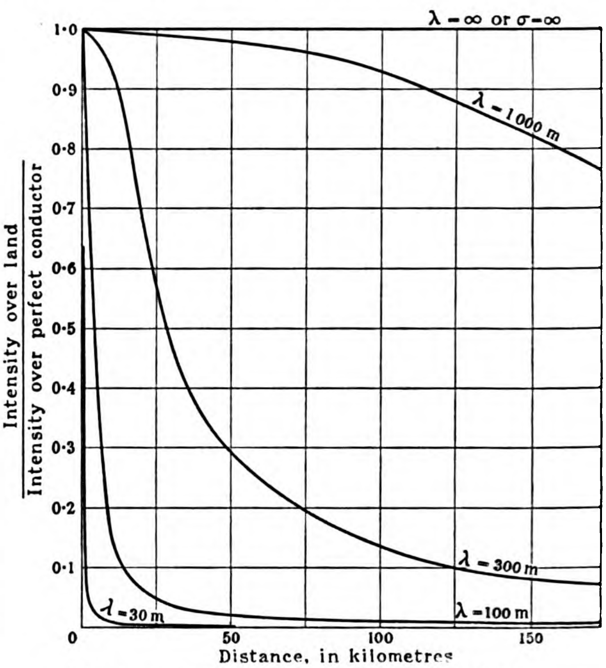

FIG. 4.—Attenuation over land ($\sigma = 10^8$ E.S.U.).

over-sea value, which is equivalent to 0·001 of the intensity at 1 km from the transmitter.

Such examples serve to illustrate very clearly the great disadvantage of the shorter wave-lengths for transmission over small and medium distances, at which the curvature of the earth and the effects of the upper atmosphere are negligible.

(4) ZENNECK'S ANALYSIS AS A PARTICULAR CASE OF SOMMERFELD'S THEORY.

In his analysis of the effect of the finite conductivity of the earth on wireless-wave propagation, Zenneck simplified the problem by making the assumption that at a large distance from the transmitter the wave may be considered plane, thereby neglecting the ordinary attenuation of the wave due to spreading. On this basis Zenneck showed that the decrease in intensity of the wave could be represented by an expression of the form

$$E = Be^{-ax} \quad . \quad . \quad . \quad . \quad . \quad (4)$$

where a is an attenuation constant depending upon the constants of the earth and the wave-lengths, viz. $a = \pi/(\mu^2\lambda)$. It is thus evident that the quantity ax is identical with Sommerfeld's ρ, and that this part of the attenuation is embodied in the value of v which forms part of equation (3) above. Under certain conditions when u approaches zero, equation (3) for the intensity takes the form of equation (4). Indeed, Sommerfeld pointed out this in his theoretical work and showed that this constituent part, which may be called "Zenneck's wave," is of the nature of a surface wave and that, apart from its attenuation due to earth resistance, the field intensity varies inversely as the square root of the distance.

It is clear, therefore, that Zenneck provided a partial solution which is valid only under particular conditions, while Sommerfeld's solution is quite general. Since Sommerfeld includes Zenneck's particular case, there would appear to be no point in making any calculations from the latter's formulæ. It is interesting, however, to ascertain under what conditions Zenneck's theory gives an approximate solution. This information is readily obtainable from Sommerfeld's theory and is recorded in Table 1.

TABLE 1.

Wave-length	Range of transmission over which equation (4) is valid	
	Over land ($\sigma = 10^8$)	Over sea ($\sigma = 10^{10}$)
m	km	km
10 000	10 000 to 32 000	Too large for practical use
3 000	900 to 3 100	Too large for practical use
1 000	100 to 320	Too large for practical use
300	9 to 31	9 800 to 29 000
100	1·0 to 3·1	1 100 to 3 300
30	0·09 to 0·3	98 to 290

This table shows that the applicability of Zenneck's solution is very limited. Thus on land and with a wave-length of 1 000 m and upwards it is never valid in the first 100 km; and at distances much larger than this the curvature of the earth would have to be taken into account and both Zenneck's and Sommerfeld's formulæ become invalid. For wave-lengths less than 1 000 m the range of validity over land is very small. Thus on 300 m it is only 22 km, and on 100 m it is only 2 km. For over-sea transmission the distances over which Zenneck's formula could be used are not small enough for the earth to be assumed plane for any wave-lengths above 30 m. It appears, therefore, that on nearly all wave-lengths at present in use for commercial purposes the conditions under which Zenneck's theory holds good are so limited as to render his formulæ of little value for practical purposes.

(5) PREVIOUS EXPERIMENTAL RESULTS.

As far as the authors have been able to ascertain, the only previously published papers which provide any reliable data upon the problem under discussion are those of Duddell and Taylor describing experiments made as long ago as 1905,* and of Bown and Gillett published in 1924.† It is significant of the lack of interest in this subject that apparently no investigation of it was carried out in the intervening 19 years.

The first of the above papers describes two sets of experiments, the first made over land in Bushy Park, Teddington, and the second over sea across the St. George's Channel. In both experiments a spark transmitter was used and was moved to various positions while the corresponding current in the receiving aerial was measured by means of a thermo-galvanometer. In the first series of experiments carried out in Bushy Park the range of transmission was quite small, never being greater than 7 500 ft. (2·25 km). Also the site of the experiments was far from uniform, the open grass spaces being interspersed among clumps of large trees of several hundred yards in extent. In view of these considerations and of the fact that the wave-length employed was 400 to 500 ft. (120 to 150 m), and of the probable serious effect of the trees on such short waves, it is not considered that the conditions of the experiments were such as to provide data sufficiently reliable for comparison with any theoretical formulæ. The experiments did, however, show quite clearly that the intensity of the waves decreased much more rapidly than the inverse distance from the transmitter, a fact which was probably due to absorption of energy by the ground and trees.

The second series of experiments of Duddell and Taylor were much more satisfactory, being carried out over an open-sea path at distances up to 60 miles (96 km). The wave-length employed is not stated, but was probably of the same order as above. Under these conditions the results of the measurements showed that the received current and, thus, the field intensity of the waves were practically inversely proportional to the distance, as would be the case for uniform spreading over a plane perfect conductor. The product of received current and distance did show a steady but small decrease over the range of transmission. This decrease represents the sum of that corresponding to the small attenuation of such waves when transmitted over sea-water, as indicated from the theoretical curve in Fig. 3, and the decrease which would be caused by the slight but appreciable curvature of the earth over a distance of 100 km.

In Bown and Gillett's experiments it is perhaps natural to find that the conditions were a little more satisfactory. The measurements were made with a portable coil receiver on the undamped-wave transmissions from broadcasting stations in New York and Washington, U.S.A. In the paper referred to the results are well represented both in the form of curves showing the decrease of field strength with distance, and as contour maps giving the curve of uniform field distribution round the transmitting station. On the wave-length of 469 m employed, these results show very clearly that the attenuation is small over river water and increasingly greater for moist grass-land and dry sandy soil. The experiments also clearly demonstrate

* W. DUDDELL and J. E. TAYLOR: "Wireless Telegraphy Measurements," *Journal I.E.E.*, 1905, vol. 35, p. 321.

† R. BOWN and G. D. GILLETT: "Distribution of Radio Waves from Broadcasting Stations over City Districts," *Proceedings of the Institute of Radio Engineers*, 1924, vol. 12, p. 395.

the high absorption which is experienced when the transmission is over tall iron-frame buildings as in the New York City area.

By dissecting the curves for the different natures of the path of transmission, Bown and Gillett compared the measured results with the well-known Austin-Cohen transmission formula, which is as follows :—

$$\text{Field strength} = \left\{ 377 \frac{h_s I_s}{\lambda x} \right\} e^{-\alpha x/\sqrt{\lambda}} \text{ microvolts per metre} \quad . \quad (5)$$

where h_s = effective height of the transmitting aerial in metres ;

I_s = transmitting aerial current in amperes ;

λ = wave-length in km ;

x = distance in km.

The attenuation due to resistance absorption is expressed by the quantity $e^{-\alpha x/\sqrt{\lambda}}$ and the measured values of α are given in the paper as :—

0·028 for dry sandy soil,
0·009 for moist soil,
0·0025 for water,

while the value of 0·0015 is commonly used in the above formula for over-sea transmission in daylight. As this attenuation formula is of an empirical nature, however, and, further, as it needs verification for other wave-lengths, it is not of much value in making comparisons with the theoretical formulæ discussed in Sections (2) and (3). Furthermore, the fact that the measurements were made over ranges which comprised patches of soil of a varying nature, of which no information was obtained as to the effective conductivity, would also make a direct comparison with theory very difficult.

(6) Conclusions.

In this paper the authors have thus arrived at the conclusion that for wireless-wave transmission over comparatively short distances under conditions where it is necessary to take into account the resistance of the earth, Sommerfeld's analysis alone leads to a means of calculating the attenuation for all practical cases. The graphs in the paper provide in summarized form the practical information to be derived from this theory. Owing to the complete lack of experimental evidence on the subject, it is as yet impossible to state whether the theoretical values are in accordance with those obtained in practice.

It is evident that what is wanted is a series of careful measurements giving either the absolute or the comparative field strengths at different distances up to say 50 or 100 km, the transmission being made over ground as uniform as possible, the conductivity of this ground having been measured by an independent method such as has already been employed in England.* It will, of course, be a condition of these measurements that any waves received from the upper atmosphere have no perceptible effect.

DISCUSSION ON

"DIELECTRIC PROBLEMS IN HIGH-VOLTAGE CABLES." *

MERSEY AND NORTH WALES (LIVERPOOL) CENTRE, AT LIVERPOOL, 15 FEBRUARY, 1926.

Mr. W. P. Fuller: The paper seems to show how very much we are in the dark with regard to the behaviour of dielectrics when it becomes necessary to use a formula with two supposed constants which are actually functions of time. As the author states, liquid dielectrics also show absorption and it is difficult to imagine systems of capacities and resistances, having different time constants, in a liquid. I think that something more fundamental than Maxwell's conception is required, and that we shall have to go to the atom to find a satisfactory explanation. The " V " curve seems to be characteristic not only of a cable but of its constituents. Some cable compounds give a " V " curve, and some do not, at any rate above 15° C. The characteristic is to be found in dry paper alone, and the curve obtained with a cable is a resultant depending on the constituent parts and on their distribution. Hence for given materials the relationship between the losses at different frequencies will depend on the proportion of oil in series with the paper fibres and the proportion in parallel, and, due to the same causes, the d.c. conduction cannot be used as a basis to deduce the a.c. loss. I am inclined to agree with the author's explanation in Section (IX) of the cause of cable breakdown, namely, that there is a deflection of the electric field in a direction parallel to the fibres due to contact effects, although the difference of contact in various parts can be only a few mils and it is difficult to see how this alone can cause a considerable field displacement.

Mr. E. L. Morland: Dielectric problems in high-voltage cables for pressures between 20 kV and 66 kV are still, unfortunately, a subject of research, and the need for reliable super-tension cable is, I am afraid, ahead of cable development. The air pockets in the impregnating medium, which at voltages up to 20 kV may not be detrimental, present a difficult dielectric problem when the voltage is above that figure. Chemical changes resulting in breakdown may occur slowly or quickly, in accordance with the condition of the dielectric, at different hot spots which are, I think, due to air entrapped during the process of manufacture and occasionally while jointing is in progress. Generally, the condition of charring takes, I think, some time for breakdown to occur, and is not affected by transient surges. This condition of entrapped air would seem to point to a radical change in the design, and possibly one solution may lie with an impregnating fluid which, owing to its nature, does not result in a cable which is unstable under working conditions, and which yet allows a more complete disturbance of the air voids each time the cable is heated under load and cooled off. This would tend to prevent oxidation and the forming and charring of leakage paths, which result in complete puncture and failure. Tests taken on sample lengths of cable, heated and cooled many times, over a range of temperature between 65° F. and 140° F., should show after each test very slight variation in the dielectric power factor of the cable, which, complying with the conditions I have mentioned, is not subject to the progressive deterioration at present met with.

Mr. P. J. Robinson: Can the author say whether any experiments have been carried out with paper impregnated with de-aerated oil, and whether samples of paper impregnated in the ordinary way have been compared from an electrical pressure point of view with samples of paper impregnated with de-aerated oil, and if so with what results? Quite recently I carried out some experiments in connection with the de-aeration of water and I thought that by covering the surface of the de-aerated water with a heavy mineral oil I could keep the air from mixing with it, but in a relatively short time the air had passed through the oil and the water was appreciably aerated. I mention this as a matter of interest, and as a lead-sheathed cable excludes all free air from entering the cable the author's opinion of de-aeration will be of considerable interest. What precautions are taken in hilly districts to avoid big pressures due to static head? Obviously, whether the insulating material is fluid or semi-plastic, it will drain to the lowest point and create a pressure there which is dependent on the head due to the elevation of the hill. Also, if precautions are taken, what head does the author consider should be fixed upon as a maximum allowable? It is obvious that any draining to one point which may be bulged owing to heating and cooling or pressure due to head will create a space at the highest point of the cable which will be under vacuum or partial vacuum conditions, in which case some of the air will be drawn from the oil by the partial vacuum so created and will create a weak spot. It would be interesting to know whether any attempt has been made in the manufacture of the cable to drive out as much air as possible by heating the cable to a temperature at which it will normally operate, as this will then allow of less free air being driven off when the cable is in service due to normal heating. Further, have any tests been made to show whether the air of absorption is freed by electrical tension? The paper refers to tests on cable only, and it is suggested that separate lengths should be cut from the cable and tested out, but as most of the trouble experienced has been in the joints it would appear essential to test the whole cable when laid, in order rigorously to prove the efficiency of the joints. It would be interesting to know how many points of a curve were taken when the models shown on the table were constructed.

Mr. C. R. Bolton: When describing the three-dimension graph models, the author mentioned that one, having obviously the worst characteristics, represented the test-results obtained from an experimental

* Paper by Mr. P. Dunsheath (see page 97).

cable built with a type of paper which at one time was considered to be the best for cable making. Does he refer to an all-manila paper, and, if so, what are the particular properties of this paper which are now found to be unsuitable? For example, has the author found it difficult to dry it thoroughly?

Mr. J. H. Collie: Can the author give any idea of the appreciable loss that takes place in a network of mains due to leakage through the dielectric, and whether these losses vary to any extent as between concentric, three-core, and single-core cables? He mentions that the leakage loss is greater in a.c. than in d.c. cables, so I presume that the loss on a given length of d.c. feeder cable is less than it would be on an a.c. cable. With regard to the question of stressing cables during testing, have the cable makers given any indication as to what they consider to be a safe, suitable testing pressure?

Mr. P. W. Cave: With reference to the cause of breakdown in the single-core cable, the author mentions that the charring may be due to heating or ionization. I suggest that it is a combination of the two, and that ionization is the predominating feature. It is comparatively easy to exclude all air from the dielectric, but I do not think it is easy to exclude oxygen, which the impregnating compound picks up from the atmosphere in the process of manufacture, and this oxygen, becoming ozonized, may lead to breakdown.

Mr. A. Monkhouse (*communicated*): The author's theory seems to me to be far more probable than anything else that has yet been published, and the astonishing point about it is that it so successfully correlates and confirms in a very simple manner the work of previous investigators who have attacked various sides of the problems which arise in considering the behaviour of dielectrics when subjected to electrical stresses. The author makes no reference to the work of Mr. Takeo Akahira (*Journal of the Institute of Electrical Engineers of Japan*, August 1923), who published some exhaustive tests on the effect of temperature and humidity on dielectric losses in fibrous dielectrics. These tests also brought out very clearly a falling-off in the value of the dielectric loss when plotted against time if the test is continued for a sufficiently long period. I have frequently observed the same phenomenon when making the highest maintained a.c. stress test on fibrous dielectrics as laid down by the Electrical Research Association, but in this case it is a significant fact that the thermocouple reading also shows a corresponding drop in temperature. The explanation of this would seem to be that the increase of temperature due to the I^2R losses in the dielectric when the stress is applied, actually dries out the moisture and increases the value of R, thus resulting in a corresponding diminution of I and consequently of the dielectric loss and of temperature-rise. Incidentally, the highest maintained a.c. test of the E.R.A. has not been mentioned by the author, but I think that this test when properly carried out is capable of affording one of the best illustrations we can have of the behaviour of dielectrics under stress and during actual breakdown, and it is to be regretted that it has not been more widely adopted. It also affords an excellent confirmation of the pyro-electric theory of breakdown of fibrous dielectrics which, I am sorry to see, the author is inclined partially to condemn, because he considers it ignores the time/voltage relationship, the importance of which he very rightly emphasizes in Section (VIII) of the paper. As I understand the pyro-electric theory, it allows that the heating due to leakage currents through the dielectric reduces the value of R and thus increases I until the rate of heating is greater than the rate of heat dissipation of which the dielectric is capable, and then the effect becomes rapidly cumulative and quickly results in a temperature being reached which produces chemical and physical changes and subsequent breakdown. Since the rate of heating, and thus the time elapsing before critical conditions are reached, is dependent on the value of I, which, in turn, is dependent on the applied voltage, it seems to me that the author is wrong in stating that the theory ignores the time/voltage relationship; in fact, his I^2R theory helps to explain and confirm the pyro-electric theory. Moreover, it is apparent that once the above-mentioned chemical and physical changes have commenced, even if breakdown is prevented the dielectric has deteriorated. In Section (IX) the author ascribes the pyro-electric theory (as he names it) to Wagner and mentions that it was concurrently advanced by Hayden and Steinmetz, but I think that Prof. Miles Walker first advanced the theory in the discussion on Dr. Rayner's paper on "High-voltage Tests and Energy Losses in Insulating Materials."* I therefore suggest that it would have been more correct to have stated that the valuable work done by the well-known research workers named confirms the theory first put forward by Prof. Walker. Fig. 46, in which breakdown voltage is plotted against the inverse fourth root of time, is exceedingly interesting. The E.R.A. has, until now, taken the "minute value" as the basis for its standard tests for determining the electric strength of materials of various thicknesses and at various temperatures. Although in the past I have strongly advocated the "minute value," I am now not at all sure that the value shown as X, if it could be determined for insulating materials of various thicknesses and at the various temperatures advocated by the E.R.A., would not be of greater commercial value to designers, etc., than the "minute value" figure. It would be interesting to know how the values of X obtained as the author shows, compare with the figures obtained by the E.R.A. highest maintained a.c. stress test. Theoretically they should be approximately the same. In connection with Fig. 26 the author does not mention what are the fibres employed in the two papers A and B. The E.R.A. recently published the results of electric strength tests on papers made from various fibres. These tests showed remarkable differences in the properties of what had previously been regarded as reliable papers, when tested at temperatures in excess of 60° C. Manila, cotton, linen and jute all figure in the manufacture of electrical papers, but, as yet, few engineers appear to appreciate the great differences that exist in the behaviour of these fibres when employed at the maximum temperatures now permitted for Class A insulation. Even greater differences can be obtained by variations in the processes of preparing the fibres for paper manufacture. There seems to be need for closer co-operation between the

* *Journal I.E.E.*, 1912, vol. 49, p. 323.

botanist, the papermaker and the electrical engineer before the great potential possibilities of papers and pressboards as insulators (particularly for e.h.t. work) are fully appreciated.

Mr. P. Dunsheath (*in reply*): I agree with Mr. Fuller that we shall have to go to the atom for the explanation of absorption, and I am very interested to note that his experiments show the presence of the "V" curve, both in the dry paper and in the oil alone. In reply to the latter part of Mr. Fuller's comments, I should say that not even a gap of a few mils would be necessary to deflect the stress from a purely radial direction; a difference in contact pressure between papers might conceivably be sufficient.

Mr. Morland's suggestion of heating and cooling a cable through many cycles, combined with a power-factor test as a criterion of quality, is along the right lines. The power factor measured is, of course, only an average figure for the whole length and it is possible to change the power factor dangerously at one point by such a series of heat cycles without appreciably affecting the average power factor over the length. Entrapped air, as suggested, is, of course, the great enemy.

Mr. Robinson's account of experiments with aeration of oil, and Mr. Cave's observations on oxidation, are both very interesting. In the ordinary manufacture of impregnated paper cables, the oil is heated to temperatures higher than those employed in service. In this operation the oil is, of course, de-aerated and, as suspected by the speaker, this is an important point. On the question of allowable head of oil, it is impossible to lay down hard-and-fast rules as there are so many factors involved and each case must be considered on its merits. On the other hand it may be safely taken that, the more fluid the oil used, the more necessary does it become to design all parts mechanically to withstand internal pressure on both the sheath and the joint box and, what is equally important, to keep the cable filled from the upper end. Because of this difficulty there is much to be said for using viscous oils. In constructing the models referred to by Mr. Robinson, points were taken every 10 deg. C. of temperature and every 5 kV of pressure.

Mr. Bolton's short question would justify a long reply. The comparison of various cable papers is an interesting, though difficult, study—difficult because of the many variables which must be eliminated in order to arrive at true conclusions. Briefly, however, manila paper does not stand heat treatment so well as papers made of certain other fibres, and is more difficult to impregnate.

In reply to Mr. Collie's query, the loss that takes place in the dielectric of a network is, of course, a function of two quantities, the dielectric power factor and the charging kVA. For a system of a given electrostatic capacity, employing a cable of a given power factor, the loss is independent of the type of cable. It is, of course, less under d.c. than under a.c. conditions. As regards the selection of a suitable test pressure, the cable makers are in agreement on cables for working voltages up to 11 000, but standards have not yet been fixed for the higher voltages.

I very much appreciate Mr. Monkhouse's kind references to the paper and the valuable observations which he has communicated. The drying-out of moisture on paper samples, as noticed by the Japanese investigator and by Mr. Monkhouse himself, could not occur in a lead-covered cable. In such a cable the power factor, rather than falling with time, is inclined to rise. Again, there is not much published evidence at present of a highest maintained a.c. stress in cables as employed by the E.R.A. for dielectric samples. Mr. Farmer, of the New York Testing Laboratories, is working on this subject and has recently given some interesting results in a paper read before the American Institute of Electrical Engineers, but the nature of the time/voltage curve for very long times is, of course, difficult to determine. Mr. Monkhouse, after stating that he would like to see me more in favour of the pyro-electric theory, proceeds to enunciate a new pyro-electric theory in which chemical change is introduced. My objection to the theory, as already published, is that all time effects are due to heating, and, therefore, steady conditions should be attained within a few hours; whereas we know definitely that the time effect in cables may continue for months. If a chemical change is to be included in the pyro-electric theory, then my views will be different from those stated in the paper, but such a radical change constitutes a new theory. Prof. Miles Walker in the discussion on Dr. Rayner's paper in 1912 certainly analysed the heating conditions in a dielectric under stress, but he dealt rather with mass heating. I think the essential feature of what is to-day known as the pyro-electric theory is the cumulative heating of individual filaments to temperatures higher than those of adjoining parts of the same dielectric. Mr. Monkhouse confirms the view of many other investigators that the nature of the fibre of which the paper is made is all-important, and I agree with him that very careful selection of paper is necessary in order to obtain the best results in dielectrics to work at high temperatures.

DISCUSSION ON "JUSTIFIABLE SMALL POWER PLANTS."*

EAST MIDLAND SUB-CENTRE, AT LOUGHBOROUGH, 19 JANUARY, 1926.

Mr. W. Pearson: The paper shows how dependent is the overall cost of power upon factors other than those commonly regarded as decisive, and, while justifying very small power plants operating under special conditions, it indicates the necessity for judging on their own merits the straight condensing generating stations of medium capacity. It is obvious that the really large station is necessary for the supply of a large concentrated load; but, as a rule, a plant of medium size can supply current much more cheaply to the area within reach of the generated voltage than a much larger station supplying from a distance, and it is difficult to see how a local advantage of this character can involve any national disadvantage. The claims put forward on behalf of super-stations supplying wide areas are based on three assumed advantages:—(*a*) Higher efficiency, (*b*) lower capital cost, and (*c*) better diversity factor. The last-named is generally fallacious in this country owing to the very general standardization of working hours, and whilst an increase in the load may be accompanied by an improvement in load factor, there is no reason why this should be more pronounced in the case of the large plant than in the case of the comparatively small one. For example, St. Helens, with a plant capacity of 11 000 kW, has a load factor of 62·36 per cent, and Maidstone with a smaller plant capacity has a load factor of 41·8 per cent, as compared with Manchester's 31·99 per cent. These figures are sufficient to show that load factor does not depend on the capacity of the generating plant. It might be expected that the large stations would, by reason of higher efficiency, show a lower fuel cost. It is, however, interesting to note that the largest undertakings for which returns are accessible (Manchester, Glasgow and Birmingham), have *coal* costs of 0·25d., 0·23d. and 0·29d. per unit respectively, as compared with Rotherham, Walsall and St. Helens, 0·19d., 0·23d. and 0·25d., respectively. Two of the above are really small stations. If total *working* costs are taken into account the three large undertakings are 22nd, 35th and 43rd in the list respectively, and of the first 30 stations the majority have total capacities of less than 25 000 kW. If a comparison be made of the total cost, or say the *average price* obtained for the current produced, the figures for Manchester, Glasgow and Birmingham are 1·32d., 1·64d. and 1·44d. per unit respectively, as compared with St. Helens 0·83d., Stalybridge 0·89d., Rotherham 1·0d. Evidently other factors are at work besides those to which so much publicity has been given in recent years. As regards capital cost, it is not generally appreciated how much the civil engineering work connected with a super-station increases the cost per kW of plant installed. Recent installations indicate that, while a fully equipped station as small as (say) 15 000 kW total plant capacity can be built for less than £13 per kW, the cost of large stations works out at £18 to £20 per kW; and experience has shown that stations equipped with large plant require, if anything, a higher proportion of stand-by plant than small stations. A station with six sets installed would necessarily have two in reserve, and a load factor of 33⅓ per cent based on the maximum capacity of the running plant would therefore represent a load factor of only 22·2 per cent on the maximum capacity of the plant in the station. If the total capital charge be taken at 8 per cent an increase in cost of (say) £5 per kW of installed capacity would nullify, as regards total cost of current, a gain of 20 per cent to 25 per cent in the fuel cost. The exponents of the super-station idea have usually based their arguments on comparisons between a small station with obsolete plant and a large station equipped with modern plant. If the comparison is between modern plant in both cases the maximum advantage which can reasonably be claimed for the large station is 10 per cent, and the figures of actual performance in this country show that even this claim is not justified by experience. If therefore the large modern station is unable to charge a lower average price to the consumers in its own immediate neighbourhood than the modern medium-size station, how can it be expected to supply at a distance (involving heavy additional capital charges upon transmission lines and transformers as well as losses in the transformation and transmission) more cheaply than the medium-size station located near to its load? The super-station is still more handicapped in respect of capital charges if compared with the installation of modern plant in an existing generating station, as the charges on the outstanding capital must be met even if a bulk supply is obtained. It is surprising how generally adaptable stations designed for reciprocating plant are for modern turbine plant of 5 to 10 times the capacity. Such developments usually involve no additional capital charge for stand-by plant, the best of the old equipment being satisfactory for this purpose. One cannot help feeling that the propaganda of the past 7 years has given the public and the Government a very erroneous idea as to the advantages of centralized generation, and the author is to be congratulated upon having presented some of the facts on the other side.

Mr. A. G. Deverill: A study of the tables of costs published in the *Electrical Times* shows that super-stations are uneconomical, and I am in favour of allowing existing stations to be equipped with economical plant, to be linked up one to the other. I contend that the supply of electricity to the consumer would be cheaper by this method than by putting down large super-stations and carrying the current long distances.

* Paper by Mr. A. B. Mallinson (see vol. 63, p. 896).

One point in favour of the small stations linked up is that they would none of them require to have 100 per cent of spare plant, such as any station has to have at the present time, as their interlinked stations would be a perfect stand-by to one another. On this point it is significant to note that, even in the East Midlands scheme, such a station as Loughborough with 6 000 kW installed and selling at the present time 4 400 000 units per annum could very easily supply another 20 000 000 units into the linked-up lines if consumers could be found to take this amount, and moreover, as the capital charges all exist on the present number of units, the additional units would be sent out into the lines at a modest profit on just the running charges. In this way the small stations would be fully loaded and long-line distribution losses would be avoided. It is obvious also that in most industrial areas in Great Britain, coalfields are somewhere near, and, whereas the freight per ton of coal is usually about 8s. 6d., I think it would be much better to generate, wherever possible, by any small or moderate-sized station in proximity to the coal rather than by very much larger stations where the chief consideration is a plentiful supply of water for condensing purposes. The larger station usually costs more than the smaller station to build and equip, and a complete power station of 10 000 kW capacity in three units of 3 000 kW normal capacity could possibly be erected for £132 000, or £13 per kW, whereas a larger station built near a river or in close proximity to a large water supply would probably cost very much more in its civil engineering requirements. The smaller station could generate just as cheaply as a station of the size of Barton, where the units cost 0·73d. at the works, to which have to be added the full amounts for capital on plant and mains. It is obvious that the so-called super-station could not have the effect of bringing down the price of electricity. For instance, Manchester has to obtain an average price of 1·32d. per unit and, whereas it was stated that a far greater consumption *per capita* would have the effect of reducing the price, this could not be done unless a very large additional number of higher-priced units were demanded and sold than will probably be the case. The newspaper talk of 1d. per unit for electricity does not attract industry at all. A works of any size would have to get its power for, at any rate, not more than ½d. per unit, and, to sum up, I think that the smaller stations linked together will provide a far better solution than will a number of large stations.

Mr. E. G. Phillips: The engineer who tries to prevent the loss of British thermal units in a modern boiler house is to be commended, but it is difficult to understand why the same individual never attempts to deal with the 60 per cent of the total heat available that is constantly escaping into the circulating water. Is it not a fact that electrical engineers on the "generating side" are too scientific to be commercial, and that they think it *infra dig.* to consider the sale of so common a commodity as hot water or even exhaust steam? My experience is that in all industrial plants, where steam is required for the "process," it is never possible for the super-station to compete even on a coal-consumption basis, ignoring the high standing charges so inseparable from these stations and their distribution networks. I do not agree with the author that the steam demand will usually be found to coincide with the demand for power; the reverse is usually the case, but this need not affect the design of such equipments. In a brewery recently completed on the back-pressure system, a battery of 5 boilers proved insufficient to deal with the steam peaks, and the power was obtained from gas engines. The present results are that 3 boilers easily supply the whole steam and power, whilst frequently only two are required. Whilst the demand for steam exceeds the exhaust available, the process main (at 60 lb./sq. in.) is fed with make-up through a relay-operated steam valve on the high-pressure main. When the exhaust exceeds the amount of process steam required, the surplus is automatically by-passed to several large thermal storage tanks and stored as hot water against the next "brew," when it is pumped to the brew tower at a temperature approximating to the final temperature required. This arrangement allows the boilers to be steamed at their most efficient load all day, irrespective of demands, supplies boiling water to the process (thus preventing delays) and also obviates the original heavy peaks on the steam side. My experience has been that the 10 per cent allowed for as lost while passing through the engine is in excess of actual practice. One great difficulty is that the existing process steam mains are insufficient in area to pass the amount of steam required at a lower pressure, and that in consequence it is frequently desirable to carry a higher back pressure than is necessary, due to the excessive cost of re-piping the works. This is a matter of little importance where the amount of exhaust made available by the high back-pressure is not in excess of the requirements for process purposes. The surprising thing is that, whilst those who have had little or no technical training in engineering matters somewhat naturally display an almost unbelievable ignorance of the great advantages of the use of back-pressure prime movers, men of prominence in the Institution still refer to the advocates of small plants working on this high thermal efficiency as cranks, and thereby create an entirely false impression amongst those who believe all they read and rarely think for themselves. Why does the British technical Press hardly ever devote any space to educating engineers and other readers to the possibilities of running small plants at 60 per cent thermal efficiency instead of purchasing from a plant rarely attaining more than 18 per cent? The American journals have, in almost every issue, descriptions of plants so working and also articles dealing with this matter in one form or another. The British technical journals suffer from an apathy which cannot be understood by those who are constantly engaged in work of this character. Cannot this inertia be overcome?

Mr. A. B. Mallinson (*in reply*): Mr. Pearson and Mr. Deverill have both dealt with the justifiable small power station as a straight condensing plant. At the present time, when the Electricity Bill is much in evidence, these remarks are of interest and I am quite in agreement with the views expressed. Where buildings have been erected close to available water, and

distribution mains radiate from them, it would obviously be a sound policy to modernize such plants and work the stations up to the full capacity of the site, whether limited by condensing water, buildings, plant capacity, or distribution. No doubt the Commissioners consider each case very carefully on its merits, but the points raised by both Mr. Pearson and Mr. Deverill are well worthy of serious consideration in view of the way the public is being led to believe that the super-power station is going to be *the only way* to get cheap electricity. I would particularly emphasize that whilst in the last few years there have been considerable improvements in super-power station units of 10 000 to 40 000 kW, there have been even greater improvements in the operating efficiencies of units of 500–3 000 kW. The only way to make a fair comparison is to compare the super-station with the small, straight condensing station where the plants are each of the same age.

The case of a brewery cited by Mr. Phillips shows how easily one can maintain the efficiency of these combined plants, even when the cycles of power and heating demand do not coincide. In bleach and dye works I have used thermal storage in the same way by storing up hot water. I have also seen plants working on thermal storage with the Ruths accumulator as a balancer. Similarly, on the other side, particularly applicable for institution work, the balance of cycles can be obtained by a storage battery, which also enables the plant to shut down through the night shift. I agree with Mr. Phillips that 10 per cent for condensation is in excess of actual practice, but I took that figure to be on the safe side. Personally, my experience has been that 6 per cent is ample. The amount of pipework used with low-pressure plants is the secret of success or failure. Many plants have been condemned on this point alone. As Mr. Phillips remarks, it is difficult to understand why technical men in England are so antagonistic to the installation of small back-pressure or heat-extraction plants. One reason for discounting the economies of such heat and power dual plants among power supply engineers is apparently that the costs per unit of such plants are not generally available. I have recently seen the operating figures of 8 plants, the works cost varying from 0·152d. to 0·302d., average 0·212d. The general run of such plants are, however, installed without meters; what the owners are concerned with is not units of electricity but overall operating cost for power and process heating. The British technical Press is much to blame in this respect; it seems to look upon the small heat-extraction power plants as being unworthy of notice, yet there is seldom an issue of the American paper *Power* without reference to such a type of plant.

I am writing this reply at a time when the country is entirely dislocated by a general strike. One hears that some London hospitals have had all their supplies of electricity cut off. Is not this another very sound argument in favour of the installation of these small power plants in public institutions and the like, thus enabling those in charge to be in entire control of their own operations in times of stress and in normal times to run on the cheapest possible lines, for themselves, the ratepayers and the country as a whole, by the conservation of coal ?

DISCUSSION ON

"AN ALL-ELECTRIC HOUSE." *

NORTH-EASTERN CENTRE, AT NEWCASTLE, 8 FEBRUARY, 1926.

Mr. W. F. T. Pinkney: Even to those of us who are familiar with the various uses and applications of domestic electricity, there are many matters dealt with in the paper which suggest new possibilities. The author's house has been extraordinarily well laid out electrically, and there are details of refinement of application which are of great interest. My own house was equipped for lighting, heating, cooking and water heating some 12 years ago, and whilst my own installation lacks the detailed refinement of the author's, it is not without interest that the general applications of electricity are very similar, although there has been no alteration to the installation other than the introduction of more modern appliances during the period. The house is an old one, and not specially designed for electrical equipment. The Newcastle Electric Supply Co. has no tariff comparable with the No. 1 Glasgow tariff, and the unit rate of the company's two-part tariff is not as favourable as that in Glasgow. The Newcastle company's two-part tariff is, however, available in remote towns and villages where the competitive forms of lighting and heating are much more costly than in Glasgow. The author refers to the cost of his house being increased by from 3 to 4 per cent by his electrical installation, but it should be noted that many details, such as the multiple switching, could not be installed in any house other than an electric house, so that it is perhaps incorrect to compare the cost of this house with a house not electrically equipped. On the question of the cost of supply the two-rate meter for registering night consumption is itself a costly item, and if multiplied by thousands would represent a very large additional capital expenditure. The consumption of energy at my own house is higher than the author's for heating purposes. This is due, however, to a very lavish use, and to exceptional uses in connection with hobbies. The cooking consumption is under 1 500 units a year, taking an average of 10 years and an average household of 4½ persons. The author's consumption for cooking seems to be on the high side. My lighting consumption is the same as the author's, and the hot-water consumption very similar, that is, 6 550 units a year (average over 10 years). The hot water is controlled by a thermostat. The hot-water cylinder is polished but unlagged, and of 30 gallons' capacity. The piping is unlagged and the heater is a circulator and not an immersion heater. It is reasonable to suppose that the consumption for water heating would drop if the system were brought up to date. I have experienced no difficulty with refuse disposal, the arrangement being similar to the author's, except that there is an existing kitchen grate in which waste paper, etc., is burned each day. On the question of reliability of apparatus, the results vary enormously in different households. In many cases where electricity is used very extensively, such as my own, maintenance costs are very low. There has been no maintenance on the water-heating system in 12 years, and practically none on the cooker in 3 years. In the case of some of our consumers, however, maintenance costs are unduly high, which points to unfair use of the apparatus. It may interest the author to know that the Newcastle company supplies energy to 5 groups of houses specially designed and equipped for the use of electricity.

Mr. H. W. Clothier: When one considers that the author is using in his house, per person, 2 756 units per annum, which is perhaps 30 times the average for this country, it is easier to realize what is required of future power stations. Everyone knows the difficulty experienced in obtaining efficient domestics. The full development of electricity in the home, avoiding waste of labour, is the ideal for which to work. How much of the prosperity of the United States is due to the use of electricity and other labour-saving domestic devices, thus liberating the personnel for productive work and thereby contributing to the national wealth? A panel of the B.E.S.A. is about to issue a new Specification for a protected type of wall plug and socket with metal casing, efficient scraping earth contact and visible earth terminals. These plugs and sockets are rated for 5, 15 and 30 amperes, and the interchangeable dimensions could be applied for inlets for the kettle, flat iron, radiator, curlers, and every other kind of "portable apparatus." It has been said in the electrical Press that we should not encourage the use of the latter in the bathroom. What are the author's views on this question? Would it not be better to develop the earthing of all portable apparatus, with a reliable form of 3-core flexibles, than to condemn the use of electricity in any specific parts of the house? The sockets in the four-room flat are not provided with switches. I presume this is because it saves much expense, and that plugs, particularly of the protected type in which the arc is encased in earthed metal, will break circuit without danger. A plug used as a switch has the advantage of forming a simple double-pole breaking device and it provides a complete isolation. I believe that some economy in house wiring would be effected by a wider application of this system for switching, and that the I.E.E. Wiring Regulations need only slight modification to put it into effect.

Mr. P. Ward: The cost of the house is assumed to be 3 or 4 per cent more than would have been the case if it had been equipped with coal and gas apparatus; the number of heating points installed is greater than is necessary, and the multi-control on the lighting installation is also very elaborate. These items go a considerable way towards making up the extra 3 or 4

* Paper by Prof. S. P. Smith (see page 289).

per cent. I notice that there is no scullery, and I would suggest that, particularly on washing days, a scullery is desirable, otherwise the damp air from the kitchen will go all over the house. I should have put the distribution board in the cloak-room. Were alternative prices for wiring obtained? In a paper recently read before the Dundee Sub-Centre, figures were given showing the cost of rubber-covered installation as 90 per cent of the cost of a screwed conduit job. It therefore seems reasonable to assume that an installation in split conduit with grip fittings could be put in at a lower cost than the rubber-covered installation, with the result that the 3 or 4 per cent additional capital expenditure would be further reduced. Presumably the bell installation is also counted in the cost of equipment, but as there would be such an installation in the house in any event, this also appears to be an item contributing towards the extra 3 or 4 per cent. With regard to the drying closet, the loading appears to be very low. It is certainly very much lower than that of any built-up cupboard at present on the market. It would be interesting to know to what temperature the chamber is raised before clothes are put in, and how long it takes to reach that temperature. It is stated that a cupboard full of clothes can be dried in 1 hour, but I hardly think this can apply to heavy goods, sheets, etc. With regard to the cooker, I notice that a table type is in use, and this is preferable wherever sufficient floor space is available. Open-type hot-plates have been used, and I would ask whether the author has ever used any totally enclosed plates, and, if so, which he really prefers, and why. With regard to the efficiency of hot-plates, it is very misleading to state what efficiency is obtained unless the conditions are known. In some tests recently carried out on a number of hot-plates under two different sets of conditions the efficiencies were found to be as follows:—In the first set of conditions, average efficiency 20·2 per cent; in the second set, average efficiency 34·1. In these tests the plates were switched on from cold. Similar tests taken with the plates already hot gave average efficiencies of 31·4 and 49·8 per cent respectively. The highest individual efficiency obtained was 67 per cent. With regard to the suggestions that self-contained vessels should be used, these, of course, are far more efficient, but experience has shown that their maintenance is more costly. When using self-contained vessels of the plug-in type it is difficult to remove the vessels from the sockets without splashing over the liquids contained in the vessels. The pins must fit tightly into the sockets to make good electrical contact. Reliability and safety are more important than efficiency. In connection with the hot water supply, whilst I agree that the heat loss is much less at 140° F. than at 180° F., it is doubtful whether for all-round purposes the best results are being obtained. By using smaller hot service pipes and running the cylinder at a higher temperature the heat losses can be cut down, and water sufficiently hot for washing dishes can then be obtained at all times of the day. The water requirements also appear to be above the normal and I think that 25 gallons will be found sufficient for a normal bath. With regard to ventilation, sufficient outside air comes in from the door and window frames in most modern buildings. The author's ventilation scheme could not apply to semi-detached or terrace houses, as external chimney breasts could not be used. I think that the best and cheapest way of ventilating rooms is by leaving an opening over the doors into the hall and by providing a fan-light over the window; by this means the vitiated air can be removed from the upper part of the room and cold draughts across the floor are avoided. Under the author's scheme it is possible to get a draught from the ventilator behind the fire, across the floor to the door. It is agreed that, for domestic purposes, heating by radiation is preferable to heating by convection. The author gives a temperature of 50° to 55° as being suitable, but normal experience shows that 55° to 60° F. is more usual. It is certainly better to heat a room, particularly a large room, from several points rather than from one, but habit dictates that all should sit round one fire. The author's consumption for heating purposes appears to be rather low; this may be due to the fact that he finds a temperature of 50° to 55° F. sufficient for his purpose. His cooking consumption appears to be higher than is usually the case for a similar household. His lighting consumption is extremely high and it would be interesting to know what is the kilowatt capacity of his lighting installation, and whether small apparatus such as kettles and irons are used from his lighting system. If the author's lighting consumption were calculated at the ordinary lighting rate prevailing in the district and deducted from his total running costs, it would be seen that his heating and cooking costs, including hot-water supply, amount to only £32 15s. per year.

Miss A. Holm: It is interesting to note that a wash boiler only is installed for laundry-work purposes. Clothes must be washed and need not be boiled, therefore I think that an electric washer would be much more useful as it would provide the means of washing silk, woollen and coloured articles as well as white clothes. The self-contained cooking vessels must be excellent for rapid heating, and I can appreciate the advantages of these for large pans such as stock-pots, steamers, and French frying baths. For general use the disadvantage of weight, the awkwardness of manipulation and the difficulty of cleansing would be against the popular use of these. Saucepans are most easily cleaned by immersion in hot water. I would suggest that a small open element would be convenient and would afford rapid heating for small pans used for sauces, etc. No provision for drying and warming towels is shown in connection with the bathroom; these could be arranged near the tank, or an electrically heated towel rail could be used. Mr. Ward raised the question of the disposal of garbage in an all-electric house; he said that it becomes a problem if the collection is only made bi-weekly by the sanitary department. This need not be so if the housewife adopts the method used by the Canadian housewife who wraps the refuse—as dry as possible—in small parcels, using newspapers for this purpose. This prevents smell, flies and rapid decomposition, and disposes of the daily papers in a convenient way. The intelligent woman wants an all-electric house, because home management can then be carried out scientifically, and leisure hours result. That it should

be the means of dispensing with the domestic servant is possibly an advantage, but many may still require this service, and the work in the electric house should appeal to a better and more intelligent type of domestic servant, because of the lack of drudgery in the daily work which is associated with the ordinary household without electrical conveniences.

Mr. R. W. Gregory: At the discussion on this paper in London, to my mind the most serious criticism was that by Dr. Margaret Fishenden, in which she pointed out that the energy consumed in the author's house for warming was only equal to that of one coal fire, and she feared the cold walls. The English are notoriously weak in the science of house-warming. They have the coldest houses in the civilized world—and are inclined to glory in the fact. I feel, however, that it only needs a few seasons of super sun-spots to raise the standard of heating required by the ordinary English householder. He will expect his home to be at least as comfortably warmed as his office or his factory, and he will think the cold passages and spot-heated rooms of the present-day barbaric. When this demand for really warm houses arrives, shall we be able to supply the necessary quantity of heat electrically? In my own house I have a central heating plant, burning coke, which keeps the house generally at from 50° to 55° F. In the living rooms I "top up" with a small coal fire. If I could obtain electricity cheaply enough, I should use it for topping-up purposes, but heat at 3d. per unit is beyond my purse. Could I use electricity for the central heating plant? These are the figures:—Average fuel consumption 5 cwts. per week. Cost of fuel 10s. per week. B.Th.U. in fuel consumed—$560 \times 12\,000 = 6\,720\,000$. B.Th.U. obtained for warming (boiler efficiency 60 per cent) = 4 032 000. An electric boiler with an efficiency of 95 per cent would consume 4 240 000 B.Th.U. or 1 230 kWh per week. With electric heating, fine control can be obtained, and this control can be automatic. This would eliminate much waste of energy, for with my coke boilers fine control and efficient stoking are difficult to obtain. I think, therefore, that one could assume that 800 units per week would give a satisfactory supply of heat to the house. To obtain this electricity at a cost equal to that of coke to do the same duty, the price per unit would have to be 0·15d. If the price were 0·3d. per unit it might still be worth while, for the sake of cleanliness and saving of labour, to use electricity in this way for house-warming. To obtain electricity at anything like this price it must be used at off-peak hours—and thermal storage would be necessary. This of course is already done in large buildings on the Continent, and a plant suitable for dwelling-houses might easily be developed. It is interesting to note that if a gas boiler were used instead of an electric boiler for this central heating system, assuming equally facile control, a boiler at 80 per cent efficiency, and gas with a calorific value of 475 B.Th.U. per cubic foot, 7 200 cub. ft. would be consumed per week. The equivalents therefore on my estimates in my own house for a central heating plant are:—10 cwts. of coke, 800 kWh of electricity, or 7 200 cub. ft. of gas per week. It will be interesting to see if electricity supply undertakings will ever obtain domestic loads such as this. As off-peak loads they are invaluable and worth trying for.

Mr. W. Cross (*communicated*): The electrical installation described in the paper is far more elaborate, as regards the switching and number of sockets, than the average consumer will install, and unfortunately the contractor preparing a scheme has to consider the initial cost if he wishes to obtain the work, though he naturally tries to influence the consumer to have a thoroughly up-to-date installation as described by the author. I am pleased to notice that the Wiring Regulations of the Institution were adhered to, as the cost of so doing does not appreciably affect the total cost of the work. The kitchen appears to be small, as it has to be used as a scullery and wash-house as well as a kitchen proper, and I should expect the vapour when washing to be rather objectionable. I am surprised that the author under-runs his lamps, as their life, if run at the correct pressure, is long. His efficiency is very considerably lower; if the pressure is 90 per cent of the normal, the watt consumption will be about 85 per cent of the normal but the lumen output will be reduced to 67 per cent of the normal. I am very interested in the suggestion that cooking utensils with self-contained electric heating elements should be used, as I can remember that about 30 years ago, self-contained saucepans, frying-pans, etc., were made in considerable quantities, though ovens and hot-plates were not then in use; possibly they will again be fashionable, especially as I understand they appreciably reduce the consumption of current for cooking. The tables giving the consumption and cost of current are of great interest, and show the importance of the heating and hot-water load to the supply undertakings, as well as the desirability of reducing the cost of current for these services if consumers are to use them to any extent. They also show that, with the tariff mentioned, one need not be specially careful in the use of current for lighting and, to a lesser extent, for cooking. In Table 3 the standing charge has been allocated to all sections, though it is an advantage from some points of view to allocate the bulk of the standing charge to lighting which is considered a necessity, thus enabling one to reduce the cost of current for other purposes which the consumer considers a luxury if it costs more than other methods.

Mr. F. H. Williams (*communicated*): Many of us, who never contemplated it a few years ago, have, since the war, been forced to become our own landlords, but usually the house so acquired has been far from ideal and the benefits which could be obtained from the introduction of electricity have been very much limited by this fact. My own house is a case in point and is a so-called 9-roomed house built some 20 odd years ago. To take advantage of the Newcastle-upon-Tyne Electric Supply Co.'s domestic tariff (the only tariff of the kind in existence in Newcastle at the time), the house was wired for electric light throughout, 8 heating plugs were installed in the principal rooms and electric cooking was arranged for. Under the domestic tariff in question there is a standing charge of 6s. 9d. per lampholder per annum, and all units, whether for light or power, are supplied at $1\frac{1}{8}$d. There are of course certain restrictions as to the minimum number of lampholders, and a certain

kilowattage of heating apparatus has to be installed. The rooms being fairly large it was appreciated that electric heating was out of the question from a financial point of view, and the power plugs were only put in for "topping up" purposes and vacuum cleaner, etc. It was also appreciated that an electrically heated clothes boiler was hardly attractive financially, either in first cost or in running cost, and, gas having been laid on, it was left connected to a wash boiler and a gas ring. The heating of the house and the hot-water supply is carried out by a combination of soft coal, anthracite and coke. The electric supply is 3-wire 250-volts (d.c.).

TABLE F.

Item	1923–24			1924–25			1925–26		
	£	s.	d.	£	s.	d.	£	s.	d.
Electricity * ..	17	13	9	20	8	0	18	1	5†
Gas	3	14	0	3	0	0	2	16	1†
Coal .. .. / Coke .. .. / Anthracite ..	23	17	6	22	10	6	20	4	0†
Total cost ..	£45	5	3	£45	18	6	£41	1	6

* Includes £2 12s. hire maintenance.
† Includes an estimated figure for the last quarter.

The cooker is on a separate circuit with its own meter, and the lighting and all power plugs are on another circuit. Table F gives the total cost of the various items for the past two years and an estimate for the current year. The family consists of 6 persons and it will be seen, therefore, that the costs are practically the same for similar conditions as in the author's house, but of course there are all the disadvantages attendant on burning the various fuels mentioned. The standing charge is approximately £6 per annum, and the actual units used were as shown in Table G. It will be seen that the units used in cooking are much lower than those given by the author, even if a percentage be added to compensate for the reduction due to the gas ring. Arising out of the general aspect of the all-electric house, I should like to ask the author if he has experienced any difficulty with domestic help due to the kitchen being fireless. The combined kitchen, scullery and wash-house arrangement described seems to leave a good deal to be desired from the point of view of the maid's comfort. In this part of the country where domestics are recruited mainly from the mining portion of the community, a good coal fire in the kitchen seems to be a *sine qua non*, and some of my friends have experienced difficulty due to the introduction of slow-combustion stoves in their kitchens. The author apparently approves of sunk-pattern switches. Whilst these are much neater in appearance than the ordinary pattern, they are more difficult to locate in the dark and the walls suffer in consequence. I have found it necessary to place a piece of celluloid beneath the switch covers to protect light wallpapers.

Circuit	1923–24	1924–25	1925–26
Cooker	1 249	1 865	1 365†
Lighting *	778	757	876†

* Includes lighting, iron, vacuum cleaner, kettle and occasional use of two radiators.
† Includes an estimated figure for last quarter.

[The author's reply to this discussion will be found on page 790.]

SCOTTISH CENTRE, AT GLASGOW, 9 FEBRUARY, 1926.

Mr. R. B. Mitchell: I propose to deal with the subject only as it affects the supply engineer. The chief feature of the paper to my mind is the storage tank, and I have to endorse all that the author says with respect to the necessity for filling up all these valleys and V-shaped depressions in the load curves, and if these means are used generally it will have the effect in time of reducing the price of electricity. With regard to the rate of charge for night-time use, I must point out that this rate of ⅜d. is only applicable to heat storage; it does not apply to any other use of electricity at the present time. In the London discussion on this paper one speaker said that he had no doubt that a very considerable loss to the undertaking would be made in selling electricity at this rate, even during the night, and another said that he had no doubt that a handsome profit is being made. The real truth of the matter is that it is something between the two. There really is a profit so far as Glasgow is concerned in selling electricity during the night at ⅜d. For the past 7 months the total works costs at Dalmarnock average out at 0·228d. Last month the figure was 0·196d., and the month before it was even lower. There is thus some difference between the works cost, which after all is the only figure which comes into the calculation, because capital charges are not affected, and the selling price in this instance. One of the arguments which I think may be used against a supply of this description, i.e. a liberal use of electricity, particularly for heating water, is that, after all, the generation of electricity is very inefficient as the thermal efficiency of the very best of our power stations is only about 20 per cent. That may be so, but it will not always be the case, and various processes are being experimented with just now which will in time put electricity undertakings on a par with gas undertakings, as they will be able to use processes which will enable by-products to be taken from the coal before the residue is put under the power station boilers. If the supply undertaking can afford to sell electricity at a price at which the ordinary consumer can afford to

purchase it and be satisfied with the results, so far as the all-in cost is concerned, then it seems to me that that is all that matters.

Mr. A. P. Robertson: Mr. Marshall has asked me to say that in his opinion the author has made one very serious omission in the equipment of his house; he has not provided a sun bath. Various institutions have installed these appliances and I understand that the treatment has proved very beneficial. Mr. Marshall agrees with the author on the question of self-contained units for cooking. I understand that he has conducted experiments with these appliances, and I believe that efficiency is greatly increased by their use. This is borne out by the author's figures. The author has been very extravagant with heating points. Four heating points in one room is very liberal, and a smaller number would be sufficient for ordinary purposes and would reduce the cost. I do not altogether agree with running separate circuits from the central point for all purposes. It is a very expensive method. When lighting, heating and cooking are all charged at one rate, there is no necessity to be economical with lighting. If a light happens to be left burning all night, it costs less than ½d. Some figures of weekly consumption are given in Fig. B. This gives the weekly readings in kWh for one year from January to January. The middle period which is blank is the holiday period. During the first half of the year the house was run with electric cooking only and occasional electric heating, and coal fires. The next half was run with electric heating, cooking and lighting, and one coal fire in the kitchen only for the hot-water supply. In the first part a very high peak will be noticed. That should not be taken into account: it was due to illness in the house, when a radiator was kept on day and night. This cost 10s. 6d. per week, but the constant temperature could not have been obtained with a coal fire, and there was no disturbance to the patient due to dust and attention to the fire. The cooking load also goes up, due to there being an extra person in the house who was a little extravagant with cooking and inexperienced. In addition, invalids require much short-time cooking, which is certainly a little extravagant. It will be noticed that the second half of the heating line reaches a peak just before the New Year. This is due to the frosty weather, and my figures bear out that the heating this year has been more than last year. The two halves of the curve show the difference between a house with occasional heating and one with electric heating. There is little difference between the cost of the first two halves, including coal. During the first half there was practically no heating.

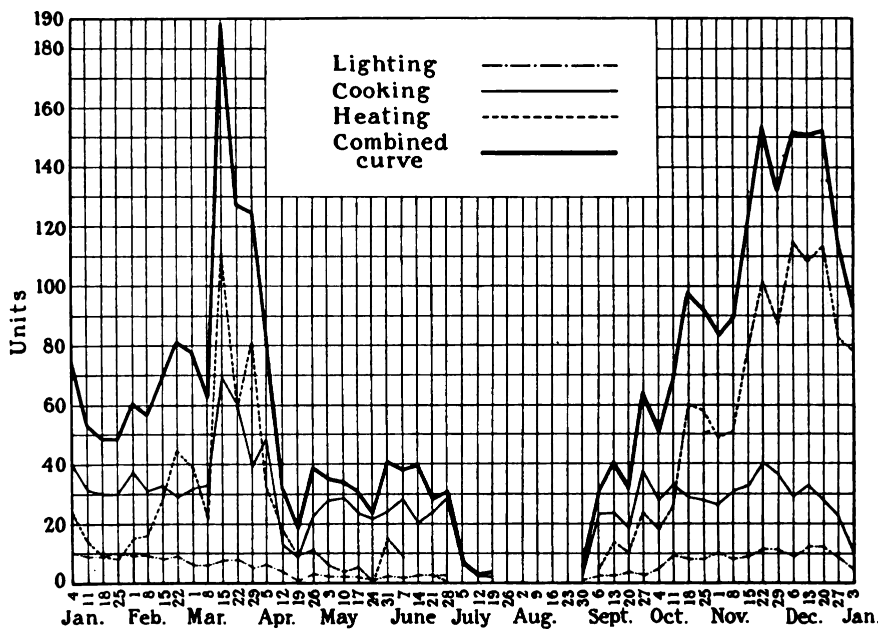

FIG. B.—Annual load curve for 6-apartment house.

The total cost of coal and electricity in the winter quarter of 1924 was £6 4s. 6d., while for the corresponding quarter of 1925 it was £5 11s. 4d. These are actual figures which I have taken from accounts. I only quote them to disprove the idea that it is very much dearer to heat electrically than with coal. The total costs are shown in Table H on page 782. I tried a good many different kinds of fires and I came to the conclusion that the fire that gives radiant heat is the best type. With the convector type it was found necessary to raise the total temperature of the room much higher than with the radiant type, which again bears out the author's contention that the atmosphere can be cooler if there is plenty of radiation. That of course if a great advantage, because cool air is better for the lungs. With regard to ventilation, my house was not built as an all-electric house and fireplaces were built in as usual. My wife at first refused any fire but a coal fire, but now we have no coal fires at

all. Ventilation is not difficult. I found that when the radiator was placed in the ordinary fireplace a great deal of the heat went up the chimney, and twice as much energy was used as was necessary. By partly blocking up the chimney, the room can be comfortably heated with half the amount of energy formerly used.

TABLE H.

Total Cost for the Year.

Electricity for lighting, cooking and occasional heating, with coal fires.

	£	s.	d.
Lighting—214 units at ¾d.	0	13	4½
Cooking—1 473 units at ¾d.	4	12	0¾
Heating—1 137 units at ¾d.	3	11	0¾
Coal—107 cwts. at 2s. per cwt.	10	14	0
Electricity supply standing charge	6	10	0
	£26	0	6

Electricity for lighting, cooking and heating, with coal fire for hot water only.

	£	s.	d.
Lighting—276 units at ¾d.	0	17	3
Cooking—1 316 units at ¾d.	4	2	3
Heating—2 994 units at ¾d.	9	7	1½
Coal—60 cwts. at 2s. a cwt.	6	0	0
Electricity supply standing charge	6	10	0
	£26	16	7½

There is plenty of ventilation in an ordinary house. Air comes in under the doors and windows, and windows can be opened slightly at the top if more air is wanted. The draught up the chimney is one of the most fruitful sources of loss of heat. In conclusion I should like to say that I agree with all the figures which the author gives.

Mr. R. Hardie: For the past 3 years my house, consisting of living-room, sitting-room, three bedrooms, kitchenette and bathroom, has been run on strictly all-electric lines. Electricity is charged on the two-part rate, i.e. fixed charge of £5 4s. per annum plus ½d. per unit for all current registered. There are four persons in the house. The annual bills have varied from £18 to £22, and I am satisfied, not only from my own previous experience but also by carefully comparing notes with tenants of similar-sized houses, that these figures could not have been improved upon had coal for heating and gas for cooking been employed. In addition, it must be remembered that the service was used without stint, and with an electric fire in every room a higher degree of comfort (particularly in the bedrooms) was obtainable than would have been the case had we been dependent on coal fires. There is, in addition, the saving in labour and avoidance of disturbance, due to the fact that no redecoration has been necessary over the 3 years, nor is the need for this even now apparent. A vacuum cleaner is in constant use, and an electrically operated clothes-washing machine, in addition to the usual numerous current-consuming devices. Details of the latest complete year are given below. The consumption for the year was 8 118 kWh (say 8 000), which, at ½d. per unit, comes to £16 13s. 4d. The annual charge was £5 4s., making the total £21 17s. 4d. The average cost per unit was therefore 0·656d.

The consumption was made up as follows :—

	kWh
Cooker and kettle	2 400
Water-heating	1 400
Living-room heating	2 500
Bedroom heating	1 300
Lighting and vacuum cleaner operated from lighting plugs	400
	8 000

Check meters were connected to the various circuits, and no coal was consumed during this period.

[The author's reply to this discussion will be found on page 790.]

SCOTTISH CENTRE, AT EDINBURGH, 9 MARCH, 1926.

Prof. F. G. Baily: The paper shows that such a house is practicable and, with certain precautions, not excessively expensive. The author's expenses are in fact little more than those of a similar house run on normal lines; but I know from personal trial how easy it is to economize in the consumption of electricity, though the ordinary person will pay half as much again for apparently the same services. Taking the chief items, cooking, warming of rooms and supply of hot water, while the first is normal for a moderate style of living, neither the warming of the rooms nor the amount of hot water would satisfy the average person who is used to comfort and has no special reason for economy. It corresponds more to the mode of life in a small flat, where saving of labour and avoidance of coals and ashes more than counterbalance the limitations, and the surrounding flats above, below and on both sides reduce heat losses in the rooms. For ordinary houses it seems a mistake to adopt electricity completely, when for some purposes gas, coke or coal are definitely cheaper or more effective or agreeable. In cooking, the electric oven is superior to either the gas or the coal-fired oven; but the electric boiling-plate has no advantages over the gas ring and is much more expensive. As the greater part of cooking is boiling, stewing and frying, the hot plate constitutes the larger part of the cost. I take Edinburgh prices for gas and electricity in the following calculations, viz. 8½d. per therm and ¾d. per unit. The electric hot-plate has a very low efficiency, given by the author as 25 per cent, and while this can be bettered I think that 30 per cent overall is the highest that can be given to it. According to tests I have recently made, the ordinary gas ring with a flat-bottomed kettle has an efficiency of between 50 and 55 per cent and with a kettle of improved design the efficiency rises to over 65 per cent, so that roughly the efficiency is twice as good. Since, total heat for total heat at above prices, electricity costs 2½ times as much as gas, the electric

hot-plate will cost 5 times as much as the gas ring for its consumption, and equally in first cost and upkeep the hot-plate is much the more expensive. The kettle with self-contained heating element has an efficiency of about 80 per cent, and with reasonable care lasts a long time, so its use may be considered, though its cost of running is still nearly twice as much as with gas, and it is more suitable for sitting-room use. As a practical point, the gas ring will boil a kettle in about half the time that the other two methods require, the hot-plate being the slowest. Self-contained cooking pots, which the author appears to desire, have been tried any time in the past 30 years or more, and the hot-plate has been introduced in their stead. They are expensive to purchase, heavy to handle, and the drastic washing that such appliances require soon destroys terminals, insulation and heating elements. Room-heating is a more complex matter. Coal fires have advantages which ensure their use in continually occupied sitting-rooms, and, while much is made of the smoke nuisance, it is a fact that the modern grate produces very little smoke, as can easily be observed in any suburb where the houses are not more than 20 years old. Between gas and electric fires there is little difference in cost. I made experiments on a small sitting-room in my house in which either gas or electric fires could be used, the sizes being selected so that each cost 1d. per hour, the gas being controlled to that consumption. The gas fire had a vent and the electric fire was placed alongside, but so that the hot air did not pass into the vent. The room was not occupied, entrance being made once an hour for reading the thermometers and adjusting the gas. This was favourable to the electric fire, as the loss of warm air was less than in ordinary use. Windows were shut and days were chosen when there was little wind, and the outside temperatures and initial inside temperatures were the same for the two tests. Repeat tests gave consistent results. Electric heating gave a more rapid effect, owing to the considerable warming of the air directly, while the gas fire operated solely by radiant heat to the walls and furniture. After some 8 hours the gas fire caught up the other, and after another 8 hours of cooling down the room was still slightly warm, while after electric heating it was quite cold. The gas fire puts more heat into the room at the same cost, but for short periods of use its effect is too slow. It was noticed that with the electric fire the room smelt stuffy, owing to the scorching of the air by the red-hot spirals, while with the gas fire the room was quite fresh, the comparison in both cases being with the air of a large sitting-room with an open coal fire. I consider that although electric fires are the best for occasional use for short periods, they are unsuitable for bedrooms when used as sick rooms, and the latter are better served by gas fires. Electric water-heating seems a vain idea for anything but a very small house or a flat. The coke-fired slow-combustion boiler is highly efficient, and, heat for heat, the price is so much less than for electric heating that a lavish use of hot water will cost considerably less than an exiguous one from electricity. Since for houses of any size central heating is the only effective method of general warming (preferably combined with small open fires in sitting-rooms) the hot water may be obtained by secondary heating from the same boiler, though there is an opening for electric or gas heating of water in the summer. It will be noticed that in the author's house there are no hot-water pipes allowing of circulation. They are all single pipes below the level of the tank, and all except one are close to the hot tank, so that only a short length of pipe needs to be emptied of its cold water. This arrangement very much diminishes losses by cooling, but restricts the positions of the hot-water supply in a way which would not be convenient in many houses. This particular house was designed for the purpose of electric operation, and is run with that object prominently in the minds of the occupiers; but if other considerations are allowed their natural claims the expense will be greatly increased. Finally, it should be remembered that there is no general warming of the house, such as is unobtrusively but effectively given by the flues of kitchen and sitting-room fires warming the walls through which the vents pass. This materially aids the drying of the house, keeping the air inside a little warmer than that outside, and in a self-contained house this is a matter of no small importance. Without it a house in this climate during the winter is certain to be more or less damp.

Mr. E. Seddon: I doubt very much whether the average user of electricity would consider the refinements made in wiring the author's house worth the extra cost, but one can readily see an earnest desire on the part of the author to show the amount of comfort which can be obtained with multiple switching points and extra heating plugs. His experience with water heating is most interesting and the remarkable efficiency of the lagging which he has adopted proves that hot-water storage is a practical and economical proposition. The immersion heater of, say, 3 kW fitted to the ordinary hot-water tank has great possibilities. One could rely on getting hot water in a definite time, whereas the boiler behind the kitchen fire is sometimes very uncertain. With regard to special low tariffs for night load, it is quite easy to see that any charge above the cost of coal will not result in a loss to the undertaking so long as the contour of the load curve remains where it is during the night, but if this part of the curve should cease to remain a valley the extra wear and tear of plant and other charges would operate against such low rates. In considering cheap tariffs for night load I am somewhat concerned about the law in respect of preferential treatment. As the law stands at present it seems to me that any consumer offering similar conditions of load whether, for instance, for ice-making or power purposes, is entitled to a rate similar to that offered for water-heating, and I think a great deal of discontent might result if an undertaking offering very low rates for this form of load is not prepared to offer the same rates for general purposes so long as the conditions of load remain the same. Looking at the author's account for electricity, I consider that his total bill would have been quite reasonable if he had not obtained the benefit of the $\frac{1}{8}$d. reduction during the night period. I might here mention that although we in Edinburgh have a comparatively large residential load as compared with our total output, the average price per unit sold

is within 0·02d. of the average price obtained in Glasgow.

Mr. W. Duncan : The paper is one of great interest to everybody connected with the electricity supply industry, as well as to contractors and to consumers. The supply undertaking's interest lies in the fact that here is a consumer who increases his annual consumption by some 16 000 units, when he starts to use electricity for all domestic purposes. To the contractor and also to the consumer the convenience and desirability of having a large number of plugs and control points is brought home in a very striking manner. It is the experience of most of us that the cost of wiring has to be considered very carefully. Convenience has to be sacrificed to economy, but it is false economy to have a very small number of plug points. Regarding the wiring of the author's house, I do not like the method of using lamp standards from a plug fused to carry 15 amperes, nor do I like the two-way switch arrangement in the bedroom. This fixes the position of the bed in the room for all time. This may have been satisfactory in the olden days, but in the modern electric house where there are no fireplaces the position of the bed can be altered at any time. A better arrangement is to have a portable lamp standard on the table at the bedside connected to a plug. The size or position of the bed can be altered at any time and the furniture re-arranged as desired. With regard to the arrangement for clothes-washing, I think that the author should have installed a modern electric clothes-washing machine instead of a wash-boiler. Hot water can be drawn from the main storage tank, and it is the experience of most users that the clothes washed in the machine do not require to be boiled. The water-heating arrangements are very satisfactory, and in offering such a low rate as 0·375d. per unit for a restricted hours' supply I think that Mr. Mitchell is to be congratulated. The switchboard diagram indicates that this rate applies for electricity for all purposes after 11 p.m., and not only for water-heating. The amount paid by the author for water-heating electrically compares well with the figure in my own case. I use a small coal-fired boiler, the annual cost of which is £5. The house is only half the size, and there are only half the number of persons in it to be catered for. Like Mr. Seddon, I was interested in the low radiation losses from the author's tank. The lowest figure that we have been able to find is 2·5 deg. F. per hour. It is a commonplace to say that the cost of an article is measured by the service rendered. In considering the cost of electricity it must be remembered that by no other medium can the same service be given. The standard of comfort, convenience and cleanliness is higher, whilst the amount of domestic drudgery which can be eliminated by means of electrically driven labour-saving devices is an item which cannot be assessed in terms of money.

Mr. F. W. Sharpley : I should like to submit the following facts and figures for the purposes of comparison. The figures refer to my own house or flat of five rooms exclusive of bathroom and hall, with three persons in the house, including a maid. Coal, anthracite, gas and electricity are used. The cost of the service for the year ending 31 January, 1926, was :—

	£	s.	d.
Coal and anthracite (partly estimated) ..	7	8	6
Electricity, power and lighting (2 meters) ..	4	4	3
Gas (for cooking)	3	10	0
	£15	2	9

The total cost per day per person works out at 3·32d. The total amount of electricity used was 636 units and includes the use of one 1½-kW fire, iron, vacuum cleaner, griller and toaster, in addition to lighting. For the purposes of comparison, I have estimated that if this house were in Glasgow, taking the same current consumption and demand, the cost would be £5 14s. on the two-part tariff, or £4 6s. 8d. on the ordinary rate, taking M (the number of units chargeable at 4½d. per unit) to be 150. That compares with the sum of £4 4s. 3d. already given for electricity actually taken in Edinburgh. Alternatively, I have estimated the cost of electricity for the author's house if this were situated in Edinburgh :—

	£	s.	d.
Lighting—568 units at 3¾d.	8	17	6
Power—100 units at 1d.	0	8	4
Remaining 15 916 units at ¾d.	49	14	9
Total cost (if in Edinburgh)	£59	0	7
Actual cost in Glasgow	43	8	0
Difference	15	12	7
Reduction if hot-water load on night rate, at 0·375d. per unit	9	8	10
Remaining difference	£6	3	9

If we estimate that in Edinburgh we could get energy for heating water during the night at the special restricted rate existing in Glasgow, then the difference is £6 3s. 9d. as shown above. The author does not mention the capital cost of the installation. I certainly consider that, at any rate, the difference between the cost of his all-electric house and what a similar house would have cost if equipped in the ordinary way for coal and gas with electric lighting, should be taken into account in the price that he pays per unit. In any comparative figures I think the number of servants in the house should be given, as it seems to me that even a single servant will make an enormous difference in the cost of running a house. The average servant has no idea of economy. I took the figures for our own house for the previous year, and I found that the cost of the gas and electricity services together were increased during the last year by 30·3 per cent over that for the previous year. In the previous year we had no maid, but this last year we had one. For hot-water heating I have an anthracite stove, and I find that it costs me almost exactly 2s. 6d. per week to give us an abundant supply of hot water day and night for all domestic purposes, and it gives us two good hot baths per day. That compares with the author's figure of 5s. 2d. per week which he gives in Table 3. We have a Ewart's gas circulator attached in case of emergency, but this is used in summer only, and then very occasionally. I should be glad if the author would give some particulars

of the lagging of his tank. He makes no reference whatever to the fireless cooker, and to my mind the fireless cooker seems the most economical way of roasting, baking and stewing. It will not poach an egg or fry bacon, but it does roasting, baking and stewing wonderfully well. It will cook meat, fowl, cakes, pies and puddings. I have one, and we find that if we heat up the iron discs which are supplied, on a gas ring for a matter of 12 to 15 minutes, we can put in a 3- or 3½-lb. joint and leave it in the cooker for the ordinary time, and be sure of finding it well cooked and ready. I believe that if these fireless cookers were fitted with a very low-rated electric element to prevent the cooling of food if attendance cannot be given for a long time, they would be ideal things.

Mr. A. Mears : The paper indicates the enormous field which is opened up for the use of electricity, and the possibility of improving the load factor of the stations. After all, costs can only come down provided load factor goes up. If load factor can be improved, the percentage of units lost in distribution will be materially reduced. This was brought out very clearly in Mr. Sayers's recent paper on tariffs.* With regard to the rate of ½d. per unit plus standing charge, this presents no great difficulty with modern plant. It is a method of charge which has a great advantage for lighting, and it does allow a user very great latitude with the use of lighting. Another feature which should be borne in mind is the labour-saving which electricity brings. We must put some value upon comfort. With a large house it is possible to save, because domestic service can be largely dispensed with. In the case of the smaller house the saving is not so apparent, but perhaps in time the housewife will realize that leisure and relief from uncongenial tasks have a definite cash value.

Mr. D. Martin : The question of cheap electricity is ever with us. Rates of ½d. and ⅜d. and even ¼d. per unit for suitable night loads are now available. A well-known electrical engineer member of Parliament has predicted a flat rate of ¼d. for all purposes in the near future, but I have my doubts about such a cheap flat rate when the cost of coal alone at present amounts to something like 0·15d. per unit in the best of the super-stations. The load curve at Glasgow (Fig. 5), however, shows how important it is we should find additional night load. The peaks at 11 a.m. and 4.30 p.m. are approximately 40 times that of the average night load, whilst the output as a whole is a daylight load. There is apparently no better method at present than that suggested by the author, viz. the accumulation of hot water during the night for the next day's domestic requirements. From a scientific and economic point of view, the production of hot water by electricity is unsound as a process by itself, but when combined with the scheme of things, as they exist, it is quite sound. There is a limit, of course, and the night load peak would not need to exceed that of the day load. To install new plant for an excess night load would not pay at the suggested tariff, which is the attraction at present. In general, any scheme which tends to flatten out the abnormal peaks is all to the good. In this respect the Glasgow supply system at present suffers somewhat by having no traction load from its tramway system; likewise there are no electrified railways in the neighbourhood, although there are fully half a dozen ripe for electrification. The practical effect of such a traction load would be to flatten the curve, due to the fact that the rush-hour loads come on before and after the peaks caused by the industrial loads. One obvious benefit with the greater output in units, with the same standing charges, would be a reduction in the standing charge costs per unit. I think that is fairly obvious. With regard to the costs of the author's installation, he has shown how the job should be done, but he omits to mention one important item of enormous advantage to the housewife. All his hanging fittings are suspended from the ceiling by means of plug adaptors. To release the fittings for spring-cleaning purposes and the like, all that is necessary is to unscrew a coupling at the ceiling. The need for a tradesman is thus eliminated. Again, he could have cut his wiring costs down by fully 80 per cent had he not run separate 15-ampere circuits from the fuse-board to each of the 31 plug points. Likewise, his multi-way switching points use up a great deal of wire. The extra convenience obtained, however, far outweighs the extra cost involved. A slight calculation will show how much more it would have cost if conduit had been used. For example, compare the costs of a 7-yard run of both systems. For vulcanized rubber cable in *screwed* conduit, customary and for long compulsory in Glasgow, there would be :—

	s.	d.
20 ft. of ⅝-in. conduit	2	11
1 bend	0	3·4
2 boxes for switch and ceiling rose	2	1
15 yards 3/·029 single-core vulcanized-rubber cable at 2·9d. per yard	3	7·5
Total	8	10·9

For C.T.S. cable clipped to pass the Institution Wiring Rules (Eighth Edition) :—

	s.	d.
7 yards 3/·029 twin-core C.T.S. cable at 10·9d. per yard	6	4·3
2 wood blocks for switch and ceiling rose ..	0	5
Total	6	9·3

This shows a saving in favour of C.T.S. of 2s. 1·6d. for a 7-yard run, equal to 3·5d. per yard for material alone. Labour is deliberately left out, but, if included, the saving would be still greater, as C.T.S. can be installed in half the time needed for conduit. In my own house where C.T.S. was used the total cost is a little under half the cost of the house next door where conduit was used. I have eleven 15-ampere plug points against my neighbour's 6, but otherwise the same lighting arrangements are observed, and fittings of similar price were installed. Here we have a big incentive to contractors to increase business, and another opening for supply undertakings to increase the domestic load. It is just this saving offered by an alternative wiring system which will make many a waverer decide in favour of

* *Journal I.E.E.*, 1925, vol. 63, p. 850.

electricity with all the advantages it has to offer. I know that the author has visions of the more universal use of electricity. Public opinion, with its increased knowledge of things electrical, is beginning to force the pace, and a far-seeing public servant should anticipate the public demand. The dreadful smoke pall which hangs over Glasgow and other cities in Great Britain is a disgrace to civilization. It once indicated great industry, but, with our present-day knowledge, it is acknowledged to be a sinful waste of our great natural resources, and it is for all of us to do our best to restore the clear atmosphere which is our birthright.

Canon C. T. Wakeham: My house is an 8-roomed bungalow, and electricity is the only form of energy and light used in it. The cost of electricity in 1925 was £49 for power and heating. Look what is added to our comforts, and to the health of the household by having electricity. There is no sweeping brush in the house, and no scrubbing on hands and knees. We enjoy perfect ventilation; there is only one chimney in the house and the Dean of Guild made us put this up before he would pass the plans. There are only four persons in the house, including a maid, but there is nothing very much to do; with the exception of washing and bed-making, everything is done by electricity. We have several plugs in every room. My hot-water supply costs me only 1s. 3d. per week, the electric heating element being switched on continually. My electricity bill for the period 5 November–9 February—the 3 heaviest months—averages £5 per month, and we have had nothing but comfort. I have nothing but praise for the electric house.

Mr. A. B. Munro: The question of the all-electric house is not a new one. For instance, in the all-electric scheme at Hazelwood, Dumbreck, about 16 houses were built on the all-electric principle in 1914. There have been many changes in the ownership of these houses, mainly on account of the unsatisfactory working of the electrical installation and the cost of operation. The original cookers supplied in these houses have been removed and cookers of a new type supplied by the Glasgow Corporation free of charge, to beat competition from the local Gas Department, who were requested by the tenants to give a supply. I have lived in one of the larger houses of a Glasgow Corporation housing scheme, equipped for all-gas working. The installation consisted of 4 gas fires, 15 lighting points, gas wash-boiler and circulator. The operating costs worked out at 9d. per day. From the figures which have been produced for all-electric working, I only wish that gas consumers were as easily satisfied as electricity supply consumers seem to be. Whatever electricity can do, gas can do at one-third of the price. I calculate that to produce the electrical energy required in a house such as that described by the author would require the consumption of something like 18 tons of coal at the generating station. That may be a conservative estimate, but on the other hand it may be an overestimate. From the national point of view I think that that is a useless waste of national resources. Electric generating stations can show a thermal efficiency of only 12 to 18 per cent. There is surely something wrong when a great industry is allowed to use up coal in such a careless and wasteful manner. The vacuum cleaner is useless and inefficient; the work can be performed infinitely better by hand. The electric clothes-washing machine is only suitable for those who do not dirty their clothes. If clothes are to be made white they must be boiled and bleached in the sun or by chemicals. The method described by the author for the lagging of hot-water tanks is excellent. There is nothing like healthy rivalry to encourage improvements and make for better service in both the electric and gas industries.

[The author's reply to this discussion will be found on page 790.]

Mersey and North Wales (Liverpool) Centre, at Liverpool, 19 April, 1926.

Mr. H. Dickinson: The general public always have the idea that electricity is so very expensive, but if the tariffs are right, as they are in many towns, the cost of electrical operation in a house is not the serious matter it is generally supposed to be. In the early days the argument now raised as to cost of using domestic appliances was used with regard to electric lighting, viz. that electric lighting was so very costly that it was impossible to use it. These views have gradually been dissipated by experience and I feel that the same thing will apply with regard to the use of electricity for domestic purposes. The author has mentioned that the cost in Glasgow is too high, but I do not agree that cost is the all-important matter. Greater convenience and comfort usually cost more, and I think that is the case with electricity. Very few people know what amounts they pay at present for coal, gas and light, and if they have to pay more for electricity they think they cannot afford it. Domestic service at the present time is a great deal more difficult, the cost of that service is great, the maids must have more freedom, and consequently the lady of the house has more work to do. By using domestic appliances she can save herself labour, get the house work completed in the early part of the day, and thus have more time for recreation and amusement. With regard to the cost of building the house, I was rather surprised that the author thinks the cost will be from 3 to 4 per cent more than that of an ordinary house. From some calculations which we made we came to the conclusion that if the house were designed as an all-electric house it could be built at a less cost than an ordinary house. The author has put in his house certain things that would have been unnecessary if he had been quite satisfied that the all-electric house was going to be perfectly successful. For instance he has put in chimney breasts and so on. The electrical installation is much more elaborate than under ordinary circumstances but I think it is advisable in order to allow apparatus of ample size to be used. I quite agree with him as regards the convenience and quality of electric cooking, and there is no doubt that his new

cooking utensils give an increased efficiency, but I am rather doubtful whether in actual practice that type of apparatus will not cause a considerable amount of trouble. If he can prevent the pots boiling dry, well and good, but I am a little doubtful and I am afraid he may have some trouble with connections to the pots as shown. One essential thing in connection with the use of domestic appliances is a good maintenance scheme. If many ovens are running on the system they must be well maintained. Boiling-plates also give trouble, but a good maintenance system minimizes the trouble to a very large extent, and I have no doubt that boiling elements will be very considerably improved. At the present time we are testing out a new type of element for which we hope to give at least a 2 years' guarantee, and we hope to be able to give a higher loading on the element than has been possible up to the present on the size that we have to use with ordinary cooking utensils. The hot-water system adopted in Glasgow is an ideal one from the supply point of view, but I do not think it will be satisfactory under ordinary conditions. It may be satisfactory in the author's case, where he turns the switch on in the evening and off in the morning, but not every one will do that. Then again the author has to use a very big cylinder; if a house is specially built provision can be made, but in an ordinary house it is difficult and in many cases impossible to install a cylinder of that size. We have therefore to be content with a smaller cylinder and are driven to look at the question from a different point of view. I should imagine that many times when the demand for hot water is above normal the temperature must fall very materially, and that there will be times (other than non-peak times) in an ordinary house when the 2-kW heater at the top of the cylinder has to be used. We are experimenting in Liverpool with the electrical heating of water. In each of 160 houses there is one small element running continuously through the 24 hours to cover radiation losses, and a larger element controlled by a thermostat raises the water to the required temperature. We may not get such a good load factor as the author gives, but the results are very good, not only from our point of view but from the consumers' as well. It is very encouraging to find that some of the consumers who have had experience of the system are recommending their friends to try it. In connection with the Corporation housing schemes four all-electric houses have been erected, three of which have been tenanted about one month. Another 250 all-electric houses are under construction. No provision whatever is made for the use of coal in these houses.

Prof. E. W. Marchant: The use of radiators is the first point to which I should like to refer. Many people have told me it was impossible to get enough heat from electric radiators. The reason was, of course, that the radiators were not big enough. We find that a 3-kW radiator in a room about 26 ft. × 22 ft. is ample. I had this fixed in the fireplace and so arranged that it could be taken away and a coal fire put in when it was wanted: we have only used the coal fire *once* during the winter. The second point is with regard to cooking. We have found cooking by electricity more satisfactory than any other method. The chief difficulty has been with the boiling-plates, the renewal of elements in which is, I think, likely to be a fairly heavy charge. I think boiling-plates are, however, superior to the special utensils the author uses. I am afraid there will be a great deal of trouble with the plugs on these utensils, as well as trouble due to the heating elements burning out when there is no liquid in the vessels. I do not think boiling-plates are quite so inefficient as the author states. We obtained an efficiency of over 40 per cent in some tests which we have made. The boiling elements are certainly the weakest point in the electric range, and that brings me to the point which Mr. Dickinson has mentioned, viz. maintenance. If there is any trouble with the boiling elements, we ring up the Corporation Electricity Department, and a man comes and puts them right. Unless there is an efficient system of maintenance in connection with electric cookers, I am sure the electric system will not be a success. As regards cost we have not a very long experience, as an electric cooker was installed only last September. We are still using a hot water boiler which burns coke, and I think there is some advantage in having one fire left for burning rubbish. Our consumption of electricity is from 7 to 8 times what it was in previous years, but the total cost for coal, gas and electricity, as far as I am able to judge from two quarters' bills, will be no more than it was previously, and, of course, the saving due to the absence of coal smoke and ashes is very substantial. A further advantage is the insurance against the stoppage of coal supplies due to strikes which the use of electricity provides.

Mr. A. S. Wilson: I feel that the author has proved up to the hilt his case that the all-electric house is a practical possibility and almost a necessity. I feel that we can now spend our time to the best advantage by seeing how this service can be handed on to all sections of the community. The tariff available to the author was a favourable one. I have been making a few inquiries with regard to the annual cost involved in average houses now using coal, gas-cooking, and electric lighting and heating and I find that on the basis of a probable consumption of about 10 000 units per annum the all-electric change-over would be a commercial proposition, apart from the advantages to be obtained in labour-saving, cleanliness and general convenience, etc. One of the most important things mentioned by the author is the insignificant cost of lighting which has been made so much of in the past; the main advantage to the consumer is now to be looked for in the adoption of electricity for cooking and heating. The author's wiring arrangements are certainly very elaborate, but there is one point which I feel should be stressed, that is, the example he has set in regard to the ample provision of plug points throughout the house for the convenient placing of portable electric fires, etc., to meet varying conditions in the home. Figures recently published show that we are very much behind other countries in regard to the number of units used per head of the population, and the author has shown how this state of affairs can be remedied to the advantage of all concerned.

Mrs. H. Dickinson: I imagine that the author's saucepans are very heavy to lift in order to turn the contents out. I certainly think that the hot-plate is not quite as efficient as it should be. Many people think that it is difficult to cook by electricity, but my experience is that it is much easier to teach even the most inefficient girl to cook by electricity than it is to teach her to cook by gas or by coal. We find that food cooked electrically tastes much better than that cooked by ordinary means. In regard to radiators, in an all-electric house it is very much easier to heat a room by electricity, owing to the fact that the radiators can be placed in any position and also owing to the ease with which the temperature can be regulated. I quite agree with the author that it is radiated heat, not hot air, that is required.

Prof. F. J. Teago: The annual costs given by the author and by Mr. Hague tend to show that, provided the tariff is right, the all-electric house is already within the means of even the small-income household. Personally, I have never yet been in a position to contemplate an all-electric house, but I have had experience of a house where only coal was available for the usual domestic requirements, and only paraffin oil for lighting. This particular combination of coal and oil possibly represents the cheapest money payment, and the dearest labour payment proposition that it is possible to obtain (what one cannot pay for in money must be paid for in labour), and the total annual cost was £15; the household consisted of three persons and no maid was kept. It is comforting to find that Mr. Hague's annual cost for his all-electric flat is also practically £15, and that for the same money payment he obtains all the required services with a minimum amount of labour. I am not of the opinion that, had Mr. Hague's household consisted of three persons instead of two, this annual cost would have been appreciably greater, provided that the extra person was not a maid living in. The author does not say whether maids, living in, are included in his household of six persons; but assuming they are, then since the maids must have light and heat, etc., the household is virtually doubled, and each part costs approximately £22 per annum, which compares favourably with Mr. Hague's cost of £15, since the author's household consists of a greater number of persons. The point I wish to make is that it is not so much the number of rooms in a house nor the number of persons forming the household which matters, but that the number of sections into which the household is divided is the important point. I feel that the Institution would be doing a great service to the electrical industry if it would collect, classify and publish statistics of the annual costs of all-electric houses, so that the general public could be supplied with some idea of the probable high and low limits within which their costs would fall in the event of their becoming owners of all-electric houses.

Mr. A. W. Lewis: I agree with the last speaker that architects are often called upon to electrify existing houses, which is a more difficult thing to do successfully. None of my friends who use electricity for cooking would go back to any other method. It can be argued, however, that the most economical use of coal is to convert it into gas and use this for heating and lighting.

Mr. J. W. Gibbs: I have recently installed an electric cooker in my house, and I am trying gradually to convert the house into an all-electric one, but I think that the maids will insist on using their kitchen fire as well. I should like to ask the author one or two questions. Who switches off the heater from the hot-water tank when he is away from home? What does he consider to be the correct temperature for a sitting-room? I am afraid that radiators are open to the same objections as an open fire, i.e. the person becomes very hot on one side and very cold on the other.

Mr. H. C. Hazel: The data contained in the paper should be valuable as a reference to members of the electric supply and contracting industries, who are daily asked by prospective consumers what their annual charges will be for electricity in the event of their equipping their houses for light, heat, cooking, hot-water service, etc. The usual questions asked by a prospective consumer are:—"What are the charges, i.e. the cost of electricity per unit?", "What would be the approximate all-in cost per annum?", and "What would be the cost of installation?". One of the reasons, I think, why electricity is not made use of, especially in homes, to the extent that it should be, is the complicated methods of charging which the supply undertakings have instituted. Glasgow has a system of standard charging based upon so many units (M) at 4½d. per unit plus ¾d. per unit thereafter, and those M units are the estimated annual consumption for lighting and include the consumer's share of capital and fixed charges. From this it would seem that each consumer must be separately assessed by the supply undertaking to fix the value of M. In Liverpool and other towns the rateable-value method has been instituted, this being a fixed charge of, say, 20 per cent of the rateable value of the house, and all the units consumed are supplied at ½d. per unit. In my opinion neither of these methods is clear to the layman and neither gives any definite indication as to what would be the approximate cost per unit to a person who proposes to build a house in any district, as on the rateable-value method the house would not be assessed until after it was built. For a house where a full use of electricity is contemplated, I suggest that a more simple method would be a fixed amount per annum for each living-room. This would not include cellars, lavatories, pantries, bathrooms, etc. Such an amount could be fixed so as to bring in a sum to cover the standard charges now received by the other methods, plus actual units metered at ½d. per unit, and would certainly be easier for the man in the street to grasp. The author has been fortunate in being able to collaborate with his architect, so that provision has been made in the layout of the house for all his wiring runs. This is a decided advantage, helping to cheapen the installation and at the same time minimizing fire risks and maintenance charges. Architects generally should co-operate more fully, when building houses, with the different specialists as to their requirements. These specialists are, as a rule, only called in when the house is almost completed, in fact just before the plastering

is to be commenced, thus causing unnecessary cutting away, etc., which adds to the cost. I think that the author's selection of C.T.S. wiring is quite a good one, especially as provision for suitable runs had been made in the house, but as no figure is given as to the cost of the wiring installation, no criticism can be made. What is the size of the service mains to the house, and what has been the maximum current noted at any one time? I note that the main switch is a 50-ampere one, and this seems to be on the small side. I should further like to ask if each room has its own radiator or if only a limited number of radiators are used and carried from one room to another. I note that the author is not satisfied with the boiling-rings, and this opinion is more or less generally held. I have installed a number of cookers, and in every case complaints have been made about the cost of boiling vegetables, etc., on the rings. I think that the only solution is to have, as the author suggests, the heating element embodied in the cooking or boiling utensil, as in the case of a kettle. The conclusions arrived at certainly show that the "all-electric" house, with electricity at an average of ¾d. per unit, is an economical proposition as compared with coal and gas, while at the same time it must show considerable saving in labour and be far more healthy. The data given should be the means of influencing many to electrify their houses on similar lines to that of the author.

Mr. P. J. Robinson: For the past two years I have occupied an "all-electric" house, but I have not had the advantage that the author has had, for I have had to convert a coal-fired house into an "all-electric" house. This has been done largely by placing radiators in the existing fireplaces, and open vents into the flues for ventilation purposes. It would appear, by comparison with figures given by the author, that my house is about 10 per cent larger than his, and the cost to me worked out last year at £51, the consumption being approximately 21 200 units. This figure is in excess of what it might have been, but a certain amount of experimental work has taken place, and these units are included in the total. The water has been dealt with by putting a constant loaded heater, controlled by thermostat, in the existing water tank, the capacity of the heater being 720 watts and of the tank 32 gallons. We have had an ample supply of hot water for all the usual purposes, but of course this does not allow more than one really hot bath a day, which on an average is sufficient for a household of 5 people. It is interesting to note the apparently good example that I have set in the immediate neighbourhood where I live, as evidenced by the number of people adopting electricity for their main uses, as 11 houses within a radius of 100 yards or so have practically been made, or are in the process of being made, "all-electric." Comparing the year 1922 with 1925 the units consumed in these 11 houses have already increased from 3 200 to 70 600, and the latter figure, showing an increase of 2 100 per cent, is rapidly increasing. On an output of this number of units, the capital charges on the distribution in this immediate district sinks to a very small figure. As mentioned by Mr. Dickinson, we are at the present time electrifying a number (some 250) of Corporation houses. We estimate that the total number of units used in these houses per annum will average 6 000 per house, which at the rate of charge of 2s. weekly plus ½d. per unit consumed, measured by means of a 1s.-in-the-slot meter, will amount to an average cost per house of 6s. 9½d. per week. I have obtained some statistics from a number of employees in the Department who live on existing Corporation estates, some using coal and gas, some gas alone, some gas, coal and electricity, and some electricity and coal; and from a group of 11 houses I find that the average cost per week is normally 7s. 4d. per house. This, of course, covers lighting, coal and gas bills. It will be interesting to see whether our estimates in the "all-electric" houses is correct or will be any greater than this, but we have estimated on the basis that water-heating will take 2 400 units, the allowance being 24 gallons of hot water per day, the mean temperature being 136° F. This is with a loading of 300 watts (continuous). These tanks are supplied with thermostats, as although thermostats tend to decrease the load factor they prevent any waste of energy if less than the stated amount is used. From the above it will be noted that the costs approximate very closely to the author's figures. I am glad to say that the architects have allowed us to collaborate with them in the design of the house. Ventilation has been provided by means of ducts discharging into the roof from each of the rooms, with hit-and-miss ventilators both on the outgoing duct and the incoming duct in the outer walls of the house. With regard to the hot-water supply, the hot-water loss in these houses has been carefully considered. There are three points of hot-water supply, wash-hand basin and bath, and the washing-up sink in the scullery. The losses in the pipe from the hot-water cylinder, which is situated on the wall between the wash-basin and the bath, are as follow: To the wash-hand basin 0·41 pint, to the bath 1·22 pints, and to the sink in the scullery 0·82 pint. Without a system of remote control I do not think it is possible to reduce this loss any further. One of the difficulties of electrifying an existing house is the enormous loss between the heating cylinder and the point at which the hot water is taken off. In some cases it amounts to 2 gallons. I am in agreement with the author that one of the principal defects of an "all-electric" house appears to be the somewhat unreliable nature of the electrical gear produced at the present day. We have tried a great number of experiments with a view to improving the reliability, and the boiling-plate referred to by Mr. Dickinson will, in my opinion, overcome many of our difficulties. Open-type boiling-plates are, in my opinion, highly undesirable, as they are liable to be damaged if milk or fat is spilt on them. In addition, if, say, a fork is accidentally dropped across an open element and the oven casing, a short-circuit is caused. With regard to the appliances with their own built-in element, one of the difficulties that seem to be almost unsurmountable is the fact that if any of these appliances are allowed to run dry they will have to be renewed, and this gives rise to an additional expense which is to be avoided in efficient service. We have, at the present time, succeeded in getting a satisfactory

element of 1 800 watts into an 8 in. × 8 in. square plate, and we are in hopes of getting one of 2 250 watts into the same area. Incidentally, with reference to the author's remarks on page 294 with regard to the lagging of tanks, cork is very expensive and we have found corrugated paper, similar to that used for the packing of bottles, placed against the tank and covered with ⅝ in. thickness of felting with canvas sewn over, the whole being finished with a varnish paint, is very efficient. In the Corporation houses an aluminium cover is being substituted for the canvas.

The Author's Reply to the Discussions at Newcastle, Glasgow, Edinburgh and Liverpool.

Prof. S. Parker Smith (*in reply*): In response to numerous requests for a daily load curve on a winter's day, the Glasgow Corporation Electricity Department have kindly taken the graph shown in Fig. C (p. 791), which may be compared with Fig. 8 in the paper for a summer's day. By a peculiar coincidence it so happened that, when this graph was taken, the kitchen fire was not in use that evening, as the maids were out; consequently the evening load should be increased by 8 amperes (2-kW fire).

In order to demonstrate the feasibility of artisans' all-electric dwellings, the details referred to in my earlier reply (see page 330) have been elaborated in an article in the *Electrician* (1926, vol. 96, pp. 346 and 354). The revised figures are based on a 10 per cent higher consumption, and it is concluded that with energy at ½d. per unit plus a fixed charge the proposition is sound.

In order to avoid repetition in the present reply, the earlier reply on page 328 should be consulted.

Newcastle.

The long experience of Mr. Pinkney is valuable, particularly in view of the less favourable tariffs in his area. With the tariff prevailing on the Newcastle Electric Supply system, a lagged tank would seem to be imperative. The two-rate meter may not always be justifiable, but is undoubtedly so in the speaker's or the author's house. As regards expense, it should be remembered that some supply undertakings fit two meters (for lighting and for heating) even in small houses.

Mr. Clothier's remark regarding efficient domestics is appreciated, and a wider use of electricity would both ease the situation and provide efficient service. It is difficult to see why electrical appliances should not be used in bathrooms, provided they are effectively earthed. Though the use of plugs as switches leads to economy in house wiring, and is not only sanctioned but adopted by some supply undertakings, the practice is risky and might lead to bad shocks and burns and rapid deterioration of the contacts. Even if a switch is provided on the appliance, there is nothing to render its use imperative, nor to safeguard the operator when plugging in in the event of a short-circuit. Clearly switchplugs to be effective must have mechanical interlocks to ensure correct use.

Mr. Ward's contentions are mainly ill-founded. The number of heating points is not excessive—many are now duplicated for convenience. No discomfort whatever is experienced on washing-days. The cloak room is for cloaks. The distribution board is in a convenient position where it is and would be inconvenient in the cloak room. The use of split conduit was ruled out from the outset, though a length of open conduit is useful where there is a danger of driving a nail into the rubber covering. The effectiveness of the drying closet is largely due to the vigorous supply of air drawn through it. As regards boiling-plates, the first preference is to avoid any type whatsoever, the second is the closed type, because it is safe though slow. It is hoped that the results obtained on boiling-plates will soon be published. None of the anticipated drawbacks of self-contained vessels were realized. I disagree with most of the speaker's views on hot-water supply, ventilation and room-heating. No auxiliary apparatus is used on the lighting circuits.

Many of Miss Holm's suggestions are helpful. Perhaps the washing machine is superior to the boiler, but it is much more costly to buy. Experience has proved the feared drawbacks of self-contained cooking vessels to be illusory, but it will be noticed that a boiling-plate is provided in the proposed arrangement in Fig. A, p. 330. Among the many desirable but not essential appliances installed, an electrically-heated towel rail has been included. The suggestion for preventing garbage becoming a nuisance is useful. Speaking generally, the all-electric house appears to greater advantage where no domestic servants are employed.

The only reply to Mr. Gregory, beyond saying I do not agree with him, is that I have never lived under less barbaric conditions than at present. The rooms are not chilly—perhaps on account of the hollow walls—and the members of the household neither complain of cold nor do they catch cold. My one grumble is that I have to work in a centrally-heated building; and I have no wish to transfer the discomfort of warmed air to the home.

To Mr. Cross I would say that the under-running of the lamps is less than he assumes. Instead of 250 volts, the lamps are rated for 260 volts—this is also advisable in case the supply voltage rises above its declared value. Mr. Cross agrees that one need not be specially careful in the use of current for lighting; all the more reason therefore to pay due regard to the life of the lamps. I do not agree with the view that the bulk of the standing charge should be debited to lighting—electrical energy should be used freely for lighting. The practice of using electricity solely for lighting ought not to be allowed to govern tariffs for the general case.

In reply to Mr. Williams, the absence of a coal fire in the kitchen has not caused any trouble with domestic help—rather the contrary. The figures in Table F will be appreciated. Whilst the annual cost is similar to

my own, it will be seen that electricity works out at about 2d. per unit. At this price it is seen that the all-electric proposition would be ruled out on a cost basis.

Glasgow.

Acknowledgment has been made in the paper to Mr. Mitchell for his hearty co-operation and pioneer work in domestic electrification. His argument should appeal to many supply undertakings and it is hoped that low-temperature carbonization at the power house to which he refers will soon permit further progress to be made in the reduction of tariffs.

Mr. Robertson has made an interesting contribution. The omission of a sun bath is admitted. The house was not built as an institution, but a sun bath can be installed if required. The liberal provision of heating points has proved a great benefit; also running a separate circuit for each point has many advantages. The figures in Table H are informative, by showing the difference made by coal fires. It will be seen that increasing the consumption from 2 824 units to 4 586 units caused the average overall cost per unit to fall from 1·2d. to 1·1d. Had the running costs been based on Glasgow tariffs, and the standing charge kept the same, viz. £6 10s., the total cost with coal fires would have been £23 1s. 8d. and with coal fire for heating water only, £22 1s. 1d., while the overall cost per unit would have been 1·05d. and 0·84d. respectively. This emphasizes the importance of cost; also the feasibility of electricity for domestic heating.

The particulars given by Mr. Hardie are very welcome. Not only can he speak authoritatively on all forms of electric appliances for the home, but he has shown how the overall cost per unit at the Glasgow rates can be made as low as 0·656d.

Edinburgh.

Prof. Baily made a long contribution to the discussion and I can only regret to state that I am in profound disagreement with him on almost every point and particularly on questions of fact. To assert that the warming of the rooms and the amount of hot water correspond to the mode of life in a small flat is as far from the truth as to assert that to live in an all-electric house is to live in the lap of luxury. Prof. Barker's figures in Table A on page 305 prove that the net B.Th.U. used per person per annum are quite normal, while ample evidence has been given to show that the costs are reasonable. Apparently the points of view are fundamentally different, for I attach great importance in the home to economy in worry and drudgery as well as in money. The leisure obtained thereby can be fully occupied by the more desirable things in life. I fail to see the object of air-heating tests with radiant fires. No dampness has been observed.

In his criticism of the low rate for heating water during night hours, I think Mr. Seddon fails to attach sufficient importance to the actual conditions. Properly considered, the domestic tariff in question is really a three-part tariff: the fixed part, the part at ½d. per unit, and the part of ⅜d. per unit. Thus the consumer's share of the fixed charges has already been met. As

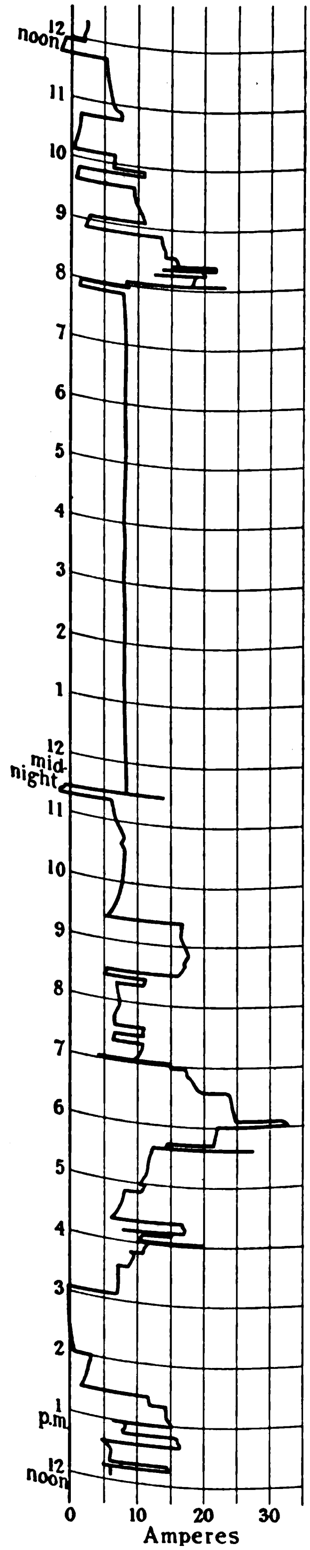

Fig. C.—Load curve for Tuesday, 16th February, 1926. Mean height = 8·69 amperes.

regards differentiation, does not Mr. Seddon make consumers at peak hours, i.e. the lighting-load consumers, pay a price corresponding to his costs in one way or another? Similarly for low-power-factor consumers.

Replying to Mr. Duncan's remarks, it would be a simple matter to arrange for portable lights in the bedrooms. Also the wash boiler can be replaced by the more costly machine, if desired. The connections are as stated, but it was not deemed necessary to make alterations after the experimental period was completed, as the matter was too insignificant. In a new layout, of course, the necessary modifications would be made. A proper appreciation of the unassessable advantages of electric working is important.

Mr. Sharpley has kindly given us his own costs. I need but repeat that ample evidence has been given to show that the Glasgow rates are comparable with rates for other modes of heating, etc. Many members will agree with the comments on the wastefulness of maids—the all-electric house naturally appears to the greatest advantage where no maids are kept. The tank lagging is cork. A fireless electric cooker has been tried. It seemed satisfactory, but could not replace the ordinary oven and utensils.

The only comment I have to make on Mr. Mears's remarks is that the small house will probably feel the advantage of all-electric working before the large house.

Mr. Martin has given a good analysis of the supply position regarding the heating of water. The substitution of C.T.S. wiring for screwed conduit should not only result in lower installation costs, but prevent much damage to old houses being wired. The modern method has other great advantages in house wiring.

Canon Wakeham's experience is valuable, more especially as it comes from a "layman" in matters electrical.

It is not surprising that the cookers supplied in 1914, referred to by Mr. Munro, should now have been replaced. I do not dispute the estimate for coal consumption. This point is dealt with in the paper (page 298). Possibly some low-temperature carbonization process may be developed for power stations. But even under existing conditions, modern power stations can produce energy at a competitive price. If one speaks of the useless waste of national fuel, what is to be said of the coal fire, which produces smoke in addition? In any case, the coal trade cannot complain in this respect. There is no need for me to champion the vacuum cleaner or the washing machine. Enough evidence in their favour has already been given in these discussions. If anyone has a right to complain it is the supply undertaking, on account of the small current consumption of the apparatus, or the consumer on account of their initial cost.

Liverpool.

Mr. Dickinson has rather misconstrued my remark that the cost in Glasgow is too high. As many speakers have shown, the cost as it stands is competitive; also full weight has been attached to convenience and comfort. Many people, however, are not prepared to take the latter for granted, particularly in view of the capital outlay required for conversion. Consequently the all-electric proposition will become more attractive when it can be definitely shown to be cheaper than any of its alternatives. It is not intended to convey that every all-electric house will cost 3 to 4 per cent more than an ordinary house. Chimney breasts are not essential, but the flues are good ventilators. Regarding the pots with self-contained elements, it need only be said that three months' experience with them is sufficient to make a return to boiling-plates unthinkable. A combination of speed and safety with a saving of 50 per cent is ideal for the consumer, however the supply undertaking may regard it. All the switching for hot water can be done automatically. The water temperature falls very little, as the incoming water mixes very slightly. Actually the emergency heater is seldom needed, and never during peak hours. It is very encouraging to learn that all-electric houses (where no coal whatever is used) are being built in Liverpool.

The weakness of the boiling-plate is indicated by Dr. Marchant, but he does not draw the natural inference. Whilst it is agreed that electric cooking would not be a success, without proper maintenance by the supply undertaking, is it not equally certain that high upkeep will ultimately prove prohibitive? None of the anticipated troubles with the self-contained utensil, such as boiling dry, has been experienced by me. An efficiency of 25 per cent would be a fair average to take for domestic-type boiling-plates.

The remarks made by Mr. Wilson are very encouraging, but more will have to be done to assist wiring and improve appliances, especially cookers, before the all-electric house can be expected to become general.

In reply to Mrs. Dickinson, it might be said that the pots with built-in elements need not be heavy —my own, though substantial, are no heavier than pots for the coal range.

The point made by Prof. Teago regarding the number of rooms in use simultaneously is important. In my house, a living-room and kitchen were always in use.

The conversion of existing houses to electric working, referred to by Mr. Lewis, need not be difficult, provided use is made of the more modern methods of wiring. It is possible to push the argument of the most economical use of coal too far. After all, the importance of obtaining from coal what is required ought not to be lost sight of.

The point raised by Mr. Gibbs regarding a coal fire in the kitchen has not arisen in my house. Any person in the house can operate the tank switches—there is no more difficulty here than with a fire. A sitting-room where the persons are well supplied with radiant heat can have a temperature of 50–55° F. With the electric fires properly placed there is no question of one side of the person getting too hot while the other side is left cold.

With reference to Mr. Hazel's criticism of the methods of charging, doubtless much could be done towards simplification and standardization. The two-part tariff is a fair one in principle, and it can be easily explained to the layman. Basing the fixed charge on the number of rooms is a well-known system; but, generally speaking, with the same price per unit the overall cost per

unit does not vary much with any of the systems in vogue. There is a decided advantage in collaboration between architect and electrical engineer—this is practically essential if the best results are to be obtained. Certainly the wiring should be done before the plastering in a new house; even in a house under conversion the amount of cutting away should be reduced to a minimum. The current reached can be estimated from Fig. 8 in the paper and Fig. C on page 791. Generally speaking, most rooms have their own radiators, but occasionally a radiator is carried from one room to another.

The figures given by Mr. Robinson will prove very encouraging to many of his colleagues in other towns. His overall cost per unit of 0·58d. is admirable. The estimated consumption of 6 000 units per annum compares well with my figure of 5 500 units; also the predicted costs agree closely. The result will be watched with interest.

Results of Second Year's Working.

It is hoped to give the requested figures for the second year, ending 10th July, 1926, in a later reply. It can already be stated, however, that the total consumption will be slightly less than in the first year; the heating consumption will be higher, on account of the severer winter, but on the other hand the cooking consumption will be lower, due to the use of utensils with self-contained elements.

PROCEEDINGS OF THE INSTITUTION.

737th ORDINARY MEETING, 21 JANUARY, 1926.

Mr. R. A. Chattock, President, took the chair at 6 p.m.

The minutes of the Ordinary Meeting held on the 7th January, 1926, were taken as read and were confirmed and signed.

Mr. H. L. Leach and Professor J. T. MacGregor-Morris were appointed scrutineers of the ballot for the election and transfer of members, and, at the end of the meeting, the result of the ballot was declared as follows:—

Elections.

Member.

Stanhope, Joseph Henry.

Associate Members.

Aust, Frank, M.Sc.
Beck, Edwin La Touche.
Burke, Reginald Thomas.
Dalby, Joseph Francis.
Ewart, George.
Flanagan, Patrick, B.E.
Flockhart, Derwent Pearce.
Goatley, Anthony Horace.
Greenwood, Harold Jackson.
Hall, Roger Vine, B.E.
Hirsch, Paul Bernhardt.
Jones, Nelson.
Kearsley, Frederick William.
Land, Alfred Edgar.
McAlonan, Francis Wilson B., B.Sc.(Eng.).
McMillan, Daniel.
Mitchell, Alexander Stewart.
Newman, John Ernest.
Plowman, William Ewart.
Schofield, Harold Hubert.
Shackell, Reginald Walter.
Stretton, Leonard Wilfred.
Sutcliffe, Gilbert George.
Tuck, Harry Playford, B.Sc., B.E.
Turner, Philip Keston.
Waters, John Henry.
Withycombe, Robert.
Yorke, Gerald.

Graduates.

Agate, Purushottam Narayan, B.Sc.
Ahmed, Hussein Mohamed.
Almond, John.
Ambalavanar, Pasupathippillai.
Amies, George.
Beale, Robert Talbot G. C.
Brown, David Gregory, B.Sc.
Brown, Edwin Lionel.
Bull, Robert.
Campbell, Archibald Stewart.
Campbell, James Philip.
Carter, Frank Alexis.
Chantrill, Ralph Lohbek, B.Sc.
Christie, Thomas Gregg, B.Sc.
Clark, Douglas Gordon.
Colson, George Basil.
Crowley, Cornelius.
Dobell, Claude Herbert.
Dore, Claude Urling.
Dunn, Leonard William.
Ely, Eric Stanley.
English, Harold.
Fisher, Henry.
Gilbertson, Frederick James.
Griffin, Reginald Michael J.
Groeneveld, Raymond.
Guthrie, James.
Hall, Cecil Stuart.
Hall, James Owen.
Handley, William Cecil, B.Sc.Tech.
Hardwick, Charles Philip.
Harrison, Reginald Henry.
Henning, Arthur James.
Hill, Albert Rowland.
Jackson, Arthur Gladstone.
Jarvis, Harry William.
King, Wallis Lovell.
Kitchen, Harold Jennings.
Krishna, Rama.
Kuperman, Moshe, B.Sc.Tech.
Law, Joseph.
Logan, Alexander.
Lown, Stephen John.
MacMicking, Julius Manus.
Mann, Samuel Alfred.
Meldrum, Francis Arnold.
Munn, Herbert Seymour.
Myers, William Henry.
Nuesch, John.
O'Farrell, Joseph P.
Orr, James.
O'Sullivan, Bernard Joseph, B.E.
Parry, Herbert Percy.
Pearson, Stanley Garnett.

Graduates—continued.

Petrides, Sophocles A., B.Sc.Tech.
Phœnix, William.
Pimley, Gordon Haldane.
Pollock, Wallace.
Reddyhough, Harry Lythgoe.
Rees, Horace Edward.
Ripley, Ronald Vincent.
Roberts, Frank Rob C.
Rouse, Wilfred Sydney.
Rudra, John Jitendranath, M.A., B.Sc.
Russell, Edward Powys.
Sankey, George Henry, B.Sc.(Eng.).
Sargent, Hugh Hamilton.
Seaborne, William.
Segrave, Michael.
Shanly; Leo Dennis.
Shelley, George Henry L.
Smith, Arthur McDonald.
Sreenivasan, Kasi, B.Sc.
Stafford, Charles Henry.
Telemat, Shafic Mustafa.
Ward, John Hunter.
Widgery, Robert George.
Woodland, Reginald.

Students.

Ahmad, Ghulam Aziz.
Ainsworth, Frank Glave.
Ambler, Alec Guy.
Ambler, Eric Clifford.
Arnold, Sidney Roger.
Ashcroft, William Alfred.
Austin, Basil Brougham.
Austin, Neville Sydney.
Baker, Edward John.
Ballantyne, Walter.
Baly, Wilfred Frank.
Bamford, William.
Barnard, George Philip.
Barrett, Arthur Edwin, B.A.
Barron, Donovan Allaway.
Barton, Henry Leslie.
Barton, Richard Bernard.
Baskett, Charles Arden R.
Batra, Rajindra Nath.
Beach, Noel Henry A.
Beanland, Charles Percy.
Beckett, Charles Stephen.
Beckingsale, Alfred Alec.
Bedwell, Albert Vernon.
Beetlestone, Andrew.
Bell, Charles.
Bennett, Clayton.
Berens, Cyril Eustace.
Berriman, Leslie.
Bisley, Eric.
Blandford, Ewart Alfred G.
Bolt, Frederick Denis.
Booth, Joseph Westwood.
Bowen, William Looker.
Bradfield, Geoffrey.
Bray, Alan Ison.
Bray, Frederick Harry.
Brett, Edward James.
Broadbent, Maurice Edward.
Broadhurst, Jack.
Bromige, Ernest William.
Burton, Gordon Victor.
Butters, John Arthur.
Calder, Alexander, B.Sc.
Calder, Rex Finlayson C.
Cameron, Thomas Tennant.
Canter, George William G.
Cartwright, Arthur Henry.
Castellan, Guy Edward.
Chakravarti, Jogendra Narayan.
Chanter, Arthur John, B.A.
Chapman, Leslie James.
Chapman, Ralph Eustace.
Chapple, John.
Chard, Frederic Delacourt.
Christmas, Francis Thomas.
Clarke, Edgar Valentine.
Clothier, George Donald.
Coke, Robert Alexander.
Collins, Herbert.
Collins, William Henry A.
Collyer, James Kimberley.
Coote, Thomas Charles.
Copping, Harry.
Corfield, William Graham.
Cousins, George Jeffrey.
Cozens, Geoffrey Gordon.

Zula-Crosse, Frederick Cecil, B.Sc.

The President: The Council have decided that the fifth award of the Faraday Medal shall be made to Colonel R. E. Crompton. The Medal is awarded for notable scientific or industrial achievement in electrical engineering, or for conspicuous service rendered to the advancement of electrical science, and I think it will

be agreed that Colonel Crompton's work comes under both these heads.

A paper by Messrs. J. Lindley Thompson, M.Sc., Member, and H. Walmsley, entitled "Notes on the Testing of Static Transformers" (see page 505), was read and discussed. On the motion of the President a hearty vote of thanks was accorded to the authors, and the meeting terminated at 8.10 p.m.

51st MEETING OF THE WIRELESS SECTION, 3 FEBRUARY, 1926.

Major B. Binyon, O.B.E., M.A., Chairman of the Section, took the chair at 6 p.m.

The minutes of the meeting of the Wireless Section, held on the 6th January, 1926, were taken as read and were confirmed and signed.

A paper by Mr. J. Hollingworth, M.A., B.Sc., Associate Member, entitled "The Propagation of Radio Waves" (see page 579), was read and discussed.

On the motion of the Chairman a vote of thanks to the author was carried with acclamation, and the meeting terminated at 7.40 p.m.

738th ORDINARY MEETING, 4 FEBRUARY, 1926.

Mr. R. A. Chattock, President, took the chair at 6 p.m.

The minutes of the Ordinary Meeting held on the 21st January, 1926, were taken as read and were confirmed and signed.

A list of candidates for election and transfer approved by the Council for ballot was taken as read and was ordered to be suspended in the Hall.

A list of donations to the Benevolent Fund (see page 278) was taken as read and the thanks of the meeting were accorded to the donors.

A paper by Mr. E. V. Clark, B.Sc., Associate Member, entitled "Power Factor and Tariff" (see page 625), and a paper by Mr. E. W. Dorey, Associate Member, entitled "The Improvement of Power Factor" (see page 633), were read (the former, in the absence of the author, by Mr. E. L. Hill) and discussed.

On the motion of the President votes of thanks to the authors, and to Mr. Hill for reading Mr. Clark's paper, were carried with acclamation, and the meeting terminated at 7.40 p.m.

INSTITUTION NOTES.

Nomination for Election to the Council.

In addition to those members nominated by the Council (see page 717) the following member has been nominated for ballot as Ordinary Member of Council:

R. F. FERGUSON (*Nominated by* Messrs. J. H. Bowden, J. Christie, J. E. Edgecombe, S. E. Fedden, H. Marryat, R. B. Mitchell, E. S. New, A. M. Sillar, W. C. P. Tapper and E. J. Williams).

Associate Membership Examination Results: April 1926.

Passed.

Aldis, R. F. (Windsor).
Anslow, C. L. (London).
Azimuddin, M. (Bristol).
Ball, R. D. (London).
Birtwistle, M. (Enfield).
Bishop, J. L. (Southampton).
Bland, J. G. (Northampton).
Booth, W. L. (Birmingham).
Brown, Harry (Edgware).
Burton, W. C. L. (London).

Smith, A. J. (London).
Symes, G. L. (Southsea).
Tennison, A. J. (East Croydon).

Surrey Group Anti-Aircraft Searchlight Companies R.E. (T.A.).

The Secretary has been asked to publish the following information:—

There are vacancies for Commissioned Officers in the above unit, which has been recently formed and consists of three companies, having headquarters at Croydon, Kingston-upon-Thames and Guildford. The Croydon Company has an out-lying section at Redhill, and the Guildford Company will probably have sections at Farnham and Woking. The Group Headquarters are at Kingston-upon-Thames.

The Companies work chiefly with the Royal Air Force, and are equipped with 90 cm and 120 cm searchlight projectors, power for which is supplied from either stationary engine sets or from petrol-electric lorries. Sound-locating instruments are provided for directing searchlight beams on to the target by sound, or for following targets in unfavourable weather. Training is carried out in co-operation with the Air Defence

Squadrons, R.A.F., who provide machines to act as targets during drill hours. An annual camp is held, lasting for 15 days, and usually takes place at a health resort.

Technically qualified men are required as officers. Candidates must be of British nationality and possess one of the following qualifications :—

(*a*) Have served for 6 months in the Regular or Territorial Army and undertake to pass Certificate " A " O.T.C.

(*b*) Have served overseas with an Expeditionary Force or in the Royal Navy for 3 months and be recommended by a Commanding Officer under whom they have served.

(*c*) Have previous O.T.C. service and Certificate " A ".

Alternatively, a candidate with no previous service may undertake to qualify for Certificate " A " within 12 months of being commissioned.

An outfit allowance of £40 is granted on being commissioned, provided the candidate has not previously received any outfit allowance during the last 3 years. Full Army pay and allowances are paid while at camp or on courses, and travelling expenses to drills, etc., are refunded. Associate Members of the Institution of Electrical Engineers are eligible for the issue of Royal Engineer pay in addition.

Full information can be obtained from the Adjutant, Surrey Group A.A. S/L Cos. R.E., 145, London Road, Kingston-upon-Thames.

The Benevolent Fund.

The following is a list of the Donations and Annual Subscriptions received during the period 26 May–25 June, 1926 :—

	£	s.	d.

ELECTRO-FARMING, OR THE APPLICATIONS OF ELECTRICITY TO AGRICULTURE.

By R. Borlase Matthews, Member.

(*Paper first received* 20*th November*, 1925, *and in final form* 29*th January*, 1926; *read before* The Institution 4*th March*, *before the* North-Eastern Centre 9*th March*, *before the* South Midland Centre 10*th March*, *before the* North-Western Centre 30*th March*, *and before the* Western Centre 12*th April*, 1926.)

Summary.

The paper deals with the progress made since a previous one on the same subject. It is also a sequel to the report of the I.E.E. Committee on Electricity in Agriculture.

The field covered by electro-farming is now so wide that the paper has been confined to the latest developments and the chief points about which information is at present required. These are classified under three headings:—

"The Rural Distribution System" draws attention to the importance of dealing with statistics on the basis of the route miles and not the area supplied. It is claimed that where a quarter of the area is arable land, the supply is profitable.

"The Farm Installation and its Uses" deals with the practical points which arise in planning a farm installation, including the special requirements of electric motors for farms. Reference is made to new methods of speed reduction and to a plan for improving the load factor by restrictive control of the larger apparatus. The latest developments are discussed, such as intensive illumination for stimulating plant growth, and the possibilities of increasing the yield of honey.

The last heading covers some of the aspects of "Work on the Land, and Haulage." The most important feature is electric ploughing, which ensures a profitable load for the supply undertaking. A specification is given of the author's ideal of an electric tractor suitable for the smaller farm. It is designed for ploughing as well as all other field operations and general haulage, and is fitted with a half creeper track and also a storage battery. The object of the latter is to enable the tractor to proceed from field to field and also to haul loads on the public roads. When carrying out field work it is intended that the machine should take its supply from overhead lines by means of a cable laid on the ground. Mention is made of a method for reducing plough friction by making the plough coulter alive. Other matters dealt with are: rotary tillers, progress in making hay without sunshine, new developments in electro-silage, and a central method for liquid-manure distribution over farm lands. In an Appendix, a bibliography of the more important references to the subject is provided.

Generally, the paper sums up the results of a great deal of full-scale experimental work carried out by the author.

Table of Contents.

Since the author presented to this Institution his previous paper on Electro-Farming,* very considerable progress has been made.

An outstanding feature of the past year is the report of the I.E.E. Committee on Electricity in Agriculture,† which coincided with the Report presented by Mr. C. Dampier Whetham, on behalf of the Research Committee to the Royal Agricultural Society of England.‡

Periodical conferences are now held in most countries. A beginning was made in Great Britain (at the Chester R.A.S.E. Show, 1925) due to the enterprise of the British Electrical Development Association. This is to be followed by a second meeting at the R.A.S.E. Show in July 1926, at Reading. Further, the new development now has its own journal—*Electro-Farming*.

It is strange that one of the most backward countries in this development is the United States of America. Out of 15 788 million h.p.-hours per annum used on American farms, only 850 million are supplied electrically. However, it seems likely that they will soon be in the van, for the matter is at present being taken up most energetically and large sums of money are being expended upon full-scale experimental work.

* *Journal I.E.E.*, 1922, vol. 60, p. 725.
† *Ibid.*, 1925, vol. 63, p. 838.
‡ *Journal of the Royal Agricultural Society of England*, 1924, vol. 85, p. 246.

The subject has now become so wide in scope that the author proposes to deal only with some of the more recent developments and, in particular, with those matters which are at present of most interest. The general problem may be classified under the following main headings :—

(i) The rural distribution system.
(ii) The farm installation and its uses.
(iii) Work on the land and haulage.

(1) The Rural Distribution System.

Route length as the basis of rural distribution.—In quoting statistics concerning urban central-station distribution, the load density is often stated in terms of annual consumption in kilowatt-hours per square mile. The same method is therefore apt to be applied to rural districts. Even in the towns the facts are much better represented by considering cable route-miles instead of square miles of supply area ; in the country this applies still more, since normally the rural population is located chiefly beside the old-established trade routes, the easy roads through the valleys and through the centres of rich arable land.

Table 1.

Units and revenue per mile of route.

	kWh per annum		Annual receipts per mile
	per mile	per km	
Rural— Lighting, cooking, heating and barn work on farms	10 500 to 22 500	6 250 to 10 400	£175 to £375
Ditto, plus ploughing ..	34 500 to 48 000	21 600 to 30 000	£430 to £600
Rural industries and lighting	4 000 to 8 000	2 500 to 5 000	£50 to £100
Totals	38 500 to 56 000	24 100 to 35 000	£480 to £700
Urban— 100 consumers per mile ..	20 000	12 500	£250 to £333

Remunerative rural areas.—Table 1 gives some comparisons of units consumed and probable income for rural and urban conditions, in terms of miles (or kilometres) of route.

There are already routes where the consumption per mile of 10 000-volt distributor without ploughing is equal to or exceeds the urban figure in Table 1.

It will be seen that the possible revenue per route mile of rural line is at least as large as that from the usual town load known to be profitably supplied. It must be remembered that villages and rural industries will take a considerable supply in addition to that consumed by the farms. Anything over 5 000 units per annum per mile is profitable. The important matter is to exercise economy in construction work. Interest and depreciation for a rural line are, of course, much lower than for an underground distributor in a city. Again, the capacity of an overhead line can be cheaply increased in the future, the only expense being for conductors, insulators and labour for erection.

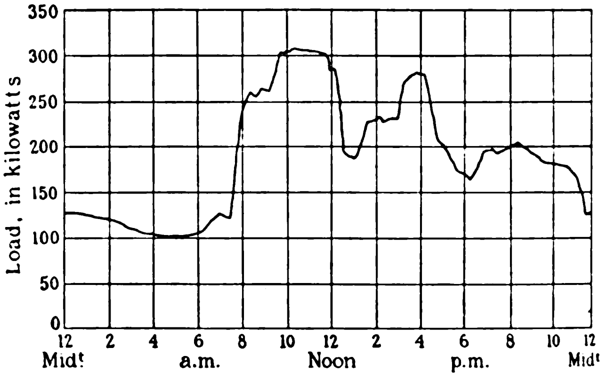

Fig. 1.—Typical load curve for an English rural distribution line.

Practical experience indicates, at the present stage, that in order to provide a remunerative electricity supply a quarter to a third of the area must be arable or rich dairy land. The point is not so much whether electric ploughing is to be employed or not—it will probably not be used in many districts for a few years—as the fact that a farmer with a good proportion of arable land needs to treat, in some way, the crops which he produces, or else he has to prepare food for stock. The amount of power necessary for these purposes has a direct relation to the area of land under the plough, and also to the fertility of the soil. In some of the more fertile parts of Europe the consumption of electricity is already 100 units per acre, without taking into account any current actually employed on the land for ploughing or other purposes. Ploughing and cultivation would have consumed an additional 60 units per acre, while treatment and handling of the crops would absorb up to 40 units per acre. Over and above all this, there is a very important load that has not yet been touched, viz. that of haulage, estimated at about 75 units per acre. Thus, under ideal conditions, it is possible to conceive a consumption of 275 units per acre, based upon present practice. As an illustration of what that would mean to this country alone, assuming that its 57 million acres of land were all suitable for agriculture, on the above basis of consumption the requirements would be about 16 000 million units per annum, whereas the present output of all the central stations in the country, including the output for railway work, is only 7 415 millions. Thus the

hypothetical requirements for agriculture would be more than twice those for all other purposes. If the agricultural consumption were only one-twentieth of this, it would be as great a load as that of the power companies on the North-East coast of England, admittedly a very large output (about 800 million units per annum).

These approximations are supported by a statement made by the United States Department of Agriculture (which has recently made a very careful survey of the consumption of all kinds of power used on farms)—"agriculture in the United States uses practically as much primary power as all manufacturing and central-station plants combined." This seems to be the position in almost any country.

Without ploughing or haulage, a figure of 10 to 30 units per acre may at present be taken as a fair average upon which to base calculations for this country. Ploughing and cultivation would take 45 to 60 units per acre, while thrashing would need 24 to 45 units per acre, depending upon the heaviness of the crop. The demand of rural industries usually amounts to 25 to 30 per cent of the purely agricultural consumption. As more industries are attracted to the country, this proportion increases. An analysis of the electricity supply to 34 rural districts in Germany showed the results set out in Table 2, and these could be very considerably improved if the farmers were shown how to make better use of the supply.

TABLE 2.

Consumption of electrical energy in 34 German rural districts (without electric ploughing).

	kWh per acre	kWh per hectare
Lighting	12·5 to 22·5	30 to 55
Power	27·5 to 42	65 to 100
Totals ..	40 to 64·5	95 to 155
Average	50	125

At the first meeting of the Electro-Farming Section of the World Power Conference held in London in 1924, the author read a paper upon "Electro-Farming Economics." * The most interesting fact elicited from the discussion was the confirmation from several countries that, if properly laid out, a rural electrical distribution scheme is profitable. The author was discussing this all-important matter recently with a prominent director of successful French electricity-supply companies. He stated that the usual definition of a rural area was—one in which it would not pay to supply electricity, based on the existing demand for power. After the lines were installed, according to his experience, so many small auxiliary industries started up in conjunction with the farm loads, that it paid the supply undertaking. The district then ceased, however, to be a rural area in the sense of the above definition.

* Paper No. 266: "First World Power Conference," London, 1924.

Extra-high-tension layout.—The layout of the line only differs from the usual practice in that additional tappings have to be provided *en route*. Normally, an extra-high-tension transmission line merely serves to link up the super-power stations in two or more important cities or towns, tapping through substations. Under conditions of rural distribution these substations will be at more frequent intervals and probably of the open-air type (and thus cheaper). It has long been customary to duplicate extra-high-tension lines, and advantage may be taken of this fact in new layouts destined to provide for any intervening rural demand. Actually it will often be found advisable to utilize two (or even three) distinct routes at some considerable distance apart. One route might be the most direct between the towns. The second (and third, if required) should go through the centres of gravity of the anticipated rural demand. In other words, what is normally an auxiliary service for the city will become the main supply for the intervening area. At the same time, it is available to render assistance to that city in case of emergency.

Distribution system.—The layout is affected by the low-tension voltage required. In the initial days of rural supply, in order to reduce line construction costs, it will undoubtedly be the practice to work with a greater voltage-drop during the day-time than would be permissible for city work.

On the Continent, low-tension supply seems to be settling down to 380 volts, three-phase, 50 cycles, for power, with 220 volts between one phase and neutral for lighting; whilst in Great Britain favour is given to 400 volts, three-phase, 50 cycles, with 230 volts for lighting. The possibilities of single-phase rural distribution and the use of galvanized steel conductors are receiving very considerable attention, but so far the methods are not utilized to any great extent. In any case the provision for the supply of heavy loads, such as ploughing and thrashing, must not be overlooked.

To maintain the above-mentioned voltages, the countryside has to be set out in circular adjoining areas of approximately 3 miles (5 km) diameter, each supplied from a 10 000-volt sub-distribution system, connected to the main extra-high-tension distribution of 30 to 220 kV. At present a 25- to 50-kVA transformer is usually sufficient for each of these substations, but the transformer capacities will have to be increased later on.

In most countries there is an average of $1\frac{1}{2}$ farms and 2 other consumers per mile (1·6 km) of low-tension distributor. Each 10 000-volt transformer station will supply about 22 farms and 30 to 40 other consumers, including motors totalling up to 300 h.p. Though the load factor per motor is low, that per farm (the more important matter) is high, based on its maximum demand. It averages at present 35 per cent, giving a consumption of 90 000 units per annum, i.e. 43 000 units per route mile of 10 000-volt distributor.

An example of extra-high-tension distribution.—Assume two super-power stations, "G" and "C," situated 50 miles (80 km) apart (see Fig. 2) and connected by a 110 000-volt line. If the district were arable there would be an area of supply of about 2 000 square miles

(1¼ million hectares). On the basis of estimates made for city conditions, it would seem almost hopeless to think of attempting to supply such an area. However, if the work is carried out on the lines suggested in this paper, basing the distribution on the route length, it will be found that an annual consumption of 96 million kWh can be supplied by increasing the length of extra-high-tension line from 50 miles (80 km) to 200 miles (320 km). In addition, there would have to be provided five open-air substations and 375 miles (600 km) of 33 000-volt sub-transmission lines; and 500 miles (800 km) of 10 000-volt feeders to the local low-tension substations would also be needed.

For the scheme set out in Fig. 2, one extra-high-tension line would go by the shortest route between the cities and two others would also be provided. Of these, one would run parallel on one side at an average distance of, say, 15 miles (24 km), and the other a similar distance away on the other side. Thus the five 110 000/33 000-volt substations may be situated at the centres of gravity of the local demands. In practice, the theoretical diagram (Fig. 2) would, of course, require considerable modification, though the routes suggested for the three extra-high-tension lines will be found to be characteristic. On approaching the towns, the density of the population and the demand for an electricity supply will increase. Also the distribution of the arable land will not be uniform. This may necessitate a modification of the position of the sub-stations.

It is assumed that the low-tension distribution net-

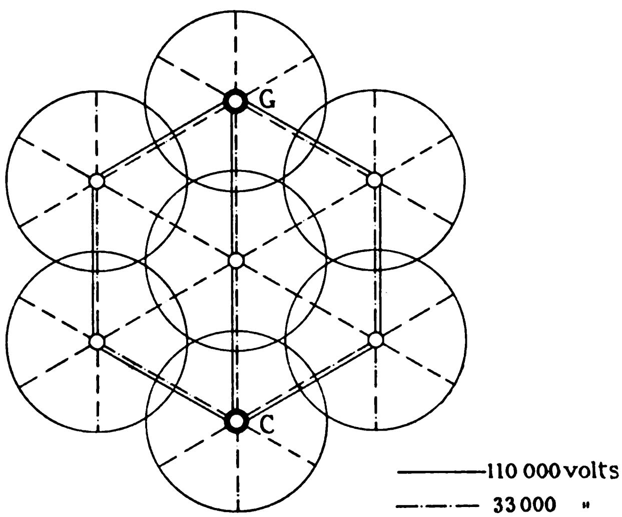

FIG. 2.—An example of extra-high-tension rural distribution between two generating stations "G" and "C," 50 miles (80 km) apart. The sides of the triangles represent distances of 25 miles (40 km).

work (380/220 or 400/230 volts) will be supplied by the local communities. Hence the power supply undertaking would have to consider only the costs up to and including the 10 000-volt substations.

Such a layout only requires one mile of extra-high-tension 110 000-volt line per 30 square miles (19 200 acres) of land (or 1 km of line per 5 000 hectares), plus a mile of 33 000-volt line per 8 square miles (5 120 acres) of country (or 1 km of line per 1 030 hectares), plus a mile of 10 000-volt line per 6 square miles (3 840 acres) of ground (or 1 km of line per 1 000 hectares). Ample provision of 33 000-volt lines is suggested, with a view to the supply of the ploughing and thrashing loads.

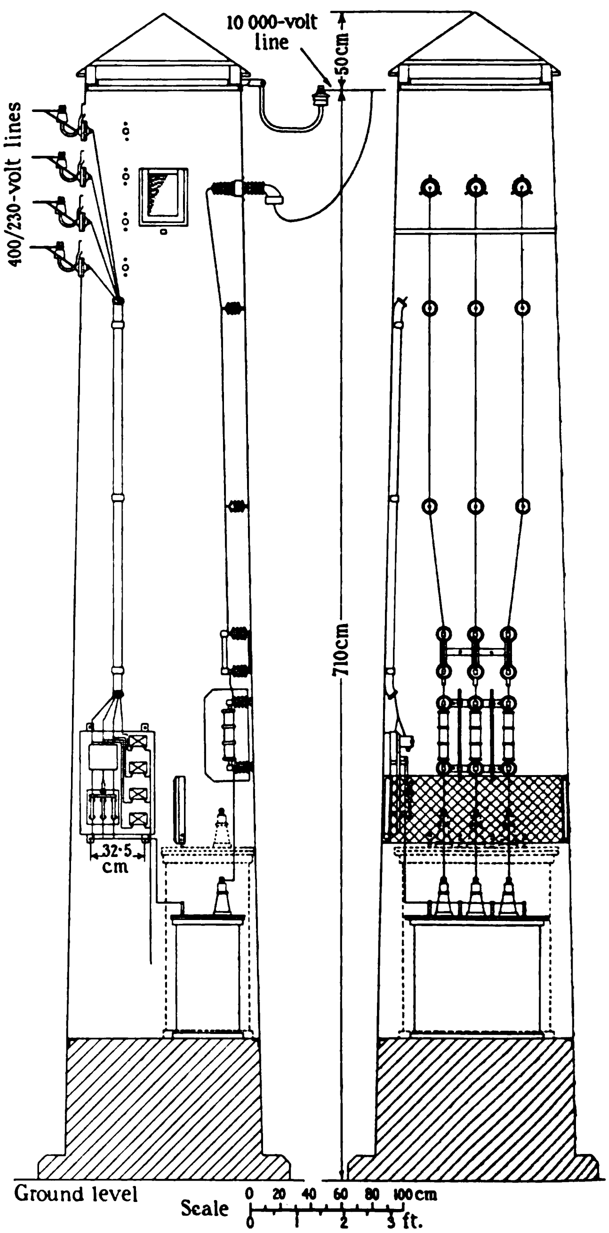

FIG. 3.—Transformer tower, with floor-level convenient for unloading the transformer direct from a vehicle.

Though the layout is hypothetical, it is based upon actual practice.

It is assumed that the economic range of a 10 000-volt line over a distance of 12 miles (19 km) is 250 to 650 kVA. Also that 33 000 volts is an economic voltage for transmissions of 25 miles (40 km) for quantities of power in excess of 800 kVA.

Details that reduce the cost of overhead lines.—The rural line is similar in costs and construction to the lines required for any other purpose. The matter that requires careful watching is so to design the line that most of the construction work on the poles, insulators, etc., can be done in the factory and not on the road side, where labour is so much more costly. Further, poles of a circular or polyhedral cross-section are to be preferred, since much time is saved if the poles have not to be aligned to match the lie of the conductors. Insulators and their cross-arms should be so designed that they can be clamped on the pole tops without any special drilling or similar work.

The high cost of tapping of the extra-high-tension lines at intermediate points is perhaps the greatest difficulty. It is receiving considerable attention at the moment. Undoubtedly the best plan is to provide a

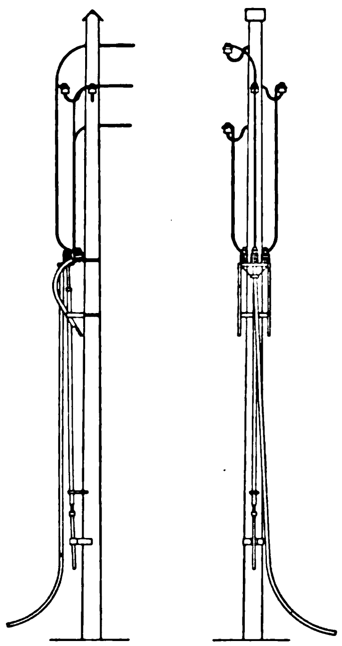

FIG. 4.—3 300-volt A.S.E.A. pole contact for portable farm transformers.

sub-transmission line at, say, 33 000 volts, connected at both ends to the extra-high-tension lines, giving in effect a ring main. From this, 10 000-volt feeders can be supplied for the 50-kVA substations at 3-mile (5 km) intervals along the rural routes. One advantage of this 33 000-volt sub-transmission is that wood or ferro-concrete poles of a simple character can be employed. Further, it reduces the tapping points from the extra-high-tension lines themselves to a minimum. Very often it is advisable to employ intermediate distribution lines at 1 500 or 3 000 volts. Maintenance work is much cheaper if the rural substation transformers are mounted at the level of a lorry platform (see Fig. 3).

Temporary connections.—Heavy loads which move from farm to farm or field to field as the work is finished are probably better connected to the 33 000- or 10 000-volt lines than to the low-pressure distribution system. The switches, protective gear, meters, etc., would, of course, be contained in portable transformer wagons, as is the present practice.

On several parts of the Continent it is permissible to connect these temporary loads by hooks on to 33 000-volt lines. In theory this hardly seems a good method, but the plant is always in charge of a skilled man and in practice the method apparently works well. It has the advantage that any convenient point on the high-tension line can be tapped. However, it is probably wiser to provide, as is done in other districts, extra insulators and poles for temporary tappings.

Excellent foolproof temporary connections are now available for 1 500 to 3 000 volts and also 10 000 volts. These can easily be used by the more intelligent farm hands (see Fig. 4). Their use means a considerable saving in transformer iron-losses, the transformers being cut out of circuit when not required.

(2) THE FARM INSTALLATION AND ITS USES.

Number of farmers using electricity.—Whilst the use of electricity is still a novelty in this country, nearly a million farmers in other countries are employing it, so that a considerable amount of experience is available. To-day over 500 British farmers are utilizing it, and the number is fast increasing. Over 200 uses for electricity have already been found on farms.* The author has 67 on his own 600-acre farm at East Grinstead. Owing to this large number of uses, a farm with one electric motor and perhaps an electric cooker cannot be called electrified. At least a dozen uses are needed to justify this description. Supply undertakings must give advice in order that the supply may be profitable both to them and to the farmers. Farm electrification means much more than belting a standard industrial motor to the existing agricultural machines, and each case must be carefully considered on its merits.

Wiring system.—The standard of wiring for farm buildings is gradually being raised, as it is very important to eliminate the fire risk. Contrary to usual town practice, it is customary to run the conductors outside the buildings under the eaves of the roof. One reason is that the buildings are usually old; again, during much of the year the wiring would be inaccessible if run inside, stored crops occupying all the available space.

For the interior wiring of the buildings where livestock is kept, such as stables and cow-houses, it is important to use conductors which can withstand a steamy atmosphere, often impregnated with either uric acid or ammonia fumes. Bare overhead conductors mounted on porcelain insulators are often used. The switches are then also mounted overhead, being controlled by turn rods running down the walls to convenient positions, where they are supported by simple bearings. Lead-composition-covered cables often give a good deal of trouble through chemical action. Where steel conduit is employed it must be served with hemp or similar material, impregnated with an oily paint. The best insulated conductor for farm purposes, in

* A selection of these is given in a paper by the present author (*Journal I.E.E.*, 1922 vol. 60 p. 726).

the experience of the author, is that known as "Maconite." This well withstands stable fumes and high temperatures such as that of a dairy steam boiler. When used in the open air, however, exposure to the sunshine seems to dissolve out some of the gums in the composition.

It is useful to provide a number of outlets for hand lamps. To avoid accidents due to faulty designs the type of hand lamp to be used should be specified. In many parts of the Continent where alternating current is used, small transformers are employed to reduce the standard lighting voltage of 220 volts to 50, or even 25 volts, for use with the hand lamp. Outlets for electric motors should be of an interlocked type, in which a plug cannot be removed or inserted unless the socket is dead.

Agricultural-type electric motor design.—On the Continent of Europe there is now an agricultural type quite distinct from the industrial type. Since the war such a large proportion of the output (75 to 90 per cent) of electrical manufacturers' motor-shops has been of the agricultural type, that such motors are now often supplied for industrial work, to the advantage of the factory using them.

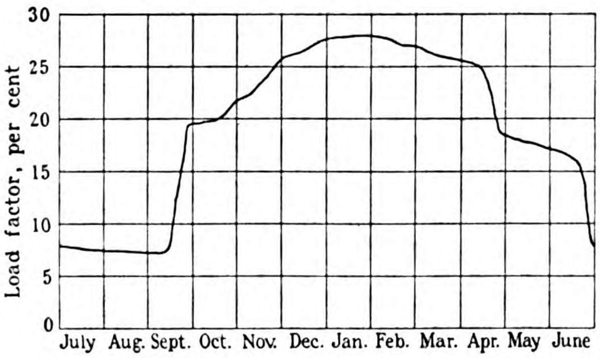

FIG. 5.—Load factor of a typical mixed dairy-farm.

The requirements are those of a mining motor, at the cost of an industrial one. The motor is expected to work in explosive and dusty atmospheres, to be left out in the rain, to have artificial-manure sacks placed on top of it, to be exposed to uric acid and ammonia fumes, and to receive practically no attention.

As lubrication is erratic, ball bearings should be used. A simple built-in overload circuit-breaker should be provided, and any starter should also be enclosed in the frame. The windings should be vacuum-impregnated so as to be moisture-proof. To keep down first cost an internal ventilation system is essential. To avoid special fixed wiring, a plug connection should be used for the cables. The motor must be capable of working in an inverted or vertical position. The outside should be smooth and easily cleaned.

Most of the motors can be started light, so that they can be of the squirrel-cage type. It is quite common to fit centrifugal clutches or sliding rotors to make starting still easier. Particularly in the larger sizes, wound-rotor motors with automatic short-circuiting and brush-lifting devices are useful, as they combine the advantages of both types.

Sizes of motors required.—A farmer starting to use electricity generally begins with one or two portable motors. After a few years, however, he finds it best to adopt what is now becoming the standard practice, and purchase motors to be permanently installed for individual drives.

The time saved through not having to re-adjust portable motors more than outweighs the extra interest and depreciation. Since each motor may be used for

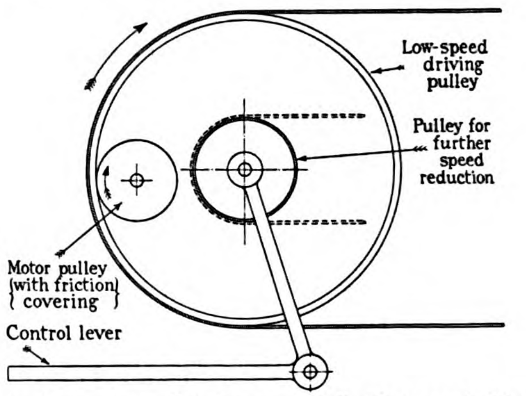

FIG. 6.—Internal friction drive controlled by cranked lever.

only a small portion of the year, it is unfair to base tariffs on the connected load, though the maximum demand may be taken into account. The farmer prefers a fixed charge plus a low rate per unit.

A 5 h.p. motor is the largest needed on most farms, except for ploughing, provided the supply engineer is in a position to recommend suitable farm machinery.

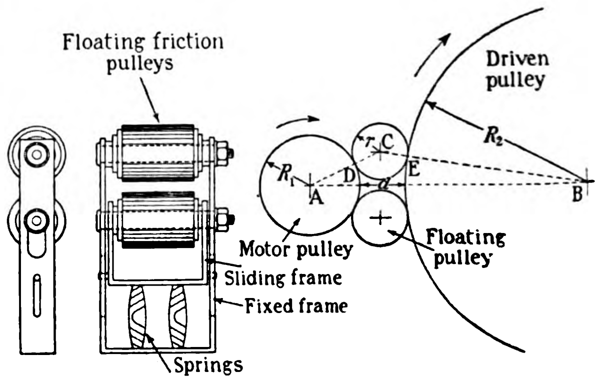

FIG. 7.—External friction drive with floating pulleys.

If this is the case, the power and load factors are much improved (see Fig. 5).

A 2 h.p. motor is useful in addition, with fractional h.p. machines for the lighter duties.

Improvement of power factor.—If the farmer cannot be persuaded to use small farm machines which can be operated by a 5 h.p. motor, he usually goes to the other extreme and uses very large ones, such as a thrashing machine combined with a straw presser, requiring a 25- to 40-h.p. motor. When such a motor is used on a much smaller load its power factor is very poor. To improve this, it may be fitted with a star-

delta switch for the stator, the star position being marked, say, " light load " and the delta position " heavy load."

As an example, a 25 h.p. motor when used for thrashing developed 24 h.p. For 10 hours a day on 120 days in the year it operated a dryer taking 13 h.p. Delta-connected, the power averaged 11·3 kW, star-connected it was 11 kW, thus saving 360 units per annum. More important still, the power factor was increased from 0·62 to 0·90. The same advantage was gained during 60 hours per annum in driving a grinding mill taking 10 kW and during 280 hours driving a chaff-cutter taking 9 kW.

are pressed together by a spring (see Fig. 7). A bracket forming a part of the machine to be driven holds the motor with its pulley at a definite distance from that of the machine. The portable friction-pulleys are sprung apart by hand and interposed between the motor pulley and the machine pulley. In this way a very convenient and compact speed reduction is obtained. Fig. 8 gives the proportions for the distance apart of the pulleys to give the best results.

Where a belt drive cannot be avoided, a device such as that shown in Fig. 9 is very useful. It gives a non-slipping drive with the pulley centres very close, the tight side may be at the top or bottom as desired, and

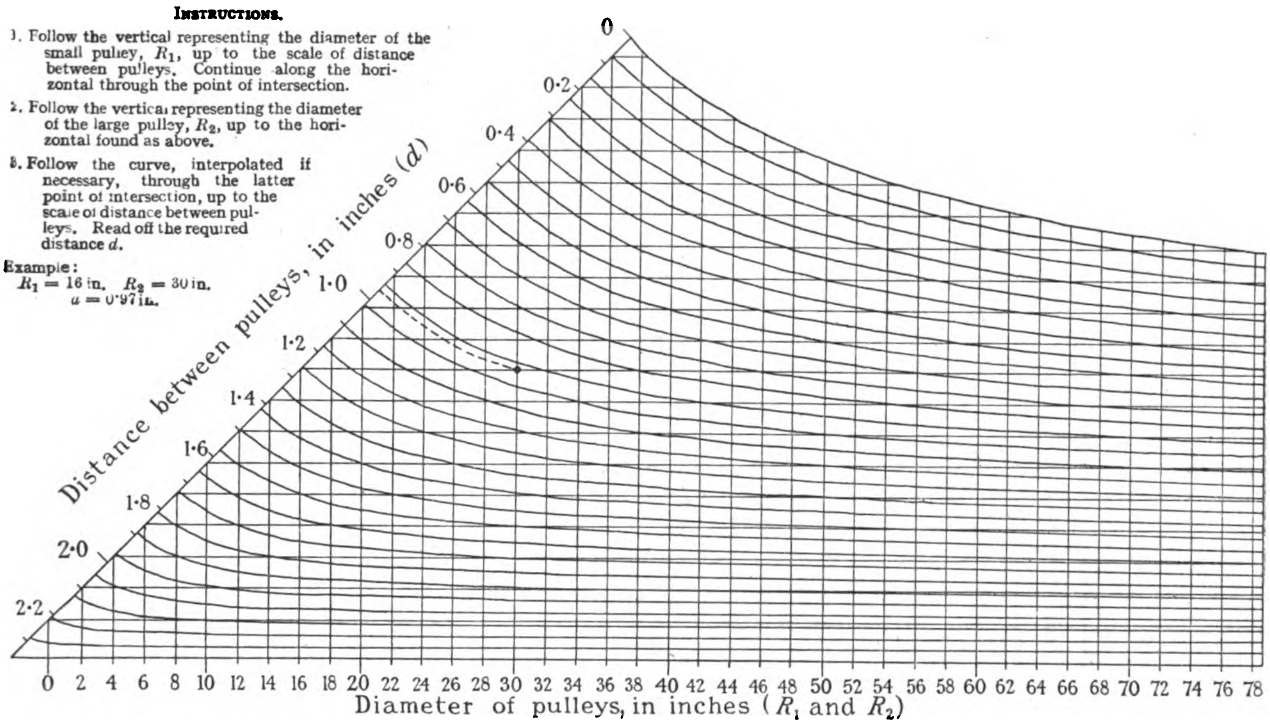

FIG. 8.—Abac for determination of distance between fixed pulleys for a tangential force of 60 lb., when using floating friction-pulleys.

Speed reduction for motors.—There are now a number of agricultural-type motors on the market, which by the use of self-contained compound-reduction gearing can be coupled direct to the machine to be driven.

This saves much time by avoiding belts, which in the hands of farm labourers unused to them give endless trouble.

For motors of 5 h.p. and under, friction drives can be used instead of gear wheels.

Diagrams are given of two examples of these. In the first case, the main reduction is done by an ingenious internal friction-pulley, the final drive being by belt (see Fig. 6). This method allows the motor to be started up without any load at all. By slowly bringing the friction-pulley in internal contact with the low-speed pulley, the load can gradually be put on. In the second case, two floating friction-pulleys are supported in a light portable frame, in which they

much smaller pulleys with a high-speed motor can be used.

Homestead equipment.—In the early stages the installation of electric power on farms has been greatly helped by the appeal to the housewife of electric lighting, electric cooking and electric washers. The apparatus supplied should be of the most robust and practical character. On some parts of the Continent to-day it is rare to find a farm without its electric washer, but it has cost one-fourth the price of the admittedly better type of washer available in this country. Whilst great improvements have been made in electric cookers of late, the designs have not yet reached the simplicity of the better-class gas cooker, though the schemes of hire and hire-purchase have helped towards this end.

Water-heaters are, of course, required in the kitchen and in the dairy. It is advantageous to couple these up

with an auxiliary fuel-fired heater. In connection with the latter, it has often occurred to the author that if a small pattern of direct-coupled electric blower were attached, it would assist the getting up of a fire.

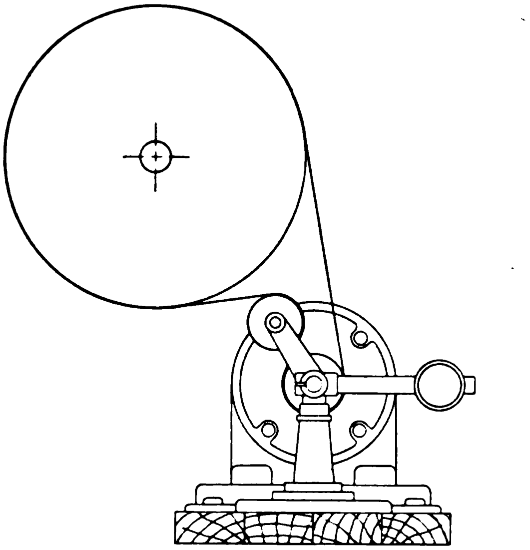

FIG. 9.—A typical counterweighted idler pulley, as often employed on the Continent.

employed 24 hours a day, the heat being stored up and utilized as required.

Economical control by multi-way switching.—It is wise to submit to the farmer suggestions that enable him to improve his load factor and thus purchase current on the most favourable terms, e.g. a method of multi-way switching, whereby, when the current is in use on one important piece of apparatus, other current-consuming devices cannot be switched on. In the farmhouse, the biggest loads are taken by (*a*) the electric oven, (*b*) the hot-plate of the cooker, (*c*) a water boiler, and (*d*) heaters for the rooms. As hot water is always useful, when other appliances are not in use the current can be switched on to the boiler, and so on, as indicated in Fig. 10. This diagram further suggests that, when the larger appliances are in use in the house, the motors in the farm buildings should be switched off. There is no practical objection to doing this, especially on the smaller farms, as it only requires a little rearrangement of the farm work.

Illumination of live-stock sheds and poultry-houses.—At least half-an-hour per day per man can be saved in the feeding of live stock by the aid of a good light.

Poultry-house lighting is now a recognized commercial practice, for the very good reason that there is an increase of 15 to 43 per cent in the egg production during the winter months, when prices are highest. This is clearly shown in Fig. 11. Contrary to the popular idea, the birds are not in any way strained by artificial lighting, as they get 10 hours' sleep each night. They are simply allowed ample time for feeding, as in the sub-tropical country where they

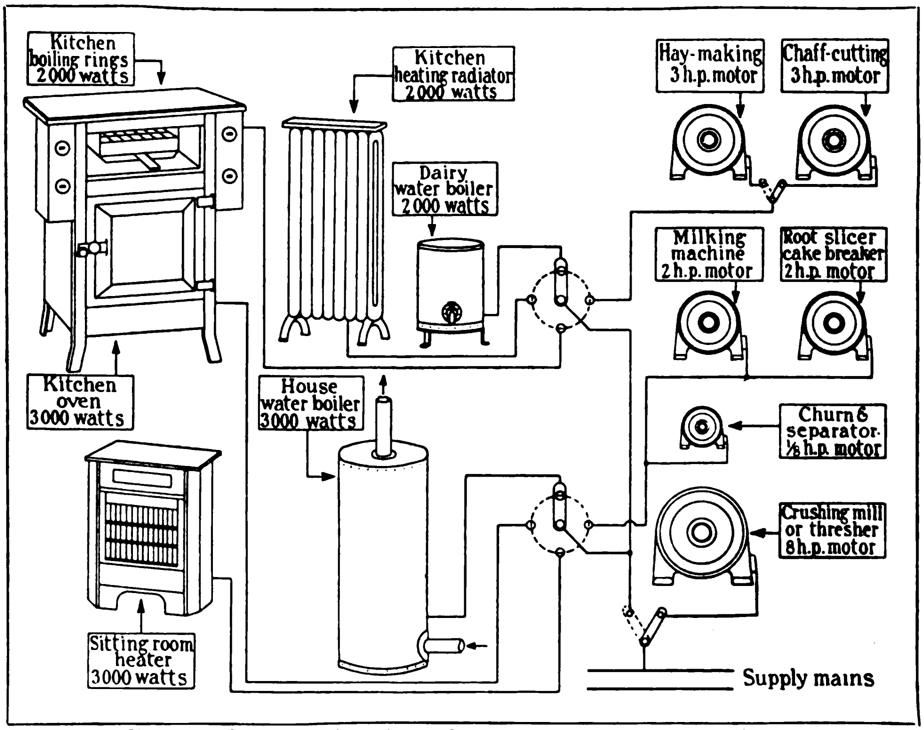

FIG. 10.—Diagram of a scheme for a 100 per cent farm load factor.
(The negative leads are omitted for simplification.)

Much work has been done of late in connection with heat-storage stoves, the heat being stored in water, cast-iron or soapstone. The object is the provision of a good load factor, as a small amount of current is

originated, instead of being partially starved owing to the long winter nights in this country.

Fig. 12 shows typical curves of poultry-farm maximum demand and load factor.

Intensive illumination to stimulate plant growth.—The author has recently obtained new results of commercial importance to the market gardener. The first is in connection with the transplanting of seedlings, and the second is one-night treatment of greenhouse plants to obtain more rapid progress. Ordinarily, when seedlings are pricked out, they are apt to fall down and become wilted by the next day. However, when electric light was applied during the night, the seedlings were fresh and vigorous on the next morning; in fact, they developed nearly a week's normal growth overnight. With six hours' light each night, daffodils flowered in four days and narcissi in seven days. In other words, the application of electric light had accomplished three or four weeks' growth in four to seven days. The illumination was much more intense than that previously tried, 1 000-watt gas-filled lamps and large enamelled parabolic reflectors being placed close above the plants.

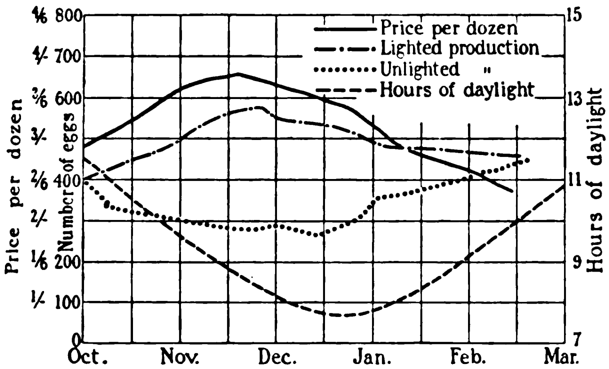

FIG. 11.—Gain in egg production due to electric lighting.

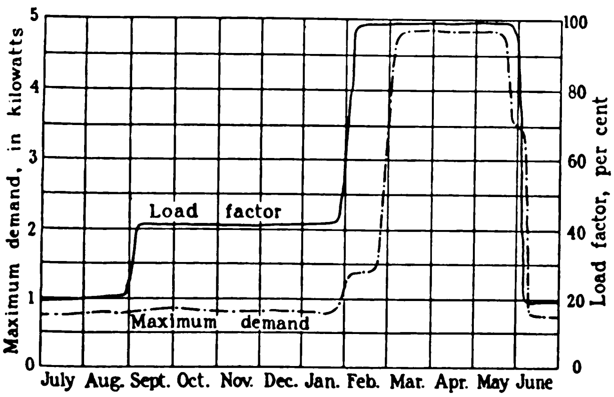

FIG. 12.—Load factor and maximum demand of a typical poultry farm.

Bees.—A novel application, which is still in the experimental stage at East Grinstead, is the artificial electric lighting and electric heating of bees in the early spring. The hives are all placed inside a house, instead of being kept in the open air in accordance with the usual practice in England. The basis of the idea is that, by this treatment, strong hives are obtainable at the time when the orchards are in bloom; thus about an additional 17 lb. of honey can be obtained per hive per annum.

Earth currents.—This, one of the earliest applications of electricity to agriculture, has lately been revived in a novel manner by M. Christofleau, in France. Confirmatory tests are at present being conducted in the author's garden. Further experimental work is, however, necessary to confirm the results obtained so far.

(3) WORK ON THE LAND AND HAULAGE.

From the point of view of the supply undertaking, the large available load, if work on the land is done electrically, means a certain amount of profit. So large a proportion of the power on a farm is used on the land, that it is also very important to the farmer himself. Hence all parties should consider very seriously the best methods of cultivation by electrical means.

Electric ploughing.—The advantages of electric ploughing are that practically unlimited power lies behind the plough, and that the cost per acre for electricity is very much lower than that for any fuel.

If electric ploughing is carried out on a large scale, the power required is so great that for an economical distribution system the voltage must be fairly high. This is a point overlooked in most discussions on rural electrification.

For motors which do not exceed about 40 h.p., 1 500- or 3 000-volt lines may be used. For larger motors the supply is usually taken from 10 000- or 33 000-volt lines. A portable transformer connected with the haulage set by a trailing cable is generally used. The motors are usually operated at 380 volts, three-phase, although one very successful equipment uses 5 000-volt motors. A meter is fitted on the low-tension side of the portable transformer. The high-tension connections are, as previously mentioned, often made by hooks where an electrician is in charge.

Most of the successful plants are of large size, capable of ploughing up to 27 acres a day (a team of horses can plough barely an acre a day). The capital cost is high. The area which can be ploughed in a season is that of a large number of average farms. For these reasons, such an equipment is only suitable for contractors or co-operative societies. Thus a difficulty in introducing it is the institution of the co-operative idea, particularly in a country where the farmers have an individualistic state of mind. Still, even in a country such as England, the steam plough has made very considerable progress in certain districts, such as Oxfordshire, Lincolnshire, and the Eastern Counties.

Ploughing is looked upon by the layman as a strictly seasonal occupation. It is, however, found in practice that an electric plough can be kept fully occupied for at least 200 days in the year, and this is quite a reasonable period over which to spread interest and depreciation. It is difficult to ascertain the costs of any form of mechanical ploughing, as the co-operative societies and companies, who generally carry it out, universally base their contract prices on the existing

horse-ploughing competition, also bearing in mind that at certain periods farmers are quite willing to pay a little above the horse rate if the work can be accomplished more quickly.

Small electric ploughs.—The demand for these is not yet very great, and they are still in an experimental stage. As the result of his investigations, the author has formed a clear idea of the most suitable type for the individual farmer.

It must be controllable by one man. It should be of the tractor type to obviate anchorages. The front wheels should have extra large pneumatic tyres. To prevent the formation of a hard pan below the surface of the ground, the pressure on the soil should be reduced to less than that due to a man's weight. This can be done by fitting in place of the rear wheels a creeper track, which may be of rubber and fabric, or rubber-tyred wheels may run on a metal track. Preferably the track should be capable of lying in a curve so as not to skid over the ground when turning a corner. On the tractor, two electric motors should be

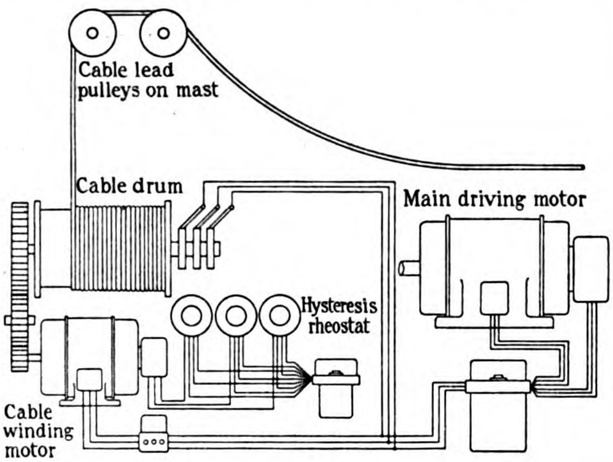

FIG. 13.—Hysteresis control for cable-winding motor of electric tractor.

fitted, one of about 25 h.p. for the main drive, and the other of about 2 h.p. for winding in the cable when it becomes slack. A derrick mast, supported on the chassis, should raise well above the ground the part of the cable nearest to the tractor. This mast should have a height of about 15 feet (4·5 m) and the cable should hang freely in the air for a distance of 35 to 45 yards (30 to 40 m); beyond this it can lie on the ground. In this way all risk of the tractor running over the cable is obviated, and the wear and tear on the cable is reduced to a minimum, since it has only to lie on, instead of being dragged over, the ground. The drum on such a tractor should hold 440 to 550 yards (400 to 500 m) of flexible cable.

A tractor of this type would plough an area of 40 to 60 acres (16 to 25 hectares) from a single contact in the middle of a field. In other words, continuous furrows of about ½ mile (800 m) in length could be ploughed. If a greater area is required to be ploughed from one contact point, it is, of course, quite easy to add another length of cable. It is, however, not often that areas of much more than 40 acres, and furrows more than ¼ mile long, are required to be ploughed at a time. Again, if a farm is equipped for electric ploughing, it is quite simple to arrange for several contact points. There are very few farms up to 500 acres which, if fitted with two distribution lines through the main axes of the land, could not be ploughed by a tractor of this type.

Fig. 13 illustrates a very ingenious hysteresis control for a cable-winding motor, which is successfully employed on the Continent. The cable-winding drum is operated by the motor through a friction drive. When the tractor is driven away from the source of supply, the cable is drawn out against the friction drive. On the other hand, when the tractor returns toward the original starting point, the cable is slackened. As the resistance to the motor drive is thus removed, the motor comes into operation and winds up the cable until it reaches a predetermined tautness. Owing to the hysteresis control, the operation of the motor is automatic; further, it will not burn out when the tractor stops or the cable drum reverses.

Major A. MacDowell has recently developed in Scotland an original form of single creeper tractor for ploughing, with which is incorporated a novel method of side-stepping the whole machine ready for the next furrow and also a new way of handling the flexible cable.

Transport.—One of the practical difficulties experienced in connection with electric ploughs is that of transport from field to field, and also the fact that they cannot be used for general haulage work on public roads. Large French tractors are equipped with petrol engines for transport purposes, which are also employed for emergency ploughing on land out of the reach of overhead lines. This expedient, however, adds very considerably to the capital cost of the equipment.

The author's proposal is to equip a creeper-tractor with storage batteries and thus employ it as an electric storage-battery vehicle for haulage on public roads, and also for haulage of timber and crops when it is not convenient to connect to an overhead line. Every farmer must have a vehicle which is capable of hauling between the farm and the nearest railway station or town, as well as for delivering loads to neighbours. A machine that can be universally employed is of considerable value to him, even if the speed is comparatively low on the public roads.

Many years ago accumulator tractors were experimented with for ploughing, but their weight was too great for practical work. Electric tractors fed by a trailing cable were also tried, but the cable lying on the ground directly behind the tractor was too easily overrun or damaged by being dragged over the ground. The advent of the creeper-track, however, coupled with the derrick support and automatic winding for the flexible cable, would eliminate these troubles. The possibilities of the four-wheel coupled drive must not, however, be overlooked.

Reference has been made to ploughing chiefly on account of the fact that it is the principal load on the farm. A tractor can also accomplish much other work,

such as cultivating, harrowing, rolling, seed drilling, harvesting, etc. All the existing farm implements except harvesting machinery can be used. With the latter, in the case of a tractor with a flexible cable, it is only possible at present to move it to and fro in a field instead of round the field. A standard harvesting machine can, however, be operated if the tractor is allowed to return light each time. It would be a very simple matter slightly to modify the standard reaper, so that instead of being a one-handed machine, it could be used on the right- or left-hand side as desired.

Reducing plough friction.—Quite a new development concerning the application of electricity to ploughing is to reduce the resistance of the soil to the ploughshare by passing a current of electricity between the coulter * and the ploughshare. An actual lubrication effect is secured by making use of a special property of soils to produce, by electrical means, a film of water between the furrow slice and the mould-board of the plough. The water in the soil seems to move from the positive electrode towards the negative. This property has, in fact, been used as a preliminary method of removing water from peat, preparatory to drying in the usual way. The idea is due to the work of E. M. Crowther and W. B. Haines, of Rothamsted Experimental Station, who have carried out a good deal of laboratory work in this connection, and eventually a full-scale series of tests at Greater Felcourt Farm, East Grinstead. Laboratory tests have shown that the friction under favourable conditions can be reduced by as much as one-third. These results have also been corroborated by Captain B. J. Owen in connection with mole draining.

Rotary tillers.—No less an authority that Sir John Russell has stated that it is impossible to say whether or not ploughing is actually an essential operation in farming. Though, so far, ploughing has been the accepted method of cultivating the soil, there are now a number of machines in existence which attack the problem in quite another way. These are known as rotary tillers. Just as the milling machine has largely superseded the planing and shaping machine in the engineering workshop, so it seems likely that the rotary tiller will have very many advantages. Certainly the action of ploughing seems very unmechanical in that really the ground is wedged over, which has a tendency to produce the very pan to which so many farmers object. Also the rotary tiller, as its name indicates, lends itself conveniently to an electric drive. Practical farmers condemned the earlier designs of these machines because they produced a fine tilth, which was apt to set down solidly after the first shower of rain. Now, however, improvements have been made in the construction of the tines or teeth, whereby both weeds and manure can be buried and the soil left in the form of clods, as is required by so many farmers. Hence, it seems probable that there will be a big future for this type of machine.
